REVIEWS

This series of volumes will inevitably become the standard general reference work.

British Birds, UK

My overall impression, and I believe I am not alone here, is that this is a sensational book...

The Condor, USA

This series is destined to become the Rolls Royce of avian handbooks.

The Ostrich, South Africa

Well at last it has been published; a book that aims to illustrate every bird species in the world and give a summary of information on the status and distribution of each.

The Emu, Australia

I think *Handbook of the Birds of the World* fully justifies itself by being so attractive, so well executed, so informative and so readable.

The Ibis, UK

In my opinion, HBW is the most important book about birds ever published.

Var Fågelvärld, Sweden

This handsome tome inaugurates one of the most ambitious publication ventures in the history of ornithology...

The Auk, USA

The highly professional level of the Handbook makes it a valuable source for ornithologists as well as other scientists interested in any information on birds.

Ethology, Germany

It is surely the most ambitious natural history publishing project of the 20th century.

IZN, UK

I consider the *HBW* to be the fundamental work of the 21st century.

L'Ornithologue, Belgium

INDEX 811

Foreword

Having spent my whole life avidly involved with both nature and art, I have evolved a number of ideas on the relationship between these two areas of study and activity. I have been struck by the drift of so-called civilized man away from nature. This is manifested by the absence of wildlife subject matter in the mainstream of art of the Western world right into the twentieth century. All other periods of history and all other cultures have normally included wildlife as a subject matter for drawings, paintings, sculpture and decorative motifs. From the nineteenth century until the present, art involving plants and animals was seen as a handmaiden to the study of natural history. Until its partial supplanting by photography, art was used simply to describe various aspects of nature. In my own work I have used nature as an inspiration for my art rather than using my art as a way to illustrate nature. I am a painter who happens to love nature and so that is my subject matter. In the same way, Dégas painted back stage at the ballet and van Gogh painted the countryside around Arles.

I would like to explore the way in which humanity's drift away from nature has been reflected in our art. I will also comment on the way in which art, particularly in recent years, has influenced our understanding of and appreciation for nature.

From earliest times some of the greatest art produced depicted wild creatures. The most famous early works are the great cave paintings of Altamira and Lascaux, dating back to roughly 100,000-50,000 years ago. These bison and deer are depicted with sensitivity and power. Of course, the artists were very familiar with every sinew, bone and muscle of their subjects. They had no doubt quarreled over every bit of the anatomy, bargaining for the different pieces. Every part of the animal had a use and a significance. It is not surprising that most of the Paleolithic drawings have an accuracy and realism that is unsurpassed to this day.

For 90% of our history we were hunter-gatherers moving through the natural world like any other creatures. When food became scarce or difficult to obtain, we moved on and nature quickly healed over. Early humans were not necessarily backward or unsophisticated; in fact, there is evidence that in many ways our ancestors were superior to modern man. In practical knowledge and understanding of ecology, for example, an ordinary hunter or gatherer is vastly more sophisticated than a contemporary professor of ecology. Recently, an ethnobotanist visited the Penan tribe of Sarawak. He asked a tribesman to walk in the tropical rain forest and describe the attributes and uses of the plants along the way. It took a long time to cover a few metres because of the overwhelming wealth of detailed information. The average Penan can name thousands of species of plants and describe what they do. How many can an average "modern" person name?

The points I wish to make here are both general and particular. In general, since the invention of agriculture, or the Neolithic revolution, we have drifted away from knowl-

Cliff-nesting seabirds in the Pribilof Islands, Bering Sea.

Painted specially for the *Handbook of the Birds of the World* by Robert Bateman.

edge and wisdom concerning nature and have become increasingly obesessed with convenience through technology. At the end of the twentieth century we must now realize the folly and indeed tragedy of pursuing this course too far, and once again become more closely connected with nature, not only in mind and deed, but in spirit.

This leads to my particular point, that is concerning the role of nature art in our lives and perhaps in a small way in the salvation of the endangered life on this planet. If art has something to say about the human mind and spirit, then surely wildlife art should have a clear and forceful voice in contemporary culture.

In order to place the art of wild animals in historical perspective, I would like to return to the so-called Neolithic revolution. As I have mentioned above, for hundreds of thousands of years humans lived as an integrated part of the natural world. Then, about 20,000-10,000 years ago, our ancestors found ways to control nature and so make life easier for themselves. Perhaps the earliest innovation was the domestication of the goat. It has been said that this one "breakthrough" was by far the most earthshaking development in the past million years, surpassing the invention of the printing press and the splitting of the atom. Nomadic tribes in the Middle East found that they could control herds of goats, guide them to pastures and water and protect them from predators. In return, the goats gave milk, meat and skins for clothing, and fibre for weaving. Man the pastoralist became much more the enemy of nature than man the hunter. All larger predators were a threat to the flocks and had to be exterminated. This same prejudice is still with us worldwide, even for example in North America, as recently seen in the strong protests against the proposed reintroduction of wolves into Yellowstone Park, USA. In addition, grazing wild animals became competitors for pasture and water and were either killed or starved. Since most of the needs of the tribes were met by the goats, the peoples did not require detailed and complex knowledge about their neighbours of other species, either plant or animal. Over the centuries nature was seen as chaotic and irrelevant to the reorganized human condition, and the prevalence of this view increased with the domestication of certain plants and other animals. It allowed humans to live in villages which needed physical and social structure in relation to the complex and confusing web of the natural world.

Art totally changed, from the realistic renderings of the Paleolithic peoples, to highly abstracted and structural designs of village people. This work may be seen in the Geometric Period of early Greece (900-700 BC), as well as in the art of prehistoric peoples in China and Europe. There are abundant examples of Neolithic-style art being practised all over the world until the middle of the twentieth century. This would include the great tribal art of Africa, New Guinea and west coast North American natives. In each case, the art is abstract with distorted images of humans and animals and plants all done in a strong, stylized and decorative fashion. Wildlife of every kind was contorted into strong curves and dynamic lines with interlocking positive and negative shapes. Thus we see lions, ibexes, eagles, bears, fish, hornbills or crocodiles woven, carved or painted into or onto fabric, canoes, pots and almost every other man-made item. This decorative art is found even in Europe until quite recently. It may be seen in rural art, on clothing and furniture, especially in more remote and mountainous areas.

As early European tribal art evolved, it departed from nature and created mythical and magical creatures. Nature is seen as mysterious and menacing. Thus we have dragons, hobgoblins and griffons. The Church became more and more dominant over every aspect of life. Nature, even human nature was seen as the enemy. The magnificent and complex cathedrals of the Middle Ages were among the most comprehensive expressions of human endeavour. And yet true nature was either distorted out of almost all recognition, or it was left out entirely. Instead we have gargoyles, fantastic animistic demons and symbolic plant forms.

The Renaissance brought a renewal of classical interest in humanity and science, but wild animals and wilderness remained "beyond the pale". As European art developed, perspective and realism in painting animals became the norm. However, the subjects were almost entirely domestic animals, typically dogs, horses, cattle and sheep. This tendency continued through the great paintings of the seventeenth century. If wildlife was shown, it was quarry being exterminated at the end of a spear or ready for the table, being hung up by its feet with a bunch of grapes. One of the superb masterpieces of Peter Paul Rubens (*Tigers and Lions Hunt*) shows huntsmen on handsome and heroic horses spearing and trampling the magnificent carnivores. Man, the greatest predator, must exterminate all other predators, or so it would seem through most of our history. There are a few exceptions to this general pattern. Dürer produced his famous

hare painting, and also an elaborate and inaccurate rhinoceros, while Rembrandt drew elephants and other zoo animals. These and the handful of other examples were created more as curiosities than anything else. For most of European history, I am not aware of any examples showing wildlife in its own domain, eye to eye, with respect.

In the eighteenth and nineteenth centuries an increasing number of artists tried their hands at accurate renderings of plants and animals. This was the great age of expeditions and a naturalist artist was an essential part of the record keeping on any such adventure. Specimens were shot, stuffed, pinned and painted. It was all part of the gathering of knowledge and accumulation of collections.

Artists such as John James Audubon struggled to show birds and mammals in scientific detail. These works were often based on freshly killed specimens arranged with appropriate plant forms. The results were sometimes artistic but to my mind they fall into the category of accomplished flower arranging. Nevertheless, the body of his work, particularly in his *Birds of America*, was a major landmark in the history of wildlife art. The great "double elephant" folio brought striking and quite accurate images of birds to a wide public.

Towards the end of the nineteenth century some powerful painters of wild animals emerged. The most famous of these, men like Richard Friese, Wilhelm Kunhert and, in the early twentieth century, Carl Rungius, catered to the big game hunter. Aristocrats had always had a taste for shooting wildlife. Now the new business elite aspired to join the "sport". These men were the patrons of a new art form, the depiction of the quarry species in its own habitat. These paintings hung on the walls along with the heads of the trophy animals. Not only the animals in the picture, but also the landscape, was intended to evoke memories of happy times in the field.

Of course, these artists were themselves big game hunters. And so, as in most great art throughout history, the artist explores what is meaningful to him in his own life. Since some of the painters were well trained and talented, they produced some excellent paintings, and indeed were on a par with the works of many of the more famous artists of that time. However, since the subject matter was outside the more conventional human-centred material, many of these pictures were not shown in major art museums. Those animal paintings which were priveleged to hang in art museums during the nineteenth century soon found their way into permanent storage as modernist curators took charge in the twentieth century.

A noteworthy exception to this practice was Bruno Llijefors (1860-1939) of Sweden. His work has always been recognized as having a position of status in Swedish art, and it continues to hang in major art museums of that country along with art of all periods, including contemporary. Llijefors enjoys a lofty reputation among wildlife artists and *aficionados* to this day. He employed great skill with brushwork and a fresh eye for his compositions. His paintings have a startling sense of verisimilitude which is almost photographic without being slavishly detailed. One definition of a masterpiece is that when you view it you feel you are seeing it for the first time, and it should seem as if it is done without effort. In my opinion, much of the work of Bruno Llijefors falls into this category. He not only produced pictures which would appeal to wealthy hunter clients, but also painted a great many pictures showing glimpses into ordinary little incidents in nature. These are treated with freshness and imagination. For this reason Bruno Llijefors has a proud place in the history of painting as an artist who looked nature eye to eye with respect.

There were others in the nineteenth century. One of the most gifted was Leopold Robert (1794-1835) of the Neuchatel area of Switzerland. He was famous as a painter of landscapes and of the human figure; a magnificent mural may be seen in the entry hall of the Neuchatel Museum. But his high position as a nature artist arises from his superb paintings of passerines and, oddly enough, of caterpillars. These are not mere scientific renderings but are small, perfect paintings showing the activities of these creatures in their habitats.

The tumultuous twentieth century has produced, not surprisingly, a multiplicity of trends in wildlife art. In the early years, artists continued to be used as illustrators of stories about animals or scientific books on natural history topics. As the century progressed, photography gradually took over this role.

There are, however, many areas of illustration in which the hand of the artist is superior to the camera. Detailed renderings of particular parts of plants or animals are shown

with far greater clarity by draftsmanship, in which certain confusing relationships of the different parts of the natural world can be sorted out and simplified. Medical and botanical art are good examples of this.

A colossal breakthrough in the understanding and appreciation of natural history was developed by Roger Tory Peterson in the 1930's. His *Field Guide to the Birds* brought clear, standardized illustrations in a very accessible form to the general public. This meant that an ordinary beginner could buy the book and become a proficient birdwatcher, able to distinguish between all of the different species. The significance of the field guide has been enormous. As S. Dillon Ripley, Secretary Emeritus of the Smithsonian Institution, writes,

> "...because of the field guide, birds have become the best known animals in the world. Peterson entered a world in which identification and study of birds was the exclusive realm of the specialist with a shotgun, and he transformed us into a world of watchers. The impact Peterson has had is incalculable; in providing the means for the popularization and refinement of bird-watching, he has immeasurably furthered bird study and the conservation movement worldwide. He enables even the most untutored person to identify birds; he showcased the unparalleled beauty of birds in his painting and photography; and by getting millions of people interested he has helped to guarantee the survival of birds."

The field guide principle has now multiplied into every area of identification of plants and animals and even rocks, minerals and stars. This has the potential of bringing *Homo sapiens* full circle and gives us some hope that modern-day man may end up sharing at least some of the knowledge of our hunter-gatherer ancestors about the world of nature.

As we approach the end of this century, the most serious problem facing the planet is the disappearance of biodiversity. The extinction of species will mean an ugly and impoverished future and may even threaten the survival of our own species. How can we preserve biodiversity if we can not even identify the different living things in our own communities, let alone in the world at large?

In my view, artwork is superior to photography in all field guides. The standardization and lack of confusing poses and lighting conditions makes good illustration irreplaceable. Photography does have its place, however, in the depiction of nature. Photography at its best is truly an art form along with drawing, painting and sculpture. In the last few decades photography has made significant technological advances. In recent years, photographers as artists have been producing a plethora of beautiful books showing nature as it had never been seen before by the general public. In many cases, the artistic merit and creativity of the photography was, and still is, truly inspirational. This has played an important role in raising the consciousness of the common person, at least in the Western world, to the beauty and value of nature.

At the same time it is undeniable that films and television have had a major impact in the same direction in recent years. Nature shows are perennial favourites, perhaps reflecting a yearning among a modern populace for the purity of the Garden of Eden that we are rapidly losing. In fact, wildlife painting has experienced a historic surge in popularity since the 1970's. When I was a teenage wildlife painter in the 1940's, I knew of only three or four Canadians and a dozen or so from the USA who painted nature. Most of them were illustrators of books or magazines. A few had, as their main job, teaching or musem work. Today there are hundreds of artists supporting themselves with their nature art, and many more are serious amateurs. The limited edition production print has increasingly enjoyed enormous popularity, especially in North America. This has meant that high quality reproductions of wildlife paintings are avidly collected, bringing wildlife images into thousands of homes and offices.

Natural history art in many forms has proliferated. It may be found as decoration on coffee mugs and T-shirts. It is often enlisted in worthy causes such as to "Save the Whales" or "Stop Killing Baby Seals". It is now so much a part of our late twentieth century Western culture that an appreciation of nature seems to be akin to virtue. One scholar theorizes that, whereas in earlier centuries religious icons, for instance of the crucifix, showed that one was a good person, now wildlife images on one's clothing or wall are the new icons of virtue.

Moving to the opposite end of the creativity scale from the coffee mugs and clothing, wildlife art can be found in major paintings commanding as high prices as most other forms of contemporary art. Although only a few pieces have found their way past the "priesthood" of modern art museum curators, a few excellent museums of wildlife art have opened in recent years. In general these have much healthier attendance records than do their so-called fine art counterparts.

Wildlife art has been directly enlisted in the fight to save threatened species and habitats. Often artwork of this genre is the best fundraiser at charity art auctions. In British Columbia, where I live, a group of artists joined forces with environmental organizations to paint a particularly precious stand of old growth Sitka spruce forest on Vancouver Island. The forest was slated to be cut but, after the raising of public awareness through the production of an elegant art book and a travelling exhibition, the logging company and government were shamed into protecting the forest.

A Netherlands-based organization, the Artists for Nature Foundation, is targeting two areas of great natural significance in order to raise consciousness and save them from development, particularly industrial agriculture. One is the Biebzra wetlands of eastern Poland and the other Extremadura of western Spain. Both are ancient cultural landscapes where human activity and nature have evolved together in a gentle interface. This results in an abundance of wildlife including many species endangered or extinct in other parts of Europe. The Artists for Nature Foundation has organized groups of leading wildlife artists from various parts of the world to draw and paint these areas. As in the Vancouver Island example, beautiful books and travelling exhibitions have resulted.

On a poster for the Munich Art Museum I read "Kunst öffnet die Augen" (Art opens the eyes). If this is true, and I believe it is, then the world of nature as seen by artists has a crucial role to play not only in bringing pleasure and appreciation of that world to mankind, but also in teaching us all what to cherish, and therefore what to protect and guard.

The following quotation is attributed to Baba Dioum:

> "In the end, we will conserve only what we love, we will love only what we understand, we will understand only what we are taught."

Let us hope that humans will become truly civilized and drift back to a deep appreciation of nature. There are signs that wildlife art at the end of this millenium may be part of an optimistic trend.

Robert Bateman

Introduction to Volume 3

Once again readers are referred to the detailed general introduction to the whole HBW series (see Volume 1, pages 15-33), where the aims, limits and structure of the project are set out.

It is clear that in a work covering all of the families in the class Aves, and each and every one of their constituent species, a high degree of uniformity in treatment is essential. However, it is equally clear that too rigorous a level of uniformity would present a number of drawbacks. Thus, while the structure itself remains untouchable and a large number of details must invariably be covered in similar depth in all families, it is considered that on a particular topic it may be useful to include a somewhat higher degree of detail in one family than in some others; for example, in this volume it was decided that, because of their special interest, descriptions of nests in Rallidae or downy chicks in Glareolidae deserved particular attention, though it should be remembered that these aspects are covered to some degree in all families. Another related policy is that a slightly greater degree of detail may be desirable in families for which even the basic details are not easily available to the average ornithologist.

One significant innovation in two families of the present volume is a subsection to cover voice; this is included within the Descriptive notes sections of all the species in the families Gruidae and Rallidae. The inclusion of a brief description of voice was originally intended only for the passerines, in part because there are many families, especially of non-passerines, for which a written description of voice would appear too subjective and perhaps somewhat pointless unless it could be expanded to a scale incompatible with the aims of HBW. However, it has subsequently been felt that the inclusion of this brief voice subsection might also be useful for a very limited number of non-passerine families.

The guiding taxonomic principles adopted for HBW were summarized at the outset (see Volume 1, page 16). Briefly, they can be considered fairly conservative at the macrosystematic level, becoming increasingly flexible at lower levels, to the extent that at the subspecific level HBW generally aims to follow all of the latest developments that appear to have gained reasonable acceptance.

The present volume contains what will undoubtedly prove taxonomically to be the single most significant deviation from traditional usage in the entire series. The Plains-wanderer (*Pedionomus torquatus*) has long been linked with buttonquails (Turnicidae), and has even at times been included within that family, although for some years now it has almost universally been awarded its own monotypic family, Pedionomidae, within the Gruiformes. However, quite recently a considerable body of strong evidence has been produced which suggests that the Plains-wanderer is not closely related to the buttonquails at all, but instead belongs alongside the waders or shorebirds in Charadriiformes. Unquestionably, the systematists have not had their last say on this matter (or any other!), but there is currently a reasonable degree of consensus in favour of this change. At the same time, as the species is endemic to Australia, and as recent

Australian literature appears to accept this transfer more or less unanimously, it seemed imprudent, confusing and perhaps even counterproductive for HBW to stick stubbornly to usage that has fallen into such disfavour within the species' only range country. To do so would have been clearly in contradiction to HBW's stated aim to provide the relevant information on any particular taxon in the place where the average reader expects to find it, since most workers, especially Australians, would presumably now expect to find this species in Charadriiformes.

The taxonomically controversial Hoatzin (*Opisthocomus hoazin*), sole member of the family Opisthocomidae, has traditionally been linked with the Galliformes, but more recently it has been placed with the Cuculiformes. As already explained (see Volume 2, page 18), it was decided some years back that, at any rate for the purposes of HBW, the most sensible and appropriate treatment for this taxon would be that advocated by E. Stresemann in 1934, namely its isolation in a separate monotypic order, Opisthocomiformes. The Hoatzin is the starting point of this present volume.

Another similar case, that of the sandgrouse (Pteroclidae), may also merit brief mention here. This family has usually been placed in the pigeon order Columbiformes, but in recent years there has been a call to shift it to the shorebird order Charadriiformes. Again, for HBW it has been deemed wisest to adopt the third major option, that of awarding the sandgrouse a separate order, Pterocliformes. Having accomodated these two macrosystematic modifications, the editors are now fairly confident that it is most unlikely that there will be any further alterations affecting ordinal level within the entire series. For example, the recent proposal to award the buttonquails their own independent order, Turniciformes, was considered an inappropriate change to introduce in HBW.

One matter deserving of explanation concerns scientific nomenclature, as laid out in the International Code for Zoological Nomenclature (ICZN). The policy for family names based on genera with the *-is* termination is that the termination of the family-group name can be either -idae or -ididae. For reasons of simplification, the shorter, simpler ending -idae is generally preferred. This policy is of particular relevance to the present volume, as it affects the case of the sheathbill family, which is preferably named Chionidae, rather than the form Chionididae; the latter form has been much used and is not technically incorrect, but the use of the shortened form Chionidae has been recommended, and so is adopted herein. A very similar case is that of a subfamily within the sandpiper family Scolopacidae: the name Calidrinae is now the recommended form, as opposed to longer version Calidridinae. However, there are exceptions: the name Otididae should be retained for the bustard family, as a special case, due to the possibility of nomenclatural confusion arising in the hypothetical case of the owl genus *Otus* being used as the basis of a family-group name.

With the introduction of the new IUCN criteria, as explained in Collar *et al.* (1994), pages 14-21, the Mace-Lande categories that appeared for some families in Volume 2 are no longer required; the new criteria are reaping the benefits of the experience gained with the Mace-Lande system, and provide a sounder basis for the application of categories. The categories themselves have changed slightly from the previous IUCN designations. The three threat categories in order of magnitude are Vulnerable, Endangered and Critically Endangered. Note that species classed as near-threatened belong, by definition, within the non-threatened category, although there can be no doubt that some of these species may shortly be reclassified to one of the threatened categories. One very slight discrepancy with IUCN is that, purely for the purposes of HBW, the category Extinct in the Wild is considered to belong in the threat categories, rather than in the extinct category, as herein it is understood not be extinction in the definitive, irreversible sense.

Throughout the texts the terms "shorebirds" and "waders" are used indifferently, as there appears to be no pressing need to establish a single term. At the same time, "shorebirds" in the Old World can be understood to include gulls, herons and perhaps even some crows, whereas "waders" in the New World is often understood to include herons, storks, ibises, flamingos and their various allies.

It is considered that the name Myanmar has now achieved almost universal acceptance, so this form has been adopted for Volume 3 onwards. On the other hand, the renaming of the South African provinces caught the editors unawares, too late to substitute all references to Natal with the new name KwaZulu-Natal.

Readers are asked to note that, as explained in Volume 1, the use of an exclamation mark with Other common names has a particular meaning, almost invariably that the name has been or is also applied to another species. Such, for example, is the case of the name "Purple Gallinule", which has been extensively used for both *Porphyrio porphyrio* and *Porphyrio martinica*, making it an inappropriate option in either case for HBW, due to the possible confusion that could result.

The accepted French, German and Spanish names come from the same sources as listed in the introductions to Volumes 1 and 2. Missing German names were kindly sent by Peter H. Barthel, Chairman of the Ständiges Komitee für deutsche Vogelnamen. Publication of the list of recommended Spanish names continues, the second batch appearing in *Ardeola* **41(2)**: 183-191.

Acknowledgements

As ever, museums have been very important in many aspects of the project. We are very grateful to the British Museum of Natural History at Tring (Robert Prys-Jones, Peter Colston, Michael Walters, Mark Adams). We should also like to thank the American Museum of Natural History in New York (Mary LeCroy, Paul Sweet), and the Smithsonian Institution in Washington (Gary R. Graves, Richard L. Zusi, Pamela C. Rasmussen, J. Phillip Angle, Carla Dove). Others who very kindly assisted in various ways include the National Museums of Scotland in Edinburgh (Bob McGowan), the Australian Museum in Sydney (Walter E. Boles), the Museum of Victoria in Melbourne (Rory O'Brien), the Field Museum of Natural History in Chicago (David Willard), and Liverpool Museum (Tony Parker).

Libraries too have again played a very important part in the preparation of the volume, and we are extremely grateful to the libraries of the Museu de Zoologia of Barcelona (María Angeles Iglesias), the Sociedad Española de Ornitología in Madrid (Blas Molina, Juan Carlos del Moral), the Station Biologique de la Tour du Valat in the Camargue (C. Perennou, J. P. Taris), the British Museum of Natural History at Tring (Effie Warr), the Centre de Documentació del P. N. dels Aiguamolls de l'Empordà (Rosa Llinàs), the Royal Australasian Ornithologists Union (John Peter), and the Estación Biológica de Doñana (José Cabot). Assistance in bibliographical matters was also received from several other ornithological organizations and staff involved in their publications, and we express our thanks to Penny Olsen (CSIRO), Nicholas Gould (*IZN*), Susanna Lawson (American Birding Association), Einhard Bezzel (*Journal für Ornithologie*), Harro Hieronimus (*Der Falke*), Jean Peck (*Birds of North America*), Raül Aymí (Grup Català d'Anellament), Ian Grant (Avicultural Society of Australia) and Taej Mundkur (AWB).

Visits to collections of live birds have proved very useful, both for the present volume and with an eye to the future, and we should like to extend special thanks to San Diego Zoo in USA (David Rimlinger), the Parque Ornitológico y Botánico El Retiro in Málaga, Spain (Geer Scheres, Eduardo Alba), and Hope Zoo in Kingston, Jamaica (Rhema Kerr).

Many people helped by providing information, often unpublished, and by clarifying particular issues, and we should like to extend our thanks to Sebastian (Bas) van Balen, Michel Devort, Geoffrey Field, Phil Gregory, Stuart Irwin, Paul Jepson, Jean-Paul Julliard, Carlos Keller, Bob Kennedy, Volker Konrad, Albert Martínez-Vilalta, Bob Medland, Anna Motis, Alan Peterson, Asad Rahmani, Richard Schodde, Mutsuyuki Ueta and all the others, regrettably too many to list, who have most kindly sent material of different sorts. Once again we are very grateful to Michael Patrikeev for sending us copies of the relevant pages of the manuscript for his forthcoming book *The Birds of Azerbaijan*. Sue McRae very kindly gave permission for the inclusion of material from her unpublished thesis. Once again, Alan Knox (Buckinghamshire County Museum) kindly checked details concerning several references of scientific descriptions, once again at very short notice!

The relative obscurity of several species in this volume meant that it was at times particularly difficult to locate reference material, especially for the plates, and we owe many thanks to Björn Andersson, Alexander V. Bardin, Albert Bertolero, Andrés Bosso, Marco Favero, Tim Fisher, Jon Fjeldså, Peter Harrison, Vladimir M. Loskot, Mary LeCroy, Mariano Martínez, Hernán Rodríguez Ponti, C. S. (Kees) Roselaar, Vadim G. Vysotsky and Claudia Wilds. Pica Press (Nigel Redman) kindly helped us with the publication of a photograph which we were particularly interested in including.

The materials used by artists, editors and some authors have been greatly enriched by two most useful agreements: with VIREO at the Academy of Natural Sciences of Philadelphia (Doug Wechsler), involving reference photographs; and the National Sound Archive of the British Library (Richard Ranft), involving recordings of bird vocalizations.

The 33 authors who have participated in the present volume variously express their sincere gratitude to David Allan, Gary Allport, Vania Soares Alves, Dan Anderson, Paulo de Tarso Zuquim Antas, Allan J. Baker, Mark Barter, Peter Becker, Albert J. Beintema, N. Belialov, O. Belialov, William Belton, Tom Benson, Walter J. Bock, P. D. Boersma, Marcel Boulet, Patricia Bradley, C. G. Bradshaw, Joël Bried, Don

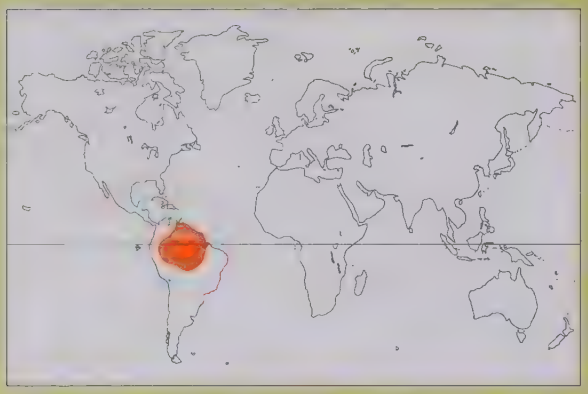
Bruning, Kees Camphuijsen, John Chardine, P. A. Clancey, C. Clinning, Charlie Collins, Sheila Conant, Courtney J. Conway, John Cooper, Jack Cowrie, Robert H. Day, Scott R. Derrickson, George Divoky, David Duffy, Charles Duncan, J. Durbin, William R. Eddleman, Graeme Elliott, the Erickson family, Peter J. Ewins, Mario Fasola, P. G. H. Frost, Sean Furness, Anthony Gaston, A. Giles, B. Giles, Alex Gochfeld, David Gochfeld, Deborah Gochfeld, Petra de Goeij, Paul Goriup, P. Gowthorpe, Alfred Gross, H. Hafner, R. van Halewyn, Brian Harrington, Ross Harris, Rod Hay, Helen Hays, P. Houde, Marshall Howe, Tom Howell, Kees Hulsman, Mike Imber, Johan Ingels, Paul Isenmann, Eve Iversen, Joe Jehl, P. A. Johnsgard, Oscar W. Johnson, Ian Jones, Gary Kaiser, Brina Kessel, Mikael Kilpi, Dick Kimber, B. King, Fritz L. Knopf, B. A. Lane, Olivier Langrand, Mary LeCroy, David S. Lee, Mercedes Lee, Fred Lesser, Yves Létocart, N. M. Litvinenko, B. Loos, P. Luttikhuizen, Francisco Mallet-Rodrigues, Jeffrey S. Marks, John Maron, Rodney Martins, David S. Melville, Peter Miles, J. A. Mills, Colin Miskelly, Doug Mock, Robert Montgomerie, Ralph Morris, Guy Morrison, William Moskoff, Taej Mundkur, Luis G. Naranjo, Inês do Nascimento, M. Angela Nettleship, Ian Nisbet, Rob Norton, Storrs Olson, Lewis W. Oring, Henri Ouellet, José Fernando Pacheco, Gary W. Page, Dennis R. Paulson, Bob Paxton, Sarah Paxton, Charles Pickett, Manuel Plenge, Sarah Plimpton, John Ralph, Bill Robertson, Chris Robertson, Danny Rogers, Kees Roselaar, Rosanne Rowlett, Margaret Rubega, Marucio Rumboll, Keith Russell, C. Safina, Paul Sagar, H. Sakalauskas, Jorge Saliva, Betty Ann Schreiber, Stanley E. Senner, Dave Shealer, Roy Siegfried, Serge Sirgouant, Margaret A. Skeel, A. Sokolov, David Sonneborn, Bill Southern, Jeff Spendelow, Ann Sutton, Jean-Marc Thiollay, Pavel S. Tomkovich, Greg Transue, Dorothy Tunbridge, Tom Van der Have, R. P. Vari, Dick Veitch, Enriqueta Velarde, Christophe Verheyden, Yvonne Verkuil, J. Viksne, F. E. Warr, Michael Walters, Nils Warnock, Doug Watkins, A. Wassink, Karen Weaver, David Wells, C. P. Wilds, F. A. Wilkinson, M. Witte, Glen Wolfenden, Robin Woods, Gilson Evaritso Iack Ximenes, Pablo Yorio, Victor Zubakin and G. A. Zweers. Several authors also offer their kind thanks to others already participating as authors of this volume.

Permission was generously granted for the use of distributional data and information from species accounts of Rallidae for the forthcoming Southern African Bird Atlas. The chapter on Charadriidae is publication number 3002, and the chapter on Scolopacidae is publication number 3003 of the Netherlands Institute for Sea Research (NIOZ), Texel.

Miquel García and César Ruiz helped most efficiently in the production of the book. For help in many different ways, our grateful thanks go to Maria Josep de Andrés, Ventura Boluda, Dolors Buxó, Juan Antonio Cantí, Carles Carboneras, Fortunato Frias, Oriol Frias, Sònia Frias, Sílvia Muray, Maria Teresa Obiols, Deli Saavedra and R. D. Wooller. Last, but by no means least, our grateful thanks go to Toni Llobet for kindly providing the back cover illustration.

Order OPISTHOCOMIFORMES

Opisthocomiformes



Opisthocomidae

Hoatzin

Class AVES

Order OPISTHOCOMIFORMES

Family OPISTHOCOMIDAE (HOATZIN)

- Large, gregarious, arboreal birds, with prominent crest, long tail and large wings.
- 62-70 cm.

- N South America, E of Andes.
- Tropical forested wetlands.
- 1 genus, 1 species, 1 taxon.
- No species threatened; none extinct since 1600.

Systematics

The Hoatzin (*Opisthocomus hoazin*) is a monotypic species of uncertain affinities. Since it was first described in 1776, there has probably been more controversy regarding its systematic position than that of any other bird species. It was originally named *Phasianus hoazin* by P. L. S. Müller, implying an affinity with the Galliformes. In an 1840 publication, C. L. Nitzsch linked it with the Musophagidae, a family which is now considered to belong to the Cuculiformes. Over the years it has variously been allied to the Tinamidae, Cracidae, Rallidae, Otididae, Pteroclidae, Columbidae and Coliidae, and recently to the Cariamidae.

Most frequently, however, the Hoatzin has been considered to share some characters with the Galliformes, and it has tended to be placed near Cracidae. Nevertheless, in recent years there has been a strong move to link it with the Cuculiformes, where it is sometimes placed in close association with the anis (*Crotophaga*) and the peculiar Guira Cuckoo (*Guira guira*). The problem is that the Hoatzin is so aberrant in both morphology and behaviour that it does not fit satisfactorily alongside any other group of living birds. Apparently, it has gone through a long and independent evolution, retaining some primitive ancestral characteristics, while evolving other, more recent, specialized features.

More conservative systematists retain the Hoatzin in the order Galliformes, based on osteological and immunological data, and possibly also on account of its microscopic feather structure. In contrast, recent evidence from egg-white protein, DNA-DNA hybridization, scleral ossicles (bones of the eye-ring) and behaviour suggest its affinities are with the Cuculiformes. However, the evidence is equivocal, and the fact that the Hoatzin has the anisodactyl foot of most birds, with a single toe pointing backwards, rather than the zygodactyl foot of the cuckoos, with two toes that can be turned backwards, has been considered a major obstacle to this view. The evidence of feather lice does not appear to help, as most of the Mallophaga genera found on the Hoatzin are unique, while the one that has been found on other species occurs widely on species such as the Green Ibis (*Mesembrinibis cayennensis*), a coincidence which is assumed to be the result of these species sometimes sharing the same habitats.

Thus, the nearest living relatives of the Hoatzin, normally regarded as one of the most primitive of modern birds, remain a subject of controversy. Currently, most taxonomists award the Hoatzin at least its own suborder, Opisthocomi. However, the lack of consensus as to which are its closest relatives, combined with a fairly generalized agreement that it is quite distinct from all other birds, suggests that the most appropriate course is probably to place it in its own separate order, Opisthocomiformes, a view advocated by E. Stresemann as long ago as 1934, which has come back into favour fairly recently.

A single Tertiary fossil, *Hoazinoides magdalenae*, dating from the Miocene 18 million years ago, was discovered in Colombia and has been linked with the Cracidae. The fossil site was in the upper Magdalena Valley in the department of Huila, an inter-Andean area beyond the present day distribution of the Hoatzin, although in that period the Andes had not yet been uplifted. Interestingly, this fossil, the only avian fossil from the site, was found in close association with a fossil monkey, *Cebupitheca sarmientoi* (see Breeding). Another fossil genus, *Filholornis*, from the Upper Eocene or Lower Oligocene of France, has been linked to both the cracids and the Hoatzin.

Recently, a new fossil family of landbirds, Foratidae, from the Lower Eocene Green River Formation in Wyoming has been erected for *Foro panarium*, a new genus and new species, based on a nearly complete, associated skeleton. The skull and mandible are most similar to those of the Hoatzin, but the postcranial skeleton shows some similarities to the Musophagidae. Also of interest is a Hoatzin-like fossil fragment which has been reported from Eocene deposits in Argentina.

Since the ancient, reptilian-like, feathered dinosaur *Archaeopteryx* had three functional claws on each wing, some earlier systematists speculated that the Hoatzin was descended from it, because nestling Hoatzins have two functional claws on each wing (see Breeding). However, modern workers believe that the young Hoatzin's claws are of more recent origin, and may be a secondary adaptation resulting from its frequent need to leave the nest and climb about in dense vines and trees well before it is capable of flight.

Morphological Aspects

The generic name *Opisthocomus* comes from the Greek, meaning "wearing long hair behind" and refers to the Hoatzin's most distinctive plumage feature, its unusual crest. Much of the time the narrow, 4-8 cm long, somewhat stiffly shafted, mainly rufous crest feathers remain individually erect in a loose manner. This crest, combined with a red iris, prominent eyelashes, and a large bright blue bare orbital and facial area that extends to the bill and around and beyond the ear, gives the Hoatzin a bizarre

The flight silhouette of the Hoatzin shows a striking lack of symmetry: the wings appear inordinately broad and the head, crowned by its permanently erect crest, almost grotesquely small. The large size of the wings is deceptive, for the body beneath them is rather slight and, although the bird may measure some 70 cm long, it weighs only 700-900 g.

[*Opisthocomus hoazin*, Hato el Frío, Llanos de Apure, Venezuela. Photo: X. Ferrer & A. de Sostoa]

and somewhat startled appearance. In addition, this large, but small-headed, long-necked and long-tailed bird often crouches and peers out from between thick leaves in a suspicious manner.

The dorsal plumage is mainly bronzy olive with prominent pale buff streaks on the nape and mantle, while the brown wing-coverts are edged with three distinctive white bars. The ten rectrices of the tail are long, dark brown and very broadly tipped buffy white. The Hoatzin's primaries are chestnut, while the secondaries are brown, like the back and the tail. Below, the throat and breast are buffy white, gradually becoming rich chestnut on the thighs and the vent. The short, laterally compressed, black or dark olive-coloured bill is stout, and the strong-looking legs and large feet are also blackish. Sexes are similar, and adults weigh in the region of 700-900 g.

In general, adult Hoatzins have the appearance of a pheasant or, in the Western Hemisphere where there are no native pheasants, a cracid. Indeed, a common name for the Hoatzin in Venezuela is *Guacharaca de Agua* or "Water Chachalaca", because it seems similar to the more terrestrial and abundant Rufous-vented Chachalaca (*Ortalis ruficauda*).

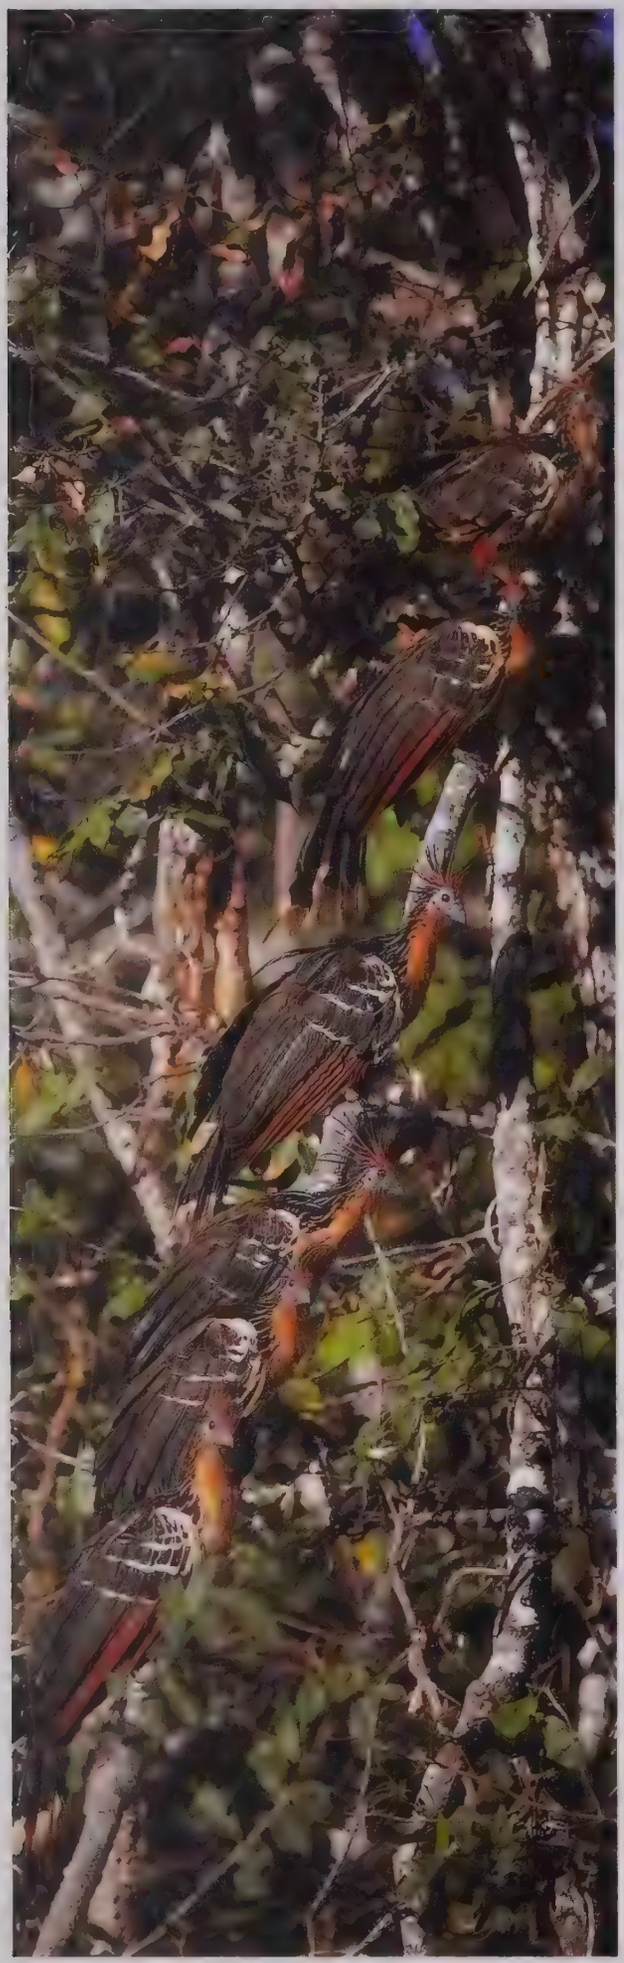
Anatomically, the Hoatzin's greatest peculiarity is its unique foregut, which is far larger than its stomach, and in which it processes great quantities of vegetable matter in the manner of a ruminant (see Food and Feeding). The foregut and its contents sometimes make up 25% of the bird's total weight, while its size imposes strict constraints on much of the bird's lifestyle. In order to accommodate this large bulk, the sternum is greatly reduced, with a consequent reduction of flight muscles, which limits the Hoatzin to flying and gliding only in short, heavy bursts. While flight appears weak and awkward, a bird can cover as much as 350 metres in a single flight, though most flying involves much shorter distances. The bird's legs and feet trail below the body during these short, somewhat laboured, flights.

Birds can grasp branches, but they climb and creep about awkwardly in the often dense vegetation of their habitat, and this means of locomotion appears clumsy. Hoatzins perch in a conventional manner, but much of the time is spent in sternal perching, resting on a sternal callus, while lengthy digestion takes place. The callosity is an elliptical horny patch of skin lying over the rear tip of the sternum.

Only young Hoatzins seem able to swim well (see Breeding), and this is exclusively a predator-avoidance tactic. Adult birds found in the water have almost certainly been frightened there, and swimming by adults is generally rare. Although their legs and feet appear well developed and strong, neither adults nor young hop or walk on the ground. Their legs and feet may have evolved for clutching onto leafy branches over water, but they are not zygodactyl as in the Cuculidae (see Systematics).

The Hoatzin's anatomy and restricted locomotion can be attributed to its folivorous diet. Adults, being essentially non-swimmers, poor fliers and weak climbers, are among the most spacially restricted of all birds. Hoatzin social behaviour probably evolved as a result of their morphological limitations.

Because Hoatzins spend their lives in, and climbing through, thick arboreal vegetation, they show an unusual amount of feather wear and breakage. This is especially evident in the severe abrading of the tail, where the wide, buffy white terminal band is often extremely worn or even missing. Moult of adults takes place, as in most birds, following the breeding season, which is the early dry season. In a six month old bird, primary moult progressed outward from the first primary, but secondary moult had two centres, beginning with the tenth and first feathers. Moult on both sides of the tail began almost simultaneously with the outer and inner pairs progressing evenly towards the third pair.



Few birds have a greater reputation than the Hoatzin for an unpleasant odour; in Guyana the species is even called the "Stinking Pheasant". The smell is described as musky or like fresh cow manure, and this smell is thought to be a result of the processing of foliage in the foregut. However, several authors in Venezuela report little or no odour; this might be the result of different species of leaves being eaten there. W. Beebe cooked and ate the flesh of birds he was preparing, and he reported that although tough, the taste was "clean and appetizing as that of a curassow" (Cracidae); he doubted that the persistent odour was connected with the crop contents.

Habitat

Hoatzins are reported to be found up to an altitude of 500 m, but most birds live in the range of about 5 m above sea-level up to about 200 m. They are completely dependent on riparian vegetation in lowland habitats of the Neotropics.

The Hoatzin's range is exclusively east of the Andes, in the drainage basins of the Rivers Amazon and Orinoco, and along the Atlantic coast in Guyana, Surinam and French Guiana, where the species is associated with rivers that flow north and northeast into the ocean. The kind of water within the habitat, be it salt, brackish or fresh, appears to make little difference to the Hoatzin because it lives entirely in trees, vines and bushes, and is thus independent of the different kinds of aquatic foods that each of these water types support. In many areas the species is frequently associated with giant arums, especially those of the genus *Montrichardia*, which constitute a favourite food. In coastal zones *Avicennia* mangroves can be similarly important.

The selection of habitat depends entirely on the existence of dense fluvial-associated vegetation, beside and overhanging sluggish rivers, streams, ox-bow lakes, swamps and lagoons.

The same thick, often thorny, vegetation provides the birds with all their basic necessities for life, namely food and nesting and roosting sites. Nevertheless, Hoatzins are patchily distributed throughout their range. Often they seem plentiful in one area, but nearby there is a hiatus in seemingly acceptable habitat; perhaps this is connected with their physical limitations.

General Habits

The Hoatzin's restriction to dense trees, vines and bushes that line the waterways of Neotropical lowlands may have evolved because of the bird's evolutionary choice of a vegetarian diet, and its consequent ruminant behaviour. The anatomical modifications necessary to accommodate the bulky foregut (see Morphological Aspects), and to slow digestion, have combined to restrict the bird's capability of movement, which in turn has behavioural implications.

Hoatzins are highly social at all times of the year, and at times can be seen in groups of more than 40 birds. Two adults will sometimes perch in bodily contact with each other. During breeding, birds occupy small, densely packed, exclusive territories (see Breeding), but in the dry, non-breeding months they live in large, tight groups of as many as 100 individuals or more.

In the past, various authors reported that Hoatzins were colonial, but long-term ringing studies showed that, when breeding, they maintain exclusive, but exceedingly small, territories. Nevertheless, in Peru a non-territorial group of 28 birds was reported to nest colonially in a single tree.

Hoatzins rain-bathe while perching in trees by spreading their wings and erecting their dorsal feathers. They often climb to exposed perches to sun-bathe, turning their backs to the sun and spreading their flight-feathers. Self-preening is frequent, whereas allopreening has not been observed, either between adults, or between adults and their offspring, in spite of the large numbers of ectoparasitic eggs often clearly visible on their faces and feathers. Some of these parasites have been identified only with the Hoatzin host, but no systematic clues, that would suggest relationships to other living bird families, have been found among those parasites so far examined (see Systematics). Head scratching is direct, under the wing. Non-nesting Hoatzins spend about 75% of the day in two forms of roosting behaviour, conventional perching and sternal perching (see Morphological Aspects).

Voice

Hoatzins are noisy, and groups of birds often call in unison, when the combination of their numbers and their curious vocal repertoire can create a great commotion.

They have a large number of vocalizations including hoarse cries, grunts, croaks, growls and hissing. Many of these calls are accompanied by the spreading of the wings and tail. Contact calls, between members of a social unit, are in a series of 3-10 grunts, "oww" or "ohh". In nest defence, birds use a wheezing, raspy nasal hiss, "waaahh", which is a response to predators, humans and low-level territorial intrusions. A high-intensity raspy hiss is used in defence of young, and a gutteral 0·5 second "rrruuh" is used in the social unit, most commonly between individuals of mated pairs. Chicks out of the nest make location calls, and young will beg for food with raspy peeps.

Food and Feeding

Formerly, it was thought that Hoatzins, near-obligate folivores, ate only the leaves of arums (Araceae) and the mangrove *Avicennia*, and were thus confined to fluvial areas where these plants grew. This idea arose because early observations of Hoatzins were made in the vegetation beside saline and brackish waters of rivers in the Guianas, near the Atlantic coast.

Hoatzins are primarily social birds, living in groups all the year round. During the breeding season tight little units of 2-8 birds typically occupy and defend a territory and co-operate in the breeding effort. Outside the breeding period the groups tend to be much larger, and such large gatherings are often rather noisy. Owing to the species' limited powers of flight, and of locomotion in general, the birds are highly sedentary, and indeed are rather sluggish, being far from nimble climbers. Most feeding activity takes place in the morning and near dusk, but birds will also feed on moonlit nights when they can become extraordinarily vocal. Otherwise, apart from preening and indulging in sun- and rain-bathing occasionally, they spend a large proportion of their time simply resting in the trees.

[*Opisthocomus hoazin*, Photo: François Gohier/ Ardea]

The Hoatzin's fundamental habitat requirement is the existence of marshy plants, preferably giant lilies (Montrichardia) *and also* Avicennia *mangroves, and it depends largely on such plants for its almost exclusively folivorous diet. Endowed with a peculiarly large crop, the bird, when it has eaten its fill, tends to become top-heavy and therefore unstable. At such times it typically rests on a sternal patch of horny skin which it situates on a branch, and the bird may remain in such a position for long periods at a stretch, in order to digest in comfort its bulky intake of green leaves.*

[*Opisthocomus hoazin*, Manu National Park, Peru. Photo: Günter Ziesler]

Nowadays, they are known to eat more than 50 species of plants. In one study in the Venezuelan *llanos*, they ate 82% green leaves, 10% flowers and 8% fruits. However, their usual diet in this region consists of fewer than a dozen species of plants, while only some four or five plant species compose three quarters of this diet over the year. Hoatzins are especially partial to the leaves of tropical legume trees, many of which contain toxic compounds (see Relationship with Man). Furthermore, they are selective, choosing to eat young leaves, tender shoots and buds, which are higher in water content, as well as being both easier to digest and more nutritious.

Other leaf-eating birds, such as the Ostrich (*Struthio camelus*) and grouse (Tetraonidae), have hindgut fermentation like horses. In contrast, Hoatzins ferment their vegetable matter in the foregut like cows, sheep, deer and kangaroos. Plant-eaters obtain most of their usable sugars from the cellulose of plant cell walls, but they have to rely on microbes, such as bacteria, protozoans and fungi, which live in the gut, to break down the cellulose by means of fermentation.

The digestive tract of the Hoatzin is one of extreme adaptation. Unlike the case in other birds, the Hoatzin's crop and lower oesophagus are the main digestive organs. In this, the Hoatzin's foregut is similar to that of cows. A thick-walled, muscular crop and lower oesophagus take the place of the cow's rumen, as the site of active fermentation under constant temperature and acidity. The crop and lower oesophagus are large and voluminous, as compared with the proventriculus and gizzard, which are the main digestive organs in more typical birds. The Hoatzin's foregut contains layers of powerful muscles with folded, ridged interiors, lined with tough, horny tissue to break down the food. In addition, there are two constrictions or filters to the flow of coarse vegetable matter, which slow down the passage of food. In many bird species, the period of time for which food is retained is often measured in minutes, but the Hoatzin holds the record. In experiments, liquids were retained for about 18 hours, and solids for 24-48 hours; these retention times are similar to those found in sheep, and are long enough to maintain stable populations of gut bacteria.

The process of the Hoatzin's foregut fermentation is complex and specialized, because it takes the place of chewing and rumination, producing usable volatile fatty acids, before the food passes through all the usual avian digestive organs. Several reasons have been suggested for this, such as the Hoatzin's high food selectivity and typical high avian energetic demands, but recent research has shown that the Hoatzin is able to digest a much higher proportion of its food than other plant-eating birds on comparable diets, and indeed that it is similar in performance to ruminants. Current speculation suggests that foregut fermentation also allows bacteria to detoxify noxious chemicals before the food can be absorbed or fed to young, while the microbial synthesis of essential amino acids and vitamins may help to give the bird a more balanced diet.

Nestling and young Hoatzins are fed from the adults' crops on this same regurgitated half-digested foliage, a sticky, greenish, pre-digested mash. It is rich in bacteria, which help to inoculate the young birds' developing crops with the necessary fermenting microbes. Because of the low nutrient value of the Hoatzin's food, the young grow very slowly.

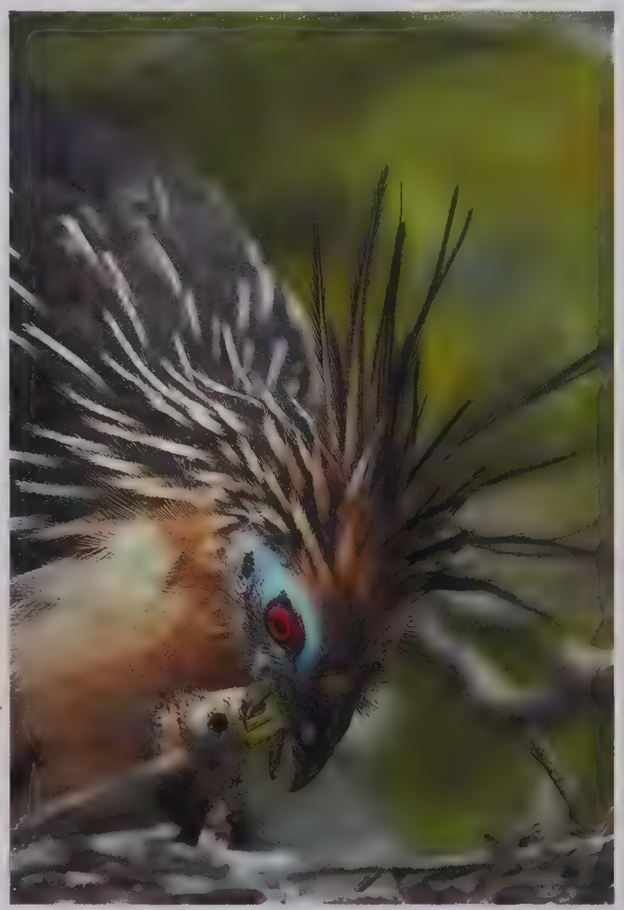
Hoatzins rarely drink, probably because 70% of their leaf diet comprises water, but when they do drink, they tip the bill into water, then tilt the head back and upwards, like most birds. There are two reports of Hoatzins eating foods that were not vegetable, namely small fish and a crab.

The principal times of diurnal foraging are in the early morning and the early evening, and they usually last one or two hours. Birds generally forage within some 50 m of a watercourse. They spend the hot midday hours sternal perching in the shade, digesting the plant matter in their crops. On moonlit nights they typically vocalize, and travel up to 300 m from their defended

The Hoatzin's clutch usually consists of two eggs. Incubation, lasting about a month, is carried out by the monogamous pair of parent birds aided by all the group members, normally their own young of previous seasons. By day ten, the chicks have developed thick dark brown down, but their growth is very slow. Though the young birds may leave the nest at 2-3 weeks old, parents and helpers will carry on both feeding and brooding them for as much as two months. It has been calculated that breeding success can be increased substantially by the participation of helpers.

[*Opisthocomus hoazin*, Venezuela. Photo: Bruno Pambour/ Bios]

territories in order to feed. Then all the birds of a social unit, excepting those individuals that are incubating or brooding, forage close together.



Breeding

Breeding takes place during seasonal rains. Throughout much of the Hoatzin's range the climate is strongly seasonal, with six months of rain, four months of drought, and two intermediate months between the seasonal extremes; as the rains begin at quite different times of the year in the regions roughly 5° north and 5° south of the equator, the timing of breeding is better described by seasonal rainfall than by month. Furthermore, because the rainfall is bimodal in the Guianas, where early observations were made, there were conflicting reports of breeding months.

The highly gregarious Hoatzins live and breed in stable social groups of two to eight birds. Two is the most common unit and more than five is rare. The extra birds are subadult and adult helpers, and ringing has shown that nearly all helpers are the young from previous nestings of the pairs they help. A few immigrant, non-breeding helpers were found, and while they lived in the territories and were accepted by territory holders, the immigrants usually helped very little, more often in territorial defence than in rearing the young. Of all first-year birds studied, 90% stayed and helped their parents during subsequent breeding attempts. By the time helpers were four and five years old, the percentage still helping in their natal unit dropped to 20% and under 10% respectively. Most of the long-term helpers were males, because in the Hoatzin females are the dispersing sex, and most of them had left their natal units by the time they were three years old.

Hoatzin helpers take part in all breeding activities except reproductive copulation and egg-laying. In general, it was found that helpers partially emancipated female Hoatzins, and also that they significantly increased reproductive success. In territories with helpers the young were able to leave the nest, which becomes increasingly predation-prone, on average a week earlier than in territories without helpers. Helpers were particularly active in territorial defence, but they also assisted with nest building, incubation and brooding, and fed both nestlings and fledglings. Yet, despite these apparently clear advantages, about 45% of Hoatzin territories did not have helpers.

These social units defend small, well defined, all-purpose territories throughout the breeding season. Breeding males of adjacent territories sometimes engage in aerial battles, flying at

The Hoatzin's diet is composed almost entirely of vegetable matter. When feeding the young, the parent or helper will regurgitate from its crop a semi-digested slimy mass, which the chick receives by introducing its opened bill well into the adult's gape. The chick often pecks at the adult's bill to provoke regurgitation. Although the young Hoatzin is well able to fend for itself after about three months, this begging behaviour can continue until it is 4-5 months old.

[*Opisthocomus hoazin*. Photo: F. Köster/ Survival Anglia/ Oxford Scientific Films]

each other from 3-5 m apart, and colliding in mid-air breast-to-breast, pecking and clawing at each other. Usually they fall back into the vegetation, locked together, before separating.

The prominent crest is used in social signalling. The male's crest is strongly erected when he defends his territory, at which time he also extends the neck and spreads his wings and tail. In the female, the crest is depressed and neck retracted when inviting copulation.

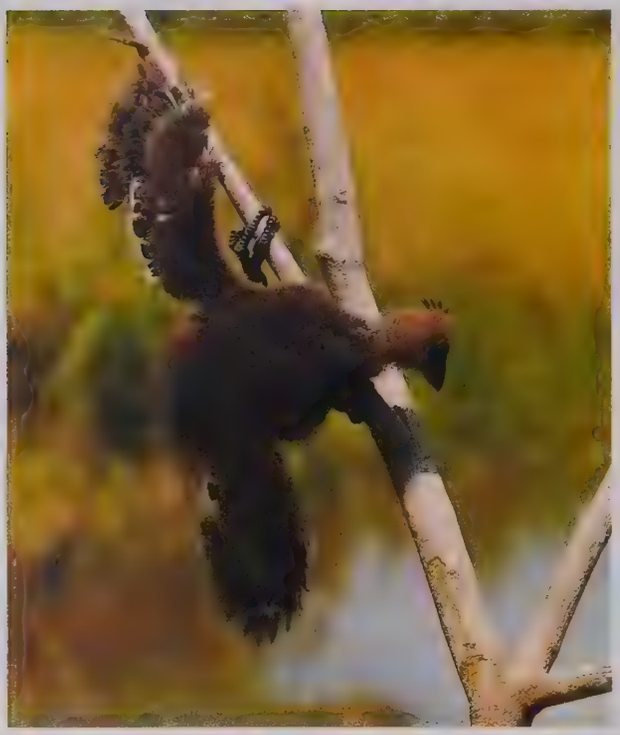
In the same study, the defended territories, all adjacent to watercourses, had a mean distance of 42 m along the water, and were defended up to 75 m away from the water's edge. Diurnal activities were usually confined to an area of 1000-3000 m².

Within breeding territories two kinds of copulation take place, display copulation and reproductive copulation. Display copulations constitute a defence strategy. They consist of brief mountings of females by the breeding male, that are directed towards territorial intrusions and displays by neighbouring Hoatzins. These display copulations take place throughout the year and are briefer than reproductive copulations, while the post-display vocalizations are louder and last longer than in reproductive copulations. On the other hand, reproductive copulations have been observed only between the breeding pair, not with their helpers; they occur only during the nest building period and shortly before the laying of the eggs.

The nest is a flat, unlined platform, 30-45 cm wide, made of dry twigs and sticks, sometimes so loosely constructed that the eggs can be seen from below. It is similar to the nest of the Green-backed Heron (*Butorides striatus*), which sometimes breeds nearby. The typical nest, with or without an overhead canopy, is in dense bushes or trees, 2-5 m above water. Successful nests and nest-sites are reused in subsequent years.

The usual clutch consists of 2-4 eggs, which are somewhat variable in shape from elliptical to oval, and which are said to resemble the eggs of rails (Rallidae). They are white, heavily overlaid with small dots and spots of reddish brown and lavender. The mean measurement of 111 eggs in Venezuela was 46·7 x 33·1 mm. Eggs are laid 1·5-2 days apart, and incubation begins with the laying of the second egg, lasting a total of 30-31 days; as with most other aspects of breeding, all members of the group co-operate. In the same study, renesting occurred as many as six times when a nest failed, as long as the rains continued. Successful nesting early in the season for units of 4-6 birds was followed, on rare occasions, by a second nesting.

The semi-nidicolous young hatch within a day of each other in two-egg clutches, but up to four days apart in larger clutches; the adults eat the eggshells. At hatching, the chicks weigh 17-21 g and are of a pale flesh colour, with sparse down, but by the fifth day the skin has changed to dark brown-black, and by the tenth day the nestlings are covered with a thick coat of dark brown down. Their eyes open within a day of hatching, and by the third day they move about in the nest using their wings and feet to help them; the legs and feet are very large in proportion to the size of the chicks. Growth is slow in the young birds, and their flight-feathers are only emerging from the sheaths by days 20-25.



Nestling Hoatzins are brooded continuously for up to three weeks, by both parents and their helpers. As early as their third day, young Hoatzins will jump out of their nests into the water below to avoid predators, although research has shown that these young have a lower chance of subsequent survival; if they are older, five or six days old, their chances of success are greater. Even the youngest birds, when fleeing predators, are able to swim by propelling themselves with alternate kicks of their feet. They can also dive and swim under water, using the wings synchronously. Although chicks can swim six metres or more, as soon as they reach the bushes and trees of their natal patch they climb up using the two claws on each wing, assisted sometimes by arching the neck over twigs and small branches, and by using their toes and bills. In this they are sometimes encouraged by vocalizations from the adults, but even without help, the young birds make peeping sounds that aid their parents and territorial helpers to find them. On one occasion, five birds of a territorial unit spread their wings over a young bird as it made its way into the safety of a dense cover of leaves. Early authors reported that the young find their way back to their nests. However, recent studies have found that the young do not return to the nest, but are cared for, brooded, fed and defended on various branches within the natal territory.

Undisturbed young Hoatzins leave the nest at 2-3 weeks of age, when they are sometimes coaxed away from the nest by the adults. The juvenile birds are still brooded and fed off the nest for up to two months. By days 55-65 these juveniles can fly short distances. The young shed their wing claws between days 70 and 100, but some individuals have been found to regrow them later; eight of 24 adults had non-functional, callused-over wing claws. The nestlings' claws are small, rounded hooks on digits two and three (see Volume 1, page 37); some authors,

When danger threatens, with the sudden appearance of an enemy, even a very young nestling will employ a predator-evasion mechanism by jumping out of the tree or nest into the water below. There it can swim, even under water as here, using both the wings and the feet to propel itself forwards. Eventually it manages to hoist itself onto the bank and then up into the vegetation or a tree, calling at the same time to enable a parent or helper to locate it more easily and so come to its aid.

[*Opisthocomus hoazin*, Guyana. Photo: Alan Root/ Survival Anglia/ Oxford Scientific Films]

The Hoatzin chick possesses a rather rare anatomical feature: on each wing are two claws which enable it to grip branches and clamber around in trees in a singularly awkward, almost reptilian, fashion; these features have been used for likening the species to Archaeopteryx. *The wings appear poorly developed for a chick of this size, but the feet, in contrast, look abnormally large, while there are already signs of an incipient crest.*

[*Opisthocomus hoazin*. Photo: Alan Root/ Bruce Coleman]

using older systems of digit numbering, report that the claws are on digits one and two.

Successful nesting in the Venezuelan *llanos* was increased by the presence of helpers, but still only 27% of 404 nests were successful. Most failures in this study were due to predation of entire clutches of eggs or of all the chicks by the wedge-capped capuchin monkey (*Cebus olivaceus*). Other predators were the tayra (*Eira barbara*) and also ants, which sometimes attacked pipping eggs or live, newly-hatched young. The occasional disappearance of young was probably caused by avian nest predators, such as the Collared Forest-falcon (*Micrastur semitorquatus*), the Bicoloured Hawk (*Accipiter bicolor*), the Great Black Hawk (*Buteogallus urubitinga*), the Crane Hawk (*Geranospiza caerulescens*) and the Ornate Hawk-eagle (*Spizaetus ornatus*). Mammalian nest predators in a Venezuelan study area, where 58% of Hoatzin nests failed, and where neither capuchins nor tayras were present, were the common opossum (*Didelphis marsupialis*), the grison (*Galictis vittata*), the crab-eating raccoon (*Procyon cancrivorus*) and the ocelot (*Felis pardalis*). The survivorship of 60-80% that was recorded for adult Hoatzins is high.

Nestlings and fledglings are fed for several months with partially digested leaf mash, regurgitated from the crops of brooding birds; young birds will put their heads into the open bills of the adults. They beg for food by pecking at the adults' bills and making high-pitched peeps, behaviour that sometimes continues until they are four to five months old. Yet, between one and two weeks of age, nestling Hoatzins begin to sample leaves near their nests, although they do not feed independently until they are 50-70 days old.

Normally, mated pairs are monogamous, though rarely they can be polygamous, but 7% of the breeding units in one study consisted of more than a single breeding pair within a single defended territory. In these unusual circumstances, which generally occurred in units of 6-7 birds, some birds used the same nest for egg-laying and others made two separate concurrent nests in the same territory.

Rarely, Hoatzins attempt breeding as yearlings, although one such male ended up with infertile eggs. About 10% breed at two years old, whereas most start to breed when they are three years old. In the same study, the recorded nest success rate of first-time breeders was comparable or slightly lower than that of the population as a whole. One breeding male lived more than eight years, but it seems highly likely that in due course long-term studies will find much older individuals in a stable population.

Movements

In accordance with their weak flying abilities, Hoatzins are essentially sedentary. This is especially true of those with the most favourable, predator-free territories on riverine islands.

During the dry non-breeding season, the most stressful time for the birds, many Hoatzins in the Venezuelan *llanos* move short distances. In particular, those with marginal or poor quality breeding territories move to nearby sites, less than 2 km away, as the water dries off and their arboreal habitats pass through a deciduous phase.

Thus, while their preferred habitat is dense gallery forest, they can tolerate the dry season months in isolated patches of woodland, if these are beside permanent water, supporting trees and bushes that do not entirely defoliate. In the following breeding season, the territorial groups return to the same territories that they abandoned when conditions became unfavourable.

The dry season, in conjunction with the local movements it forces, is the time of greatest natural mortality amongst Hoatzins. A logical consequence of this is that drought years have a strong negative effect on their populations.

Relationship with Man

W. Beebe once described the Hoatzin as "tame to an absurd degree". Thus, the large, sedentary Hoatzin, that lives in conspicuous, highly social groups is well known to all people who share its Neotropical lowland habitat. Nevertheless, there are two quite different cultural reactions to Hoatzins which vary through the nine countries that support populations of the species.

The oldest human relationship with the Hoatzin is, of course, that of indigenous tribal people. In Brazil, these people collect the birds' eggs for consumption. They also occasionally eat the birds themselves, and will take adults for their feathers, for medicinal purposes, and again to use as fish bait. In complete contrast to this, in neighbouring Venezuela Hoatzins are generally despised because they are said to give off a repugnant odour (see Morphological Aspects). The bird's odour, or at any rate its reputation for being both smelly and inedible, has no doubt conferred a measure of protection on it in some parts of its range. Tribal people are, however, a declining element throughout South America, as they become integrated into the contemporary cultures of their sovereign states, or simply wiped out.

Very recently there has been renewed scientific interest in the Hoatzin, as microbiologists and botanists are intensively studying the bacteria and enzymes in the bird's foregut. The natural detoxifiers that it contains, if isolated and transferred to domestic grazing species, such as cows and goats, should permit these mammals safely to eat more native kinds of forage that currently remain toxic for them. This could result in important ramifications both for domestic animal husbandry and for the environment.

Status and Conservation

At present, the Hoatzin's natural habitat still covers an immense area of South America, so the total population is probably still large, and the species relatively secure, at least for the time being. However, future developments will require close monitoring.

The most serious threat to the species is the fast and permanent conversion of its habitat into agricultural concerns, most commonly for rice culture. This has already happened in Guyana, Surinam and Venezuela. Plans for the dyking and canalization of rivers on a vast scale in the Venezuelan *llanos*, if brought to fruition, would seriously affect Hoatzins in that zone. In all nine of the countries with extant Hoatzin populations, there are heavy pressures emanating from many sources that push for the "reclamation" of "useless" frontier lands, in the name of progress, and to accommodate increasing human populations.

This adult Hoatzin, tending two chicks, reveals all its many-coloured splendour. For good reasons it is locally named "Cigana" or "Gipsy", in allusion to its extravagant apparel: the bright blue orbital and facial patch contrasts with the rufous of the crest, chestnut of the primaries, and richer chestnut of the thighs and flanks. The native populations of northern South America have, of course, long known of such a conspicuous and sedentary bird, but it is not generally accepted as a game bird on account of its frightful odour. It has, however, suffered some persecution, and in Brazil, for example, is no longer to be found in the vicinity of big cities.

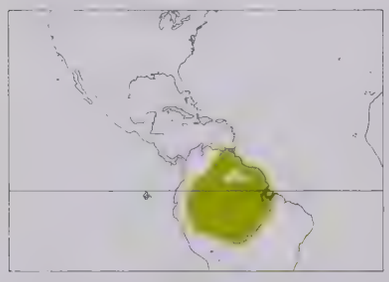
[*Opisthocomus hoazin*, Tambopata Reserve, Peru. Photo: Günter Ziesler]

The preservation of small, isolated patches of intact habitat in a vast area of agriculture, although carried out with the best of intentions, is most unlikely to be of much benefit to the Hoatzin. It must be stressed that the bird's very limited capability for dispersal, in itself a probable reason for its patchy distribution in undisturbed habitat, means that it is extremely poorly designed for escape from rapid habitat changes, even though suitable unaltered habitat may be available only a few kilometres away.

The Hoatzin is a bird that thrives in its native habitat, if given sufficient protection. A good example can be seen in the Venezuelan *llanos* on the Masaguaral cattle ranch, which has been maintained as a private nature reserve for the past 30 years. It is here that much of the most recent research on the Hoatzin has taken place. In the early 1970's the Hoatzin population here was limited to about 20 individuals along the small Guárico River, on the eastern edge of the ranch. Since then, this population has expanded to over 200 birds, in part because of constant protection, and also because some Hoatzins lost their former habitat to rice fields now bordering the south-east side of the ranch. Researchers now believe that the available habitat on the east side of this ranch is saturated. In addition, an isolated area of woodland islands, 5 km to the west on the same protected ranch, and adjacent to a permanent water source maintained in the dry season by deep well pumps, has been naturally colonized from an unknown source.

Similarly, at Limoncocha, close by the River Napo in eastern Ecuador, Hoatzins were an increasing population during the 1970's around a small freshwater lake maintained and controlled by a colony of missionaries. However, the missionaries have since left the station, although the consequences for the Hoatzin population remain uncertain at present. Early in the present century, in Guyana, it was noted that Hoatzins readily spread to the margins of newly constructed canals that served agriculture, if these canals were bordered with the vegetation that the Hoatzins preferred. These examples clearly suggest that existing Hoatzin populations could be maintained easily in suitable habitat in national parks, with no effort other than strict control of human activities. Unfortunately, at present there are few parks within the vast continental range of the Hoatzin that offer adequate protection.

Numerous attempts have been made to maintain Hoatzins in captivity. One zoological society sent three expeditions to Guyana in the early 1960's to collect Hoatzins, acclimatize them and bring them back live. They were unsuccessful in keeping Hoatzins alive in captivity, although a single female survived for nearly six months. In 1989, six Hoatzins were imported from Venezuela by the New York Zoological Society. One bird lived for only a year, but the others have now lived more than five years in the Bronx Zoo. These birds laid and then broke several eggs; no chicks have been hatched yet. What is perhaps more remarkable is that these birds are currently fed on readily available, standard zoological leafy greens and locally grown browse, rather than on any of the exotic, often toxic, plants of their native habitat. It took biologists and nutritionists nearly one year to adapt them gradually to their captive diets. This significant breakthrough suggests the possibility of successful captive breeding in the future.

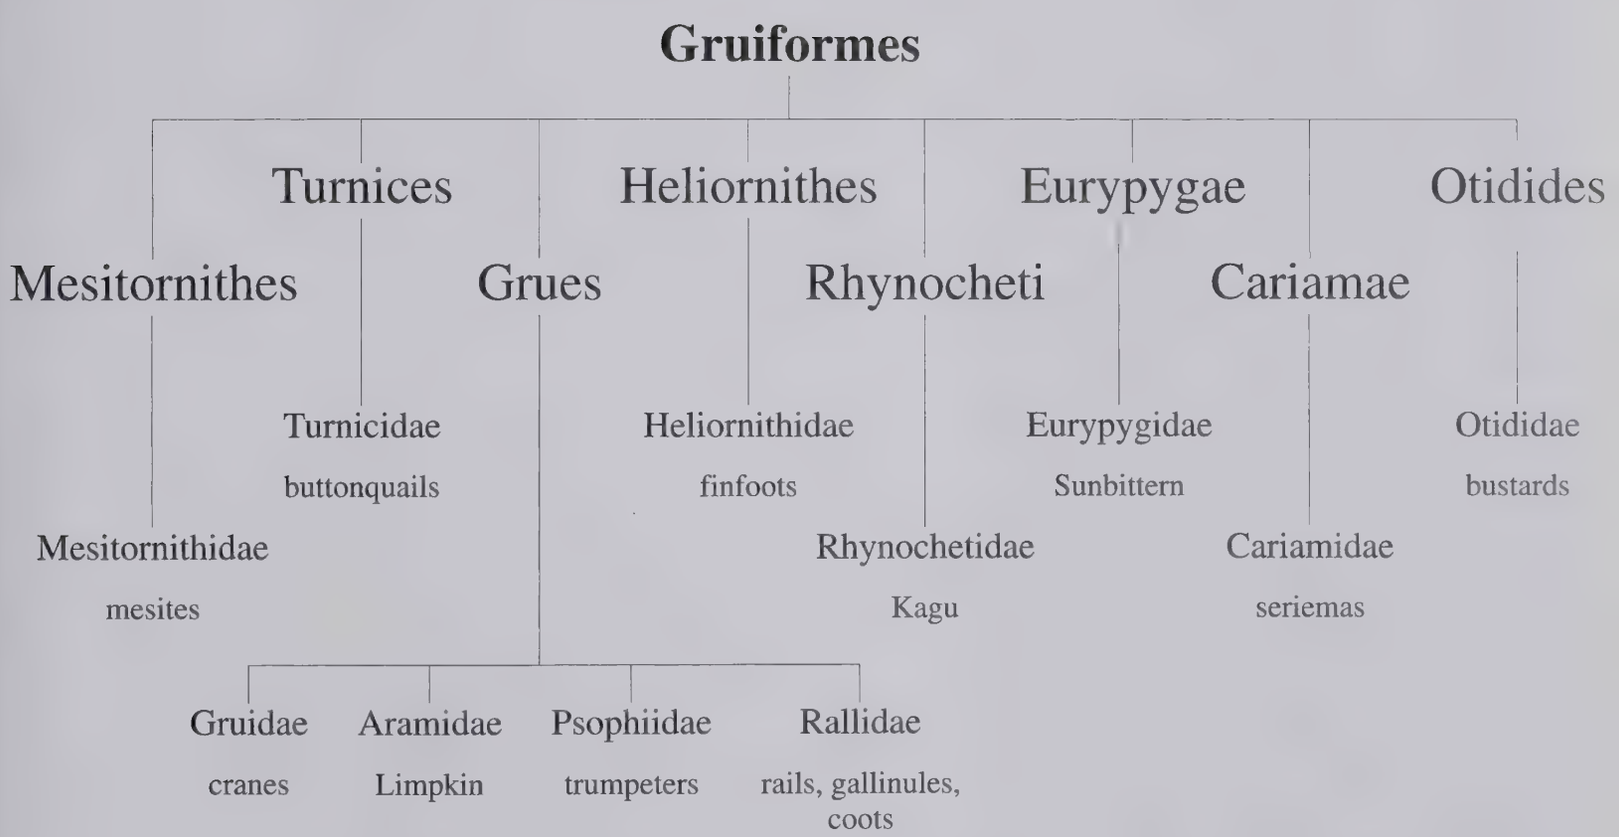


Genus *OPISTHOCOMUS* Illiger, 1811

Hoatzin

Opisthocomus hoazin

French: Hoazin huppé **German**: Hoatzin **Spanish**: Hoazín



Taxonomy. *Phasianus Hoazin* P. L. S. Müller, 1776, Cayenne.
Monotypic family of uncertain affinities. Some morphological similarities with Galliformes, especially Cracidae; recent work suggests relationship with Cuculiformes, near Crotophaginae; closest relatives and position in linear hierarchy remain controversial (see page 24). Monotypic.
Distribution. E of Andes, from Colombia, Venezuela and the Guianas S to Ecuador, Peru, N & C Brazil and Bolivia.

Descriptive notes. 62-70 cm; 700-900 g. Unmistakable. Above dark brown with olive reflections and large white streaks; head rufous with long, narrow, erectile crest; below pale buff to rich chestnut on thighs and vent; broad wings chestnut and brown with white bars on coverts; tail long and broad, with wide pale buffy white tip. Iris red; bare facial skin bright blue; legs, feet and smallish bill black. Female similar to male, but crest said to be slightly shorter. Immature resembles adults.
Habitat. Confined to arboreal vegetation bordering lowland waterways in Neotropics, typically alongside streams, rivers and lakes, of fresh, brackish and salt water; often in vicinity of giant arums (*Montrichardia*, *Caladium*); in coastal zones, frequently associated with *Avicennia* mangroves. In dry season, some populations may be forced to occupy less favourable woodland habitats if normal preferred habitat dries out.

Food and Feeding. Near-obligate folivore; the only bird species known with foregut microbial fermentation, similar to that of ruminants; lengthy digestion of large amount of plant matter, sometimes toxic and low in nutritive value, has influenced morphology, locomotion and social behaviour (see pages 25, 26). Around 80% of intake consists of new growth of green leaves and buds, with over 50 species of plants recorded, e.g. *Montrichardia*, *Avicennia*, *Cecropia* and water hyacinth (*Eichhornia*); a few flowers and fruits taken in season. Feeds in social groups mainly in early morning and near dusk, and also on moonlit nights.
Breeding. Nests in rainy season, dates varying with locality. Monogamous pairs with up to six helpers, mostly their own young of previous season; rarely polygamous; groups defend small, all-purpose territories beside water. Nest placed in dense trees and bushes over water; unlined, open, flat platform of dry sticks. Usually 2 eggs (2-4); incubation 30-31 days, by all members of social group. Chicks have dark brown down; able to escape predators by diving into water and swimming, then clambering back up into vegetation; normally leave nest at 2-3 weeks old, but unable to fly until c. 60 days old; dependent on adults of social unit for food for 2-3 months. Sexual maturity at 2-3 years.
Movements. Highly sedentary; adults do not swim, walk or hop, and have weak flight abilities. During dry season, some social units from suboptimum habitats join others on short migrations of up to 2 km, to arboreal vegetation situated beside permanent water.
Status and Conservation. Not globally threatened. Widespread in suitable habitat, but very patchily distributed; still locally numerous, but little information available on status from most of range. In French Guiana, has declined due to persecution and is now very local; in Brazil, no longer found close to cities. Due to morphological limitations, a consequence of folivorous diet, unable to move far when habitat becomes unsuitable, notably as result of large-scale clearing, e.g. for rice cultivation or hydrological projects.

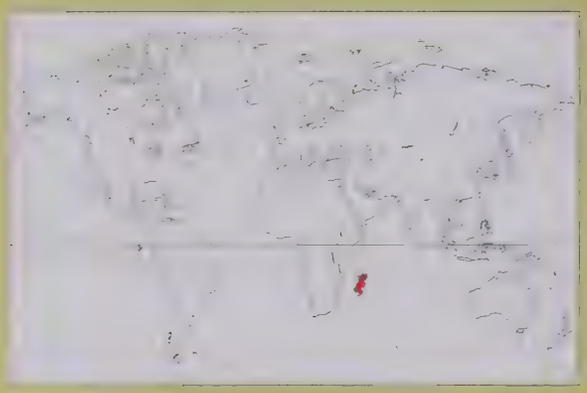
Order GRUIFORMES



Class AVES

Order GRUIFORMES

Suborder MESITORNITHES

Family MESITORNITHIDAE (MESITES)

- Medium-sized terrestrial birds with long, full tail, short wings and stout legs.
- 30-32 cm.

- Madagascar.
- Forest, woodland and thicket.
- 2 genera, 3 species, 3 taxa.
- 3 species threatened; none extinct since 1600.

Systematics

The origin and nearest relatives of the mesite family remain mysterious. Since the first scientific description of the family, various authors have associated it with the Columbiformes (pigeons and doves), the Galliformes (pheasants and allies) and even the Passeriformes, in particular the family Cinclidae (dippers). On the basis of structural characters, however, current consensus places the mesites within the Gruiformes, as "primitive" relations of the rails (Rallidae). Compared with the members of that family, they lack pervious nostrils, and their ample tail is composed of 14 rectrices rather than 12, amongst a number of other differences (see Morphological Aspects). The family has always been regarded as ancient, although no fossils have ever been found, and it is frequently considered sufficiently distinct from the rest of the Gruiformes to warrant its own suborder, while some authors have gone further and awarded it a separate order of its own.

The view of the mesites as primitive is, however, open to question; many of their characters seem to be highly derived, implying that the birds have undergone considerable change since evolutionary divergence from other birds. They might better be regarded as advanced birds, early offshoots well adapted to the Madagascan environment before the arrival of humans. Unlike the vast majority of bird families, no DNA analysis has been published, although preliminary results of such research confirm that the birds do indeed belong in the gruiform assemblage.

Mesites, the name originally given by Geoffroy Saint-Hilaire to the genus now containing the White-breasted Mesite (*Mesitornis variegata*) and the Brown Mesite (*Mesitornis unicolor*), was rendered invalid upon discovery that a genus of weevils had already been given this name. The genus was re-named *Mesoenas* after Reichenbach's description of 1862, but it was eventually established that Bonaparte's name *Mesitornis* had precedence, having been published earlier, in 1855. The family name has also been changed accordingly, by tracking the generic name from Mesitidae through Mesoenatidae before reaching its current form.

The validity of the two currently recognized genera has never been challenged since their creation, which was primarily on the basis of bill form and egg structure and form. However, early authors repeatedly confused the Brown Mesite as the female of the White-breasted Mesite, and thus all records of the latter species prior to 1929 (apart from the type specimen) actually refer to the Brown Mesite. This muddle began with the original type description of the Brown Mesite in 1845, wherein Des Murs put forward the suggestion that the two mesites might, in fact, only be two sexes of the same species. Even though Hartlaub had accepted the two species by 1877, misunderstanding was rife until the 1930's, when Lavauden finally laid to rest the belief that only a single species was involved.

No species could be described as well researched in any aspect. The White-breasted Mesite has been more extensively studied than the other two, while the Brown Mesite, in particular, remains very poorly known.

Morphological Aspects

Mesites are terrestrial birds, roughly the size of large thrushes or small doves. However, in shape they do not resemble either of these groups; they have a distinctive mien that is totally their own. The small head, the long, broad tail and the very thick and extensive undertail-coverts give an almost cylindrical look at times. The tail is usually held closed and only rarely widely fanned out. Short, rounded wings and strong legs characterize all three species and are associated with markedly terrestrial habits and infrequent flight. The bill is slightly or markedly decurved, relatively stout at the base and of short to medium length, according to the foraging specializations of each species (see Food and Feeding). The plumage is generally rather sparse. It is interesting to note that all three species lack oil glands, crops and aftershafts, while they are amongst the few Gruiformes to possess powder-downs.

All mesites are generally rufous brown, with variably paler underparts. These are blotched or spotted black or rufous brown in two of the three species. There is a pale streak above or behind the eye, with bare skin around the eye itself; the prominence of these markings varies within and between species. The legs are pale in colour and tend to be conspicuous in the gloomy conditions of the forest floor. After the post-juvenile moult there is no known variation in plumage with age or season in any species, and only the Subdesert Mesite (*Monias benschi*) is sexually dichromatic.

There is no published information on moult patterns in adult birds. The growth of the wing-feathers and their coverts in chicks seems to occur very early on, compared with the undeveloped state of the body feathers, and suggests a conspicuous relationship with other bird groups with precocial young that show delayed feather development, such as the rails.

Many physical characters seem convergent with rail-babblers (*Eupetes*) and the Sunbittern (*Eurypyga*), two other genera of terrestrial tropical forest birds, and comparisons have also been drawn with the Kagu (*Rhynochetos*) and the Neotropical earthcreepers of the genus *Upucerthia*.

Carriage is horizontal, markedly so in the two *Mesitornis* species, which hold the head and tail flat in a line with the plane of the back, accentuating their cylindrical look. The Subdesert Mesite often holds its head and tail more erect relative to its body.

Mesites generally walk slowly along the ground, never hopping, and running only when threatened, when chasing potential prey, or occasionally when crossing an open area. Each step is accompanied by a gentle head bob and tail flick in the Subdesert Mesite; the tail flick is less regular and the head bob less pronounced in *Mesitornis*. On one occasion a White-breasted Mesite was watched shivering its tail almost continuously, while walking about foraging; this movement was only visible during good close-up views using binoculars, and so may occur more commonly than is realized.

Flight has only been recorded in birds moving up to, or down from, an elevated roost-site, or as an extreme predator evasion tactic, such as when being chased by humans; the wingbeats are vigorous and noisy, like those of a gamebird, and the birds rarely fly more than 20-30 m at a stretch. One White-breasted Mesite was observed to fly for 80 m, but this is exceptional.

Habitat

Mesites occupy a variety of native forest and woodland types, from closed canopy forest through lower, stunted woodland to more open spiny subdesert thicket. No species occurs habitually in plantations, and the extent of use of open woodland varies between the species.

Traditionally, the three species were seen as allopatric, giving a pattern whereby the three major lowland forest types had their own mesite species: the Brown in the eastern humid forest; the White-breasted in the western dry forest; and the Subdesert in the south-western spiny forest. This pattern, elegant in its simplicity, was upset in 1990 by the extraordinary finding of a pair of White-breasted Mesites deep in the eastern rain forest, only 10 minutes' walk away from where sightings of the Brown Mesite had been made. The record was utterly unexpected in the light of previous knowledge, and was all the more baffling because the site, Ambatovaky, is towards the eastern edge of the widest remaining block of rain forest, and thus about as far as possible from the western forest, this species' typical habitat. Further developments are awaited with great interest.

Among all the birds of the forests of western Madagascar, the White-breasted Mesite is one of the species most limited to undisturbed forests. As a terrestrial insectivore, it is a member of a feeding guild recognized as being notably susceptible to forest change throughout the world. Too few data are available on the feeding habits of the other two mesite species to enable the drawing of similar conclusions about them.

Although local seasonal movements may occur in at least one species (see Movements), mesites do not generally move between habitats for purposes of roosting, feeding and breeding. None of the species is generally distributed throughout its main habitat type, with the possible exception of the Subdesert Mesite, but there is no indication which features of the habitat, if any, may be limiting the birds to particular geographical areas. As the Subdesert Mesite appears to be quite catholic in its choice of habitat, it is likely that its range is limited by an inability to disperse across the two large rivers which bound its range. Extensive recent work on the White-breasted Mesite has revealed differences in productivity between forest close to rivers and that at greater distance. This has important implications for conservation (see Status and Conservation).

Mesites typically feed on the ground in areas with thick leaf litter under a rather sparse herb layer. White-breasted Mesites feed preferentially in areas with larger leaves, a denser canopy and shrub layer, and a paucity of dead sticks atop the leaf litter;

The three species of mesites are endemic to Madagascar and all three are rare. Until recently they were held to be allopatric, each species occupying a different type of lowland forest habitat, but the finding of a pair of White-breasted Mesites (Mesitornis variegata) *well away from their usual western dry forest home has caused pause for thought. While further investigation into distribution is needed, it is made difficult by the elusiveness of all Mesites and the dense nature of their forest habitats. The range of the Subdesert Mesite is very restricted: it lives and breeds in the spiny forest of south-west Madagascar, an arid strip of land between the coast and the inland hills, covered in bizarre xerophytic scrub vegetation, including many endemic cactus-like plants and weird trees, such as the tall, many-branched* Didiereas *and dwarf baobabs. Like the other mesites, this species requires plenty of thick leaf litter on ground free of herbaceous growth where it is able to forage freely, probing energetically with its bill for invertebrates and vegetable material, such as seeds and small fruits. At the same time, despite its strongly terrestrial nature, it requires suitable trees or shrubs in which it can place its nest and roost at night.*

[*Monias benschi*, near Ifaty, Madagascar. Photo: Peter Morris]

The White-breasted Mesite is the best documented member of the family. Even so, data are still rather limited and the species is known from only four main sites. Monogamous, it forms a long-lasting, perhaps permanent pair-bond, and moves around the forest in small groups consisting of the parent birds and their most recent young. Pairs and groups maintain and defend territories, and territorial fights sometimes occur. White-breasted Mesites are known to rest and roost regularly in their small social units and choose sites, normally on a horizontal branch up to 4 metres off the ground, where they spend the night remaining in close bodily contact.

[*Mesitornis variegata*, Ankarana, Madagascar. Photo: Frank Hawkins]

such sticks would prevent the birds sifting through the litter. Nests are placed in the shrub layer, not on the ground, although birds usually walk up lianes to their nests, rather than flying up.

The White-breasted Mesite roosts 1·5-4 m up in shrubs or small trees within the forest. A roost-site of a group of Subdesert Mesites was 3·5 m above the ground, in the crown of a low, densely branched tree, on a branch 4 cm thick. Roosting sites of the Brown Mesite remain unknown as yet, but are expected to be similar to those of the other two species.

General Habits

So far as is known, mesites are exclusively diurnal. As they have distinctive and far-carrying cries, and large amounts of nocturnal survey work (for lemurs) have been carried out in some areas known to support mesites, the lack of records suggests it is unlikely that nocturnal activity is common, if it ever occurs at all. This contrasts notably with some other medium-sized terrestrial forest birds, such as woodcocks (*Scolopax*). White-breasted Mesites feed most intensively in the early morning and the late afternoon; the midday period, which is particularly hot in the west of the island, is spent in dense shade, the birds often mostly resting, with desultory feeding.

All three species are mainly restricted to the ground, except for roosting and nesting. The birds walk up shallowly sloping branches into trees to roost, visit their nests, or evade predators. They may rest on their tarsi when roosting, whether up a tree on a horizontal branch, on a fallen log, or sometimes on the ground itself. The Subdesert Mesite, although previously described as "apparently unable to fly", is most certainly capable in that regard. Several observers have found these birds either at dawn or dusk at their roost-sites, after hearing their loud calling. When approached, the birds may take off and fly 25-30 m away before landing. Indeed, such elevated roost-sites may be regularly used, and the Subdesert Mesite actually seems to be the species structurally best adapted for flight and arboreal locomotion. Interestingly, it retains its bobbing gait (see Morphological Aspects) while clambering around in tree crowns.

The social unit consists of the pair and their most recent young in the White-breasted Mesite, but it is larger in the Subdesert Mesite, although precise intra-group relationships have never yet been established for this species. The pair-bond for White-breasted Mesites lasts for longer than one season and possibly for life. Adult Brown Mesites apparently live in pairs, since a high proportion of the few observations made have been of groups of two birds, even though the most widespread local name for the species (see Relationship with Man) suggests that it too occurs in family parties, perhaps containing only one young, in the post-breeding season.

Groups, at least of White-breasted Mesites, tend to move around together and approximately to co-ordinate activities such as feeding, resting or preening. Allopreening is commonly observed in the White-breasted Mesite, mostly between the members of the adult pair, but also, more rarely, between an adult and a juvenile. Feather-shaking is noticeably audible.

Within White-breasted Mesite groups, occasional disputes arise over larger food items. Pairs or groups maintain overlapping, but defended, territories. Territorial battles occur occasionally between groups of White-breasted Mesites, with individual adults fighting individual adults in the opposing group. This involves antagonists flying up in air, pecking and scratching at each other like fighting cocks. It may be that males fight males, and females females; juveniles watch but do not participate. Mesites roost and rest in close bodily contact, usually with all members of the group together.

Adult White-breasted Mesites are preyed upon by Henst's Goshawks (*Accipiter henstii*), but they show little reaction to passing individuals of the two sympatric species of native diurnal mongoose-like carnivores, the boky-boky (*Mungotictis decemlineata*) and the vontsira (*Galidia elegans*), suggesting that they may not be regularly attacked by these species. All species react to the presence of a major predator, such as a nearby person, by making for dense vegetation; if the stimulus is weaker, they may freeze, behaviour which makes them vulnerable to human predation.

The Brown Mesite is considered difficult to see by birdwatchers and researchers alike: O. Appert tells of how he spent six days searching a forest for the species, but managed only one brief sighting, although the "song" was easily heard (see Voice). This difficulty has traditionally been attributed to the bird's great shyness, and other surveys of suitable rain forest have had similarly poor, or

even worse, sighting rates. By contrast, in one area, the Masoala Peninsula, daily sightings are possible at some seasons. The other two species are much more easily seen, probably for the simple reason that they occur at higher densities.

Appert describes a form of predator-evasion behaviour called "Camouflage-stillness", in which at the sound of human pursuit, for example, a group of Subdesert Mesites will suddenly scatter simultaneously in all directions, after which the birds stand motionless in the shadows, or fly up onto branches and then lie pressed against them, as if frozen still, for up to half an hour. This freezing behaviour is clearly similar to that shown by *Botaurus* bitterns, another genus of cryptically brown, largely terrestrial birds that inhabit densely vegetated areas. Such species tend to live in areas of low light intensity, and, provided they can remain motionless, they stand a good chance of avoiding detection by potential predators.

Voice

Vocal communication seems to be of crucial importance to mesite life, and the wide vocabularies of these birds include both resonant and harmonious sounds.

All three mesites have "songs", which in the White-breasted Mesite are known to be important in territory defence. White-breasted Mesites, and probably also Brown Mesites, have closely synchronized duets, lasting between 30 seconds and one minute, in which the male and female have different parts. The duet is started by the male, which may also sing individually, in which case the song is much shorter. Rarely, females may sing alone or may initiate duets, especially if female song is heard from a nearby group. Males frequently sing unaccompanied, particularly when the female is on the nest. Subdesert Mesites also have a song which appears to come from more than two members as a chorus. Territory holders are stimulated into vocalizing by hearing other groups calling.

White-breasted Mesites sing all year round, but more frequently in the period October to December, early in the breeding season. Duetting has interesting social implications: sometimes it certainly involves females singing to females in other groups. It may facilitate the holding of the territory all year round by birds in which plumage is not sexually dimorphic and the adults are long-lived. Although a third member of a group, presumed to be a juvenile, sometimes joins in the duet, this individual's performance is almost always crassly timed and incomplete; usually the duet is performed solely by the male and female. These duets may parallel those performed by other visually inconspicuous birds of the tropical forest understorey, such as many Neotropical wrens, notably those of the genus *Cyphorhinus*.

The Brown Mesite's song, heard particularly between September and February, was described by Appert as a loud, far-carrying, prolonged series of calls "hütjühütjü..." (as transcribed in German), oft-repeated and somewhat reminiscent of the call of the Cuckoo-roller (*Leptosomus discolor*), and also perhaps similar to, but not really confusable with, the loud "song" of another ground-dwelling denizen of the rain forest, the Madagascar Wood-rail (*Canirallus kioloides*), which A. L. Rand well described in the 1930's as "a rather loud, sharp series of whistles, delivered with a rising inflection, that often seemed about to end several notes before it did".

Appert found that Brown Mesite singing was most intense in the early morning, in the period around half an hour on either side of sunrise, and that it was initially delivered from the roost-site, as occurs in the Subdesert Mesite. Song continued to be heard occasionally during the rest of the morning, until about 11:00 hours, but never in the afternoon or evening. This pattern of a strong peak in the early morning echoes that shown by various other highly vocal, territorial inhabitants of rain forest, most notably the gibbons (*Hylobates*) and the grand old man of the Madagascar rain forests themselves, the indri (*Indri indri*). This timing makes full use of the still, cool morning air, which allows calls to carry far and with minimal distortion; thus listening conspecifics may more easily assess the location of the territory being defended.

The Subdesert Mesite too sings mostly in the early morning: in the breeding season the song consists of strophes 33-45 seconds long, whilst outside the breeding season birds sing less frequently and employ shorter strophes. The song starts with a loud, excited series of "züzüzü zizizizi" (transcribed in German) followed by a single, precise "ürr" at a deeper pitch. This is repeated in its en-

For mesites vocal communication seems to be of paramount importance. Both males and females perform alone, in duets, and even in chorus. A certain amount of song is heard throughout the year, presumably for territory maintenance, but it is more frequent from the onset of the breeding season. The Subdesert Mesite sings quite melodiously in the early morning during the breeding season, but more sparingly at other times. The length of the phrases may vary, but a single phrase may last for up to three quarters of a minute. This species is locally known as "Naka", in imitation of its alarm calls.

[*Monias benschi*, Tuléar, Madagascar. Photo: Dominique Halleux/ Bios]

tirety, so that a rhythmic sequence develops: "züzüzü zizizizi ürr, züzüzü zizizizi ürr...". The "zü... zi..." series changes somewhat during the course of a single song, such that only the sharp, high "zi" notes can be heard. The "zü..." and the "zi..." notes are probably made by the same individual, whilst the "ürr" is thought to be made by a second individual, the song thus being a duet, as in the genus *Mesitornis*.

The alarm call is rather similar in all species. It is quite loud and sharp or hissing, and is variously transcribed as "tsssk", "zik" or "tschiä", amongst others. Various other calls are much less well known; as in other aspects, the White-breasted is the best studied species.

The White-breasted Mesite shows a limited repertoire of other calls. A quiet "tschht" is given under mild alarm, accompanied by tail-wagging and head-bobbing. A very quiet "pop-pop-pop-pop-pop" while feeding is probably mostly a juvenile contact call. Birds may give a quiet "bub-bub-bub....", sounding like teeth chattering, for about five seconds, on the reunion of members of a pair or group, after they have been temporarily separated; while calling they circle around each other in a seemingly appeasing fashion, with feathers fluffed out. Another similar call, a continuous clucking noise sounding like a distant motorcycle, was heard from a lone male as he climbed up small shrubs, carrying small sticks and prospecting for nesting sites. A much louder call, associated with display, is given immediately after mating; the loud "quee-quee-quee" or "pew-pew-pew-pew" usually lasts only three or four whistles, probably to prevent predators locating the source of the sound, as, though brief, it is very penetrating. A high alarm or contact-seeking call is also given during intra-group conflict.

The Brown Mesite makes a regular, though infrequent, contact call: a distinctive sharp, but low, chicken-like "cluck" or "tschuk". As the birds forage in pairs, they may sometimes be separated, but even then they continue to give contact calls. Appert described the alarm call as a nervous "zik", repeated a few times. Subdesert Mesite chicks in the hand made sharp piping calls, like domestic hen chicks.

Despite the birds' efforts to feed quietly (see Food and Feeding), they can at least sometimes be located by the sounds of rustling leaf litter, particularly when they are probing the ground below.

Food and Feeding

All three species feed on insects, seeds and small fruit in varying proportions, with small adult and larval invertebrates predominating. Crickets, cockroaches and spiders are the dominant invertebrate groups eaten by the White-breasted Mesite, and most of those taken are less than 1 cm long. The Subdesert Mesite also feeds on cockroaches, other recorded items being grasshoppers, caterpillars, beetles, millipedes and seeds; pieces of shell and sand have also been found in the stomachs of collected specimens. Villagers also report that this species eats parts of orchids. In the White-breasted Mesite, seeds feature more in the diet during the dry season. The smallest land vertebrates in the world inhabit the forests of Madagascar, and it is not surprising that on occasion mesites may eat the tiny *Brookesia* chameleons, as some of the species are smaller than the large terrestrial invertebrates. Like them, the chameleons are common in the leaf litter.

Brown and White-breasted Mesites forage by walking slowly around suitable areas, taking a meandering path and investigating their surroundings quietly and methodically. White-breasted Mesites have been intensively studied while foraging. They use three main feeding techniques, which are, in order of importance: flicking over the uppermost dead leaves in the litter layer, and gleaning from the surface; the lifting up large leaves to look underneath for large invertebrates; and gleaning from stems and leaves in the low herb layer. Additionally, rolled-up dead leaves are picked up and thrashed against the ground or the roots or trunk of a tree to shake out any hidden prey, such as beetle larvae. In contrast, the Subdesert Mesite feeds predominantly by probing and digging below the litter layer, as might be deduced from its more robust, longer and more curved bill, but it also makes occasional pecks above ground while walking along.

The shorter and slightly curve-tipped bill of the two *Mesitornis* species is attached to the skull at an angle and position that permit the bird to lift leaves and look carefully underneath without flicking them over. Such leaves are released back to their original positions if nothing is underneath, minimizing disturbance which might flush prey, and noise which might attract predators; a sudden grab is made at any prey located beneath leaves. White-breasted and Brown Mesites may run to chase invertebrates flushed from the leaf litter. During the dry season White-breasted Mesites become more likely to dig at the ground, though they are not known to leave dimples in the soil in the way that feeding Subdesert Mesites usually do. Based on his field experience of the species in the 1970's, Appert suspected that the Brown Mesite might also be responsible for leaving such feeding dimples in the upper soil layer under the leaf litter, as well as in rotting wood, but neither he nor any subsequent observer has proved this.

White-breasted Mesites are often accompanied by Crested Drongos (*Dicrurus forficatus*) which take insects flushed by the mesites and may rob them of larger prey items. Madagascar Paradise-flycatchers (*Terpsiphone mutata*) also take insects flushed by White-breasted Mesites, and both these passerines have been observed following Subdesert Mesites. Foraging White-breasted Mesites may also attract a variety of other small birds, including Madagascar Magpie-robins (*Copsychus albospecularis*) and Long-billed Greenbuls (*Phyllastrephus madagascariensis*), and even another threatened species of similarly restricted range, Van Dam's Vanga (*Xenopirostris damii*). They are also followed by Coquerel's Couas (*Coua coquereli*) and Hoopoes (*Upupa epops*), although the reasons for this are unclear, as there is no interaction with these species; in such associations, both species may possibly enjoy better predator detection.

The diet of chicks remains entirely unknown, in part because adults become very nervous of human observers when accompanied by small chicks, making observations difficult. It is thus not clear whether the chicks are capable of feeding themselves immediately from hatching, as do many unrelated precocial birds, or whether they are absolutely dependent on parental feeding for the first few days, as is the case in other families in the order Gruiformes, such as bustards (Otididae) and rails. Such parental feeding occurs at any rate in *Monias*, with even half-grown young begging for food, but its importance remains unknown.

Mesites, at least the White-breasted, seem to drink only rarely. There is a recorded instance of a bird taking several sips from the water-filled shell of a dead African giant snail (*Achatina fulica*).

Breeding

The two *Mesitornis* species probably show a monogamous mating system, whereas there are suggestions that *Monias* is polygamous, with different females laying in the same nest. Mesites, at any rate the White-breasted, are territorial, and in this species there is some temporal and spatial overlap in territory, but when two groups meet there may be a loud singing competition or even what amounts to a pitched battle (see General Habits).

A similar phenomenon may occur in the group-living Subdesert Mesite: Appert described a kind of ritual fight display, which he saw only once, in November. There were at least three sets of two males in an unusually open, sandy, clear area, a seismic line bulldozed through the subdesert thicket. The males in each couple were opponents and jumped high in the air facing each other, rising up to 30 cm above the ground, but not touching, and staying separated by about 30 cm. In the meantime some females, and also apparently some males, ran here and there, sometimes remaining in the area of the fights, and sometimes disappearing temporarily into the thicket beside the clearing. There was a continuous chorus of loud, excited "zizi ürr zizi ürr..." calls (see Voice). The birds were spread out over 40-50 m of ground, and thus it was not always easy to distinguish the sexes. The lack of other sightings of this phenomenon he put down to the general lack of such open areas in the region where he carried out most of his observations. He heard the same long, drawn out, excited choruses on other occasions at other places in his area, but was not able to see what was going on, presumably due to the impenetrability of the thicket.

The Brown Mesite is a secretive, and thus rarely observed, bird living in remote, dimly lit parts of humid forest. Only two nests have been discovered to date, and consequently information concerning its breeding habits remains fairly scanty. The construction is of interwoven twigs and sticks, thinly lined with grass, and placed in the fork of a tree, 1-2 metres above the ground. It is situated in such a way that the bird can gain access without having to fly. Considering the size of an adult, the single egg seems disproportionately large, but as yet no explanation for this has been offered.

[*Mesitornis unicolor*, Madagascar. Photo: Dominique Halleux/ Bios]

All species breed in the rainy season, with eggs being laid between October and April; those from the latter month probably belong to replacement clutches. The main breeding season of the Subdesert Mesite is in the first half of this period, the austral summer, with a peak in November and December. However, chicks of this species have even been obtained in June, taken when they were following a female. Likewise, there is a May breeding record for the White-breasted Mesite. Copulation has been observed once in July, but this was more likely to be part of the pair-bonding process, rather than a serious attempt at fertilization; it occurred after a bout of allopreening.

The White-breasted Mesite nests so far found have all been 1-3 m above ground in rather thin clumps of vegetation. They are very difficult for human observers to locate, as the selected tangles greatly resemble numerous other clumps in the neighbouring understorey. Subdesert Mesite nests are situated in bushes or shrubby trees, 0·6-2 m above ground, and are usually reached by the birds' climbing up liane tangles. Only two Brown Mesite nests have been found to date, and both were at similar heights in forks of sloping trees well provided with low branches. In all species, the nest consists of small dry twigs, forming a rather loose, flat platform, lined with some leaves and fibres. Clutches usually number 1-3 eggs, but assessment of the number of eggs laid by individual females is complicated by the possibility of more than one female Subdesert Mesite laying in the same nest.

Eggs are in the form of a short ellipsoid, with the poles almost equally rounded. They are whitish or light yellowish brown and variably spotted reddish; the markings may appear a faded brownish or greyish when the pigmented layer is overlain by other shell layers. Surprisingly, given the similar size of adults of the three species, average egg dimensions vary between the species: the Subdesert Mesite, the largest species, lays eggs averaging 37 x 28 mm; in the White-breasted Mesite, the smallest species, the eggs measure 33 x 26 mm; Brown Mesite eggs are a surprisingly large 44 x 30 mm. It is not known why the Brown Mesite lays such anomalously large eggs, if indeed it truly does so, as only two eggs have been measured.

The division of parental care is poorly known for two of the species and utterly unknown for Brown Mesite, for which only two nests have been recorded. Both were at the incubation stage, with females sitting; so confiding were the birds that the collectors were able to remove them by hand. In the White-breasted Mesite, females appear to do all the incubation, while males remain in the vicinity of the nest, singing occasionally. In the Subdesert Mesite, both sexes incubate and care for the young; at a nest with two eggs, one male and two females were observed. The young are nidifugous, but it is not known how they get to the ground from a nest that is usually 1-3 m up, nor when they leave the nest. In the two better known species, both adults attend the growing family and this is also extremely likely to be so for the Brown Mesite. The length of post-fledging care is unclear, but, at least in the White-breasted Mesite, it may possibly last longer than one year. Because of this extended period of chick-care, group size in the non-breeding season can be used as a measure of breeding success from the previous season. It is probable that birds do not breed every year. The age of sexual maturity is not known for any species.

There is little information on nest predators. There is a documented instance of a White-breasted Mesite nest being depredated by the large snake *Leioheterodon madagascariensis*. Otherwise, possible predators may be conjectured from the animals known to be in the area and their habits. Rodents, both of the native genera *Eliurus*, *Macrotarsomys* and *Nesomys*, and introduced rats (*Rattus*) in some areas, are likely to be the cause of some losses, although adult mesites may be capable of repelling such as these. The extent of colonization of remote forest by *Rattus* species is questionable. Although some visitors reported that these rats were swarming throughout forests several decades ago, many recent workers have found that in primary forest introduced rodents are rare or possibly even absent, and always greatly outnumbered by native species. Nonetheless, it is likely that mesites breeding at the edges of forests sustain heavy predation from rats and have low breeding success. It is likely that nests are also robbed by various birds, notably Hook-billed Vangas (*Vanga curvirostris*).

Movements

White-breasted Mesites hold stable territories of 2-15 hectares, and they tend to move roughly 0·5-1 km around their territory during the day. Roost-sites are not usually the same from one night to the next. Taken together, these findings may imply that resources are depleted by feeding, and that different parts of the

territory are used from one day to the next, or they may be part of a strategy to minimize predation.

No seasonal movements are either known or likely for the white-breasted or Subdesert Mesites, but the Brown Mesite may perform altitudinal migrations. It appears to be common in forests on the Masoala Peninsula at any altitude from sea-level up to 500 m during the austral winter, but is apparently absent or much rarer in the same area during the breeding season. This may imply that the species moves uphill during the breeding season, as do many other birds on forested tropical mountains.

Relationship with Man

The three species are all well known to their human neighbours in Madagascar. The Subdesert Mesite is known as "Naka", in imitation of its calls. In the Menabe area, White-breasted Mesites are called "Agolin'ala", from "Agoly", the local name for the White-throated Rail (*Dryolimnas cuvieri*), and "ala", meaning "forest", on account of the roughly similar appearance of the two species. However, at Ampijoroa, the same mesite species is named "Tolohon'ala", from "Toloho", the name for the Madagascar Coucal (*Centropus toulou*), again combined with "ala", although in this case the reasons are less intuitively explicable. In the Ankarana region, the White-breasted Mesite is known as "Fangadiovy", meaning "excavator of yams", although this name is equally applied to many other medium-sized ground-foraging birds in Madagascar, such as ground-rollers (Brachypteraciidae). There is no evidence of any mesite species taking root crops, and indeed they would be most unlikely to do so; the name may provide extra justification for killing them, in much the same way as some lemurs, for example aye-ayes (*Daubentonia madagascariensis*), are regularly accused of stealing chickens.

The Brown Mesite is known as "Roatelo", meaning "two-three", in the northern and central rain forest areas. Although it was previously suggested that this might be a description of the repetition of elements inherent in its "song", the name in fact appears to refer to the species' occurrence in small groups. In the southern rain forests of Madagascar, this name is not recognized, and the name "Tsikozala" or "Tsikozan'ala" is used instead, based on "Tsikoza", again a local name for the White-throated Rail, and, once again, "ala". Appert noted that the Brown Mesite shared this latter name with Madagascar Wood-rail in this area, and that local people did not distinguish these two species in the field, although they well knew the differences in the hand.

All three mesite species are hunted, especially in forest adjacent to human habitation. One of the capture methods is trapping with nooses, though these are usually intended for larger birds such as the Madagascar Crested Ibis (*Lophotibis cristata*), couas (*Coua*) or the Helmeted Guineafowl (*Numida meleagris*). Other methods include chasing on foot until the birds are exhausted, killing with a sling-shot or bow and arrow, and chasing with dogs into trees, where the birds can be knocked down with sticks or sling-shots. White-breasted Mesites become more timid, sing less and are generally unapproachable in otherwise suitable habitat near villages; densities are also very low in such habitats, implying that hunting and general disturbance have reduced populations.

In the north and central parts of the rain forest, but not in the south, the Brown Mesite is the subject of a powerful taboo, or "fady", which prevents hunting and, in some areas, even the speaking of its name. If young birds are taken, the adults are believed likely to follow the hunter back to the village; this behaviour is taken as evidence of human-like devotion to offspring, which, in turn, deserves human-like respect. In other areas this taboo engenders a terror of the birds themselves. Mesites are by no means unique in this aspect; some of the most powerful fear-inducing animals in Madagascar's forest include the tiny *Brookesia* chameleons, which may measure less than a thumbnail in length. Although this "fady" could conceivably be of occasional local importance in maintaining numbers of the species, taboos are often limited to members of individual families or groups of families, and immigrants to an area often do not respect them. Thus, they are unlikely to have a decisive effect on conservation at the species level, particularly as it is questionable whether hunting *per se* is responsible for the rarity of any of the species.

The White-breasted Mesite is not known to be associated with any taboos, although it is, of course, possible that a taboo so powerful as to preventing the speaking of the bird's name, being difficult to elucidate, could pass unnoticed. However, in areas where it occurs it is well known to local hunters as easy quarry which tastes good. Fortunately, it is not usually targeted because it is too small,

One of the few details that have been established so far as regards the breeding habits of the Brown Mesite is that incubation can be carried out by the female. The role of the male is unknown, and would be difficult to forecast based on the other species, as female White-breasted Mesites (Mesitornis variegata) *are known to perform the entire task alone, whereas in the Subdesert Mesite* (Monias benschi) *both sexes incubate.*

[*Mesitornis unicolor*, Madagascar. Photo: Dominique Halleux/ Bios]

Until recently the Brown Mesite's chick was thought to be blackish, but this photograph demonstrates that such reports were quite unfounded! In fact, an identical error was made with the chick of the White-breasted Mesite (Mesitornis variegata)*, illustrating just how poorly known these species were, and indeed still are. Most details of breeding have yet to be established for all three mesite species, but it seems quite likely that the chicks may be cared for by their parents for an extended period, at least in the White-breasted Mesite.*

[*Mesitornis unicolor*, Madagascar. Photo: Dominique Halleux/ Bios]

although it is taken opportunistically. A fascinating recent "taboo" is emerging at Ampijoroa Forest Station, adjacent to Anakarafantsika. This site has hosted much biological research in recent decades, especially in the botanical gardens, and hunters from neighbouring villages now regard animals in this site as the property of foreigners and accordingly do not hunt them! The mesites in this area are noticeably bold with respect to people.

Status and Conservation

The mesite family is one of the most threatened of all bird families. The latest review of the conservation status of the world's birds by BirdLife International classes all mesite species as globally threatened, placing them in the category Vulnerable. Mesitornithidae is the only bird family of more than two species in which all of the species are classified as globally threatened. All three species are forecast to suffer a rapid population decline in the near future, a decline which is expected to exceed 50% over the next 20 years. This gloomy outlook is based on the high rates of destruction, degradation and fragmentation of the indigenous forest types to which the birds are restricted.

The White-breasted Mesite and the Subdesert Mesite have particularly small ranges on a global scale, rendering them especially vulnerable to habitat-related pressures, which are caused in the main by subsistence agriculture, commercial exploitation for timber and charcoal, and bush fires; hunting may have an important effect locally. In addition, the Subdesert Mesite is also considered to be at risk simply due to the very small size of its population, in conjunction with the aforementioned decline.

The precise distribution of the Brown Mesite within its range appears to be much less patchy than is that of the White-breasted Mesite, and the relative paucity of records must be at least partly due to the bird's shy and retiring nature, combined with the density of the rain forest vegetation, which easily hides the birds and greatly impedes the quiet following up of suspected mesites by observers. Also, ignorance of the bird's loud "song" has certainly inhibited progress in the process of determining the species' distribution. It will undoubtedly prove the most resilient of the three species because of its extensive geographical range, its wide altitudinal tolerance and the relatively large number of subpopulations. Nevertheless, along with all fauna strictly confined to primary rain forest, the Brown Mesite has suffered from a massive destruction and fragmentation of its habitat in the recent past, and this is set to continue at a rapid rate in the future.

As the habitat of all three species is being reduced in extent and being fragmented by humans, additional threats, such as human predation and the effects of introduced mammals, may start operating at a significant level locally, leading to the extinction of isolated populations. Recolonization of such areas would appear unlikely, even if the habitat remained suitable, since all species appear to have poor dispersal capabilities. The productivity of White-breasted Mesite populations is locally heterogeneous, with areas near water sources being the best quality habitat and holding the most successful breeding pairs, at least in the species' southern centre of distribution. These areas are thus disproportionately important in sustaining populations over a much wider area. Unfortunately, they are also a focus for subsistence agriculture and settlement by Madagascar's burgeoning human population. It is clear that the loss of these areas of forest through destruction or degradation might well cause the decline of mesite populations over much larger regions; a similar scenario may be equally applicable to the other two species.

The area of forest in Madagascar has dwindled markedly over the last thousand years, and the process is continuing at present. This suggests that the area of potential habitat for all three species has been massively reduced through human activity. The forest habitat of the two *Mesitornis* species, in particular, has declined by more than 70%. These two species both occur in several designated protected areas, but the level of real protection afforded in these areas is low. The Subdesert Mesite occurs in no protected areas. Another member of a family endemic to Madagascar, the Long-tailed Ground-roller (*Uratelornis chimaera*), also in a monotypic genus, has an almost exactly congruent range. For both of these species, identification of population centres and the development of an action plan for their conservation are high priorities.

Although it has been suggested that Brown Mesite populations may suffer through competition with Madagascar Wood-rails, no evidence has been put forward for this. Indeed, it seems from Appert's observations that the two species have different feeding methods, the rail mainly gleaning from the surface of the forest floor and leaf litter, the mesite apparently also commonly digging into the upper layer of the soil for food items (see Food and Feeding). Moreover, these species have co-existed for so many thousands of years that they are unlikely to be serious competitors anyway: population declines through interspecific competition are difficult to demonstrate, but, where they have occurred, they usually involve at least one non-native species.

No captive breeding has been attempted and, in common with the experience with several other Gruiformes, it may be barely practicable. No species is currently accorded legal protection.

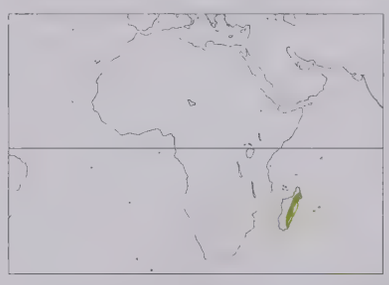
Genus *MESITORNIS* Bonaparte, 1855

1. White-breasted Mesite

Mesitornis variegata

French: Mésite variée **German**: Kurzfuß-Stelzenralle **Spanish**: Mesito Pechiblanco
Other common names: (White-breasted) Roatelo

Taxonomy. *Mesites variegata* I. Geoffroy Saint-Hilaire, 1838, Madagascar.
Formerly placed in genus *Mesoenas* (see page 34). Recent anomalous record from rain forest may prove to belong to subspecifically distinct population, but no relevant specimens known to exist. Monotypic.
Distribution. Madagascar. Known only to occur in three widely separated small areas in W & N, between 12°44' S (Analamera) and 20° S (Menabe forests); however, single anomalous record from E (Ambatovaky).



Descriptive notes. 31 cm; 103-111 g, female may be smaller and lighter, but not apparent in field. Pale creamy to white supercilium and throat; breast also pale cream, sometimes tinged rufous; black crescents on sides of breast and upper belly; back rufous brown. Development of rufous breast band linking moustachial stripes is highly variable in extent and tone in northernmost population; birds of southernmost population have thick, bright bands. Some birds have noticeably grey nape. Bare skin round eye grey to bright blue. Such variability might be related to age or sex, or both, but nothing known. Bill intermediate in length between those of *M. unicolor* and *Monias benschi*, and much less curved than that of latter; paler underparts than *M. unicolor*. No seasonal variation, nor significant changes due to feather wear. Juvenile up to 1-2 months old similar to adult, but throat and supercilium yellow-buff with smudgy blackish longitudinal marks; thenceforth probably indistinguishable from adults.
Habitat. Primarily found in dry western forests, at altitude of less than 150 m. Single recent anomalous record from lowland rain forest at 350 m.
Food and Feeding. Mainly feeds on small adult and larval invertebrates, but also takes some plant matter. Food items recorded as being taken, in order of frequency: unidentified seeds, 3-5 mm in diameter; crickets, 5-10 mm; cockroaches, 5-10 mm; spiders, 5-15 mm; beetles, adults and larvae, latter up to 20 mm long; centipedes; mantids; and moths and flies. Seeds made up 17% of items in number, rest invertebrates. Other items recorded include dwarf terrestrial chamaeleon (*Brookesia*) and crystallized exudate of homopteran bug nymphs of family Flattidae. Species inhabits seasonal environment and diet accordingly varies: small invertebrate prey commoner in dry season, larger prey more frequent in wet season. Forages on forest floor, gathering food mainly from leaf litter, but also from low vegetation. Main foraging techniques include gleaning from surface of leaf litter, low vegetation or spiders' webs, leaf-turning and leaf-lifting; also leaf-thrashing and sometimes a short chase of flushed invertebrates; occasionally probes into soil, mainly in dry season. See page 38.
Breeding. Active nests found Oct-Apr, with egg-laying peaking Nov-Jan. Apparently monogamous, with long-lasting pair-bond. Nest is loose flat platform of 20-30 sticks; placed 1-3 m up in shrub layer, in clump of dead vegetation or live bush. Clutch 1-3 eggs; incubation performed mostly or entirely by female, period unknown; chick uniform red-brown (not black as previously suggested). Post-fledging care probably long; birds live as family groups of breeding pair and most recent young.
Movements. No evidence to suggest that species is anything other than sedentary; groups maintain same territory all year round, at least in some sites.
Status and Conservation. VULNERABLE. Does not occur in at least some seemingly suitable forests between known centres; this may be due to past forest clearance and subsequent regeneration. Combined population at two main centres (Ampijoroa and Menabe) estimated at 7000-38,000 breeding adults. Group density, group size and site fidelity highest in selectively logged forest near rivers in Menabe area, and in undisturbed plateau forest at Ampijoroa. Populations at northern sites (Ankarana and Analamera) probably much smaller. Numbers at Ambatovaky and other eastern sites, if any, unknown. Major threats stem from habitat loss, caused, in order of importance, by subsistence agriculture, bush fires and intensive commercial exploitation. Birds hunted, and even taken when incubating. Selective logging may not itself threaten species, but increased hunting pressure, as result of improved access, may reduce habitat quality in logged areas. Ankarana, Analamera, Ambatovaky, Ankarafantsika, and Andranomena (part of Menabe) are all officially protected; other parts of Menabe subject to intensive commercial exploitation, as is much of Ankarafantsika. All three forests in W are subjects of current open-ended conservation management initiatives, with varying degrees of success.

(1993, 1994), Hawkins, A.F.A. *et al.* (1990), King (1978/79), Langrand (1990), Lavauden (1931, 1932, 1937), Milon *et al.* (1973), Nicoll & Langrand (1989), Rand (1936), Safford & Duckworth (1990), Thompson & Evans (1991, 1992).

2. Brown Mesite

Mesitornis unicolor

French: Mésite unicolore **German**: Einfarb-Stelzenralle **Spanish**: Mesito Unicolor
Other common names: Brown Roatelo

Taxonomy. *Mesites unicolor* Des Murs, 1845, Madagascar.
Formerly placed in genus *Mesoenas*. Monotypic.
Distribution. E Madagascar, from near Tolagnaro (Fort Dauphin) to Marojejy; not recorded in apparently suitable Sambirano region of NW Madagascar.

Descriptive notes. 30 cm. Sexes apparently similar in size and plumage. Whitish streak behind eye varies in intensity and extent, sometimes tapering down to form side-margin of throat; chin and throat whitish, tinged rufous, but similarly variable. Rufous brown head sometimes has pinkish grey tinge. Bill is shortest and straightest of any mesite. Eye large, giving "soft" expression. Neck can look relatively long and slender when extended. No information available on seasonal variation in plumage, on juvenile plumage, or on effects of wear.
Habitat. Humid eastern forest, especially areas with thick leaf litter and sparse covering of herbs and saplings. Most of the known sites are in remote and relatively undegraded forest. Recorded from sea-level up to c. 1100 m in Ranomafana; also found around 900 m at Perinet and 700 m in Marojejy.
Food and Feeding. Little known. Known to take invertebrates from forest floor. Forages by walking about slowly, probably for the most part using techniques similar to those recorded for *M. variegata*.
Breeding. Like other mesites, breeds in rainy season, Nov-Dec. Nest is platform of slender twigs lined with small amounts of grass, placed in fork of sloping trees 1-2 m up. Only 2 nests found to date, both initially containing 1 egg being incubated by female. Chick rich rufous buff (not blackish as previously suggested). No further information available.
Movements. Difficult to assess significance of absence of records from certain sites at given times, as species is frequently overlooked at sites where and when it is known to be present. Strong possibility

of altitudinal movement, at least on Masoala, birds being found only rarely below 700 m during breeding season, but commonly below this altitude in Apr (local winter).
Status and Conservation. VULNERABLE. Apparently present over wide area, but very patchily distributed within that habitat and possibly prefers lower-lying areas, which are the most vulnerable to human encroachment. In area of 4 km² at Ambatovaky, at least 4 pairs were found; also, 3 pairs heard calling along 2 km of path. Conservation may be complicated by possibility of species being altitudinal migrant. Threatened by forest clearance for subsistence agriculture, especially in lowlands and flat areas; also recent upsurge in commercial exploitation in what remains of lowland forest. Likely to suffer predation by rats, but there is dispute as regards degree of rat presence in forest (see page 39); certainly in relatively undisturbed areas, introduced species unlikely to be common enough to affect populations of present species. Claimed perhaps to sustain competition from Madagascar Wood-rails (*Canirallus kioloides*), but this seems unlikely (see page 41). Suffers only limited hunting pressure in some areas owing to local taboo (see page 40), but in other areas certainly hunted, with dogs used to flush birds into trees. Incubating females have been picked up live off nests. Species recently found to be present in 4 protected areas, Marojejy, Perinet, Ranomafana and Ambatovaky; the first three are currently the objects of conservation programmes.
Bibliography. Andriamampianina (1981), Bartlett (1877, 1879), Collar & Andrew (1988), Collar & Stuart (1985, 1988), Collar *et al.* (1994), Dee (1986), Delacour (1932), Dowsett & Forbes-Watson (1993), Evans *et al.* (1992), Forbes-Watson & Turner (1973), Hartlaub (1877), Humblot (1882), King (1978/79), Langrand (1990), Lavauden (1931, 1932, 1937), Milne-Edwards & Grandidier (1885), Milon *et al.* (1973), Nicoll & Langrand (1989), Rand (1936, 1951b), Safford & Duckworth (1990), Thompson & Evans (1991, 1992), Webb (1954).

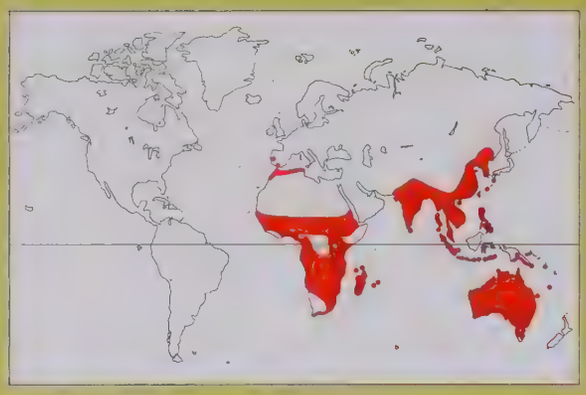
Genus *MONIAS* Oustalet & G. Grandidier, 1903

3. Subdesert Mesite

Monias benschi

French: Mésite monias **German**: Moniasstelzenralle **Spanish**: Mesito Monias
Other common names: Monias, Bensch's Rail

Taxonomy. *Monias Benschi* Oustalet and G. Grandidier, 1903, Vorondreo (25 km east of Toliara), Madagascar.
Monotypic.
Distribution. SW Madagascar, from R Mangoky in N to R Fiheranana in S, occupying a strip 200 km long and 70-80 km wide between coast and start of hills inland.



Descriptive notes. 32 cm. Bill relatively long and decurved; legs longer than in *Mesitornis*. Greyish brown above, with long white supercilium. Male has black crescents on underparts, female has extensive rufous throat and breast. No known colour variation with season, age or wear, but juveniles duller overall than adults.
Habitat. Restricted to spiny subdesert thicket, from sea-level up to 130 m. Tolerates at least some habitat disruption, perhaps because can be found even in relatively open areas provided there is access to sites rich in leaf litter. Areas where vegetation is so dense as to impede passage are eschewed, as are those entirely lacking shade.
Food and Feeding. Terrestrial invertebrates; also small amounts of vegetable material, e.g. seeds and small fruit. Digs for prey below surface of ground more than other mesites, probably leaving characteristic dimples in ground (see page 38).
Breeding. Main egg dates Dec-Jan. Species may prove to be polyandrous or polygynous, or even to have variable mating system depending on circumstances; at a nest with 2 eggs, 1 male and 2 females were observed; in another case 2 males accompanied a gravid female; species regularly occurs in groups of 2-6 birds, rarely up to 10; males and females seem equally common in an area as a whole, but proportions may vary greatly between groups. Nest is exposed, flat, open platform of few twigs with leaves and bark, 20 x 30 cm in size; situated 0·6-2 m up in bush or tree. Clutch 1-2 eggs. Sexes share incubation, feeding and care of young; chick blackish brown, sometimes described as chocolate brown, with paler markings around head and on underparts, as well as dark flecking on underparts in pattern resembling that of adult. No data available on incubation or fledging periods.
Status and Conservation. VULNERABLE. Within its limited range, species occurs patchily at high densities, but may be rare in some areas. Total area within which populations occur amounts to only 14,000 km², and parts of this are unsuitable for the species; apparently suitable habitat extends beyond its known range, but appears to be unoccupied. Forest is under pressure from subsistence exploitation for crops, grazing by goats and commercial exploitation for charcoal; rate of forest decline in the area is not known. Hunting with dogs and noose-trapping are common near villages, but, fortunately, over large areas of forest there is no surface water and little human habitation. Rats may predate nests in some areas, and hunters sometimes take adults from their nests. No protected areas within range, nor any known conservation measures in progress within species' specialized habitat. Extent of forest is undoubtedly shrinking, so overall population must be declining.
Bibliography. Appert (1968), Bangs (1918), Collar & Andrew (1988), Collar & Stuart (1985, 1988), Collar *et al.* (1994), Dee (1986), Delacour (1932), Dowsett & Forbes-Watson (1993), Forbes-Watson & Turner (1973), Griveaud (1960), Hartert (1912), King (1978/79), Langrand (1990), Lavauden (1931, 1932, 1937), Lavauden & Poisson (1929), Milon *et al.* (1973), Nicoll & Langrand (1989), Rand (1936), Rutgers & Norris (1970), Safford & Duckworth (1990), Steinbacher (1977), Turner (1981).

Class AVES

Order GRUIFORMES

Suborder TURNICES

Family TURNICIDAE (BUTTONQUAILS)

- Small, plump, quail-like terrestrial birds, with short legs, no hind toe and a rudimentary tail.
- 10-23 cm.

- Afrotropical, Oriental and Australasian Regions; peripheral in SW Palearctic.
- Grassland to forest, from sea-level up to 2500 m.
- 2 genera, 16 species, 59 taxa.
- 5 species threatened; none extinct since 1600.

Systematics

The origins and affinities of the buttonquails are obscure and disputed. There are no known pre-Pleistocene fossils to help elucidate the evolution of the family, which has variously been allied with the fowls and true quails (Galliformes), the shorebirds (Charadriiformes) and, by recent consensus, the rails and related birds (Gruiformes). Some early taxonomists saw possible connections or certain anatomical similarities with the tinamous (Tinamidae), mesites (Mesitornithidae), sandgrouse (Pteroclidae), pigeons (Columbidae) and even the passerines. Until recently, the buttonquails were almost invariably allied with the superficially similar Australian Plains-wanderer (Pedionomidae), but current opinion strongly favours the idea that the Plains-wanderer is instead related to the seedsnipes (Thinocoridae) of South America (see page 534). Recent DNA-DNA hydridization data suggest only that the buttonquails are either an ancient and distinct group without close living relatives, or a recently derived group, the rapid genetic evolution of which has obscured its connections with other families. However, an affinity with the Gruiformes should certainly not be ruled out, and it is probably most convenient to leave Turnicidae in its traditional position in that order, at any rate for the time being.

It is clear that the buttonquails only superficially resemble the true quails (*Coturnix*), and differ from them in many anatomical respects. The characters which readily distinguish the buttonquails include the lack of a crop and a hind toe, and in females an enlarged trachea and inflatable bulb in the oesophagus which combine to produce a specialized vocal organ for "booming". This is visible as an inflated, pulsating neck in calling birds. Buttonquails also have relatively larger and more "loose-fitting" wings, with greater expansion at the carpals, than the true quails, which have short wings that are often hidden by their rump feathers.

There are only two genera in the family, the large and widespread genus *Turnix* with 16 species and the monotypic, African *Ortyxelos*. The latter has traditionally been placed first in the family sequence, implying a primitive or ancestral condition, but modern taxonomists place it last, instead implying an advanced or derived condition. *Turnix* species are dumpy and generalized, with females that boom. *Ortyxelos* is tiny, gracile and longer-tailed, and its females do not boom, as they lack the necessary vocal apparatus; the species seems specialized for life in deserts.

Within the genus *Turnix*, there are recognizable groups of related species. The most widespread group is that of the Common Buttonquail (*Turnix sylvatica*) of Eurasia, which also includes the Red-backed Buttonquail (*Turnix maculosa*) of Australasia and the Black-rumped Buttonquail (*Turnix hottentotta*) of Africa. An endemic Asian group consists of the Yellow-legged (*Turnix tanki*) and Spotted Buttonquails (*Turnix ocellata*). A possible "Gondwanan remnant" group comprises the Barred Buttonquail (*Turnix suscitator*), which may have colonized Asia from the Indian plate, and the Madagascar Buttonquail (*Turnix nigricollis*). Two endemic Australasian groups seem most closely related to each other: the Black-breasted (*Turnix melanogaster*), Chestnut-backed (*Turnix castanota*), Buff-breasted (*Turnix olivii*) and Painted Buttonquails (*Turnix varia*); and Worcester's (*Turnix worcesteri*), the Sumba (*Turnix everetti*) the Red-chested (*Turnix pyrrhothorax*) and the Australian Little Buttonquails (*Turnix velox*). These Australasian species may also represent a "Gondwanan remnant", long isolated on the Australian plate, with one member, Worcester's Buttonquail, having recently colonized the Philippines via Wallacea. The Black-breasted Buttonquail may actually belong with the Madagascar and Barred Buttonquail group.

Opinion has differed on the taxonomic status of very similar, allopatric forms within *Turnix*. The Common and Red-backed Buttonquails were often considered conspecific until it was suggested that the ranges of the two forms met in the Philippines; although the existence of such sympatry is now contested, current opinion nevertheless recognizes them as separate species that probably form a superspecies. Again, the Chestnut-backed and Buff-breasted Buttonquails are often treated as conspecific, but they differ in plumage, egg colour and particularly bill size and shape. Similarly, the poorly known Worcester's and Sumba Buttonquails are suspected to be conspecific, and even possibly only subspecies of the very similar Red-chested Buttonquail; for the meantime they are probably best kept separate, pending further information. This group follows Bergmann's and Gloger's Rules: the tropical island forms, Worcester's and the Sumba Buttonquails, are smaller and more brightly pigmented than the Red-chested Buttonquail of the subtropical semi-arid zone.

In contrast, the race *nana* of the Black-rumped Buttonquail is often considered a separate species, due to constant, though minor, differences in plumage and eye colour, which may constitute a recognition signal. Also, some populations of *nana* are migratory, whereas the nominate race is sedentary, but until stronger evidence can be produced it is probably safer to treat these two forms as conspecific. Similarly, the New Caledonian

race of the Painted Buttonquail is said to differ more from the nominate race than the latter does from the Buff-breasted and Chestnut-backed Buttonquails, and may therefore deserve full species status.

Taxonomic views have also differed on the validity of some subspecies described for *Turnix* species. Generally, there has been a recent trend towards a reduction in the number of recognized races, as it became apparent that some variation is individual or seasonal, or related to age and sex, rather than geographical. This is particularly the case with Australian species, and the "oversplitting syndrome" displayed by ornithologist G. M. Mathews early this century. Many of Mathews' *Turnix* "races" were based on very small series of specimens and minor variation, and are now regarded as invalid.

Normal notions of sexual differences are overturned where buttonquails are concerned, for it is the females which are larger and more brightly coloured than the males, their markings being much more strongly defined. This pair of Red-chested Buttonquails allows a direct comparison of the sexes as they crouch side by side. The female on the left is noticeably plumper than her partner while his plumage appears distinctly washed out beside hers.

[*Turnix pyrrhothorax*. Photo: F. Lewitzka/ Nature Focus]

Morphological Aspects

Turnix buttonquails are small birds, ranging from 12 cm in length and 30 g in weight in the smallest species, to 23 cm and 130 g in the largest. The Lark Buttonquail (*Ortyxelos meiffrenii*) is even smaller at 10 cm and 20 g. In all species, the head is small, without ornamentation, and the neck rather short and slender. Buttonquails have short, laterally compressed, unspecialized bills varying from slender, in mostly insectivorous species, to stout, in mainly granivorous species. With rather short, stout legs and three forward-pointing toes, but no hind toe, they are adapted for walking and running in amongst grass and other low ground cover. The lack of a hind toe is correlated with a terrestrial way of life, and in this respect the buttonquails resemble some of the ratites and other ground-dwelling birds. A hind toe would only be a hindrance; some other terrestrial birds such as the true quails have a much-reduced hind toe raised above the level of the other toes, but the buttonquails have done away with it altogether.

The tracheal enlargement in female buttonquails is of particular note. Compared with the unspecialized trachea of the male, that of the female is slightly longer and much swollen towards its base. This greater diameter and volume of the sound-producing organ permits loud, low-frequency calls. These sounds are resonated by the enlarged oesophagus, which is inflated with air like a tiny balloon just before the female begins to boom.

The soft tail feathers of *Turnix* are so small as to be almost hidden by the overlying coverts. At rest, the wings appear short, partly because the primaries are hidden by the long tertials and inner secondaries. This is in keeping with the fact that, during the day, buttonquails only fly to escape danger. On flushing, whirring and quail-like, they reveal quite long wings and strong, rapid flight, and they often fly far. However, they are reluctant day-time fliers, and soon brake to drop and freeze, or run in cover, seldom flushing a second time in quick succession. By contrast, they readily fly under cover of darkness, and apparently make long distance seasonal movements at night (see Movements). This is probably because their white "gamebird" muscle tires quickly in bursts of escape flight, and they are vulnerable to predation during sustained flight, which is rather weaker and more fluttering. Buttonquails' day-time flight is usually low and direct, although the Painted Buttonquail often weaves between trees.

Buttonquails are shades of brown, grey and rufous, with black mottling and vermiculation and fine pale streaks, for camouflage. The dorsal surface is coloured like the bird's usual habitat. The ventral surface is paler and plainer, though often with spotting or barring on the sides. Females are larger and brighter than males, and often have stronger rufous or black markings on the foreparts. Some species, such as the Spotted and Yellow-legged Buttonquails, are strongly and attractively spotted (ocellated) on the wings. The female Black-breasted Buttonquail has black foreparts spangled white, which may not be a disadvantage on the dimly lit, litter-strewn floor of its rain forest habitat. Juveniles are small versions of adults, with duller and more mottled plumage.

The Lark Buttonquail is an exception. It is the size of the smallest *Turnix*, but is more courser-like, with a slender bill. It has somewhat longer and stiffer, white-tipped tail feathers, and longer, boldly patterned wings: white shoulder patches and trailing edges contrasting with the dark flight-feathers. Its fluttering, lark-like or butterfly-like flight is wavering and erratic.

Buttonquails' normal gait is a strong walk. When feeding, they walk furtively by slinking low through cover, often slowly and jerkily, as they stop to pick at food items. When alarmed, they variously creep mouse-like into shelter, run in bursts and pauses with the head held high, or run rapidly and erratically from danger. The smaller *Turnix* species also have a peculiar gait, in which they creep slowly and stop periodically, mid-step, to rock the horizontally held body backwards and forwards on the stationary feet, much like a chameleon. Various, sometimes fanciful, explanations have been proposed for this "Rocking" gait, which appears to be an intention movement, and suggests some hesitancy or caution on the bird's part. Sometimes, this gait is used by an aggressive bird about to chase another, or by a submissive bird approaching a dominant bird. It is also used by male and female during initial stages of pairing, and if they meet during later stages of the breeding cycle. At other times it is used by a single, apparently suspicious or alert, bird creeping from one patch of cover to another.

Many, perhaps all, *Turnix* species undergo two moults per year: a complete post-breeding moult, and a partial pre-breeding moult involving the head and body only. In some species, though by no means all, the non-breeding plumage is duller, and females then tend to resemble males. Primary moult is descendant but skips from the eighth to the outermost (tenth) feather before the ninth is shed. Interrupted moult, perhaps related to seasonal conditions, is common in some species. Both sexes develop brood patches: the male two large lateral patches, and in some species an additional small central patch; the female has two lateral patches, which are smaller than the male's.

Habitat

The family Turnicidae is widely distributed in the warmer parts of Africa, Eurasia and Australasia, living in the drier parts of the tropics and subtropics, but extending to temperate regions of the Mediterranean, South Africa, East Asia and Australia. Buttonquails live almost entirely on the ground, where they obtain all their food and where they roost. They require cover in which to hide from predators and place their nests.

Buttonquails generally live in grassy or low brushy habitats, including grassland, steppe, savanna, forest clearings and secondary growth. The smallest species can live in sparse, arid grassland and deserts, remote from surface water, which they do not need. The small and medium-sized species can live in disturbed and man-modified habitats, such as agricultural landscapes, where they occur in pasture, crops and weedy fallow fields. The larger Australian

Turnix *buttonquails are small, somewhat dumpy, terrestrial birds. The most apparent features of the Painted Buttonquail, one of the larger species, include the red eyes, the rather fine bill and the typically cryptic, richly patterned plumage of subtle shades. The short, sturdy legs carry three forward-pointing toes, but no hind toe, as is often the case with terrestrial birds. The wings are fairly long, endowing the bird with a surprisingly strong flight action, although buttonquails are generally rather reluctant to take to the air, and normally prefer to walk or run away from danger.*

[*Turnix varia varia*, Australia.
Photo: R. Seitre/Bios]

species live in grassy open forest or woodland with abundant litter, the two "red" species (Chestnut-backed and Buff-breasted) being found mostly on stony hills. One species, the Black-breasted Buttonquail, is exceptional in being largely restricted to the drier types of rain forest or softwood scrub, with deep leaf litter.

Buttonquails forage in accumulated mulch, and use dry soil for dust-bathing. On their daily foraging, some species follow well defined runways or trails, which are marked by their footprints in the dust. They nest amid rank or tussocky grass, sometimes near a tree, bush, log or fallen branch. The Lark Buttonquail can nest amid sparse grass and low herbaceous plants on stony or sandy soil.

During seasonal migrations or post-breeding dispersal, buttonquails sometimes appear in atypical habitats. This is probably because they migrate at night, and must descend either at dawn or wherever they become tired. At such times, individuals find themselves in hostile human environments such as urban areas, where they are easily disorientated by bright lights and sometimes collide with buildings (see Movements).

General Habits

Buttonquails are secretive and difficult to observe in the wild. They are shy and elusive, and their reaction to potential danger is to squat immobile, relying on their camouflage colours to escape detection. If approached, they creep or run away, often invisibly through cover, or, if pressed, they burst startlingly into flight. Occasionally, a bird freezing before or after an escape flight can be picked up by hand, or may be stepped upon. The presence of buttonquails is revealed by the booming calls of females, by characteristic feeding scrapes (see Food and Feeding), or by chance sightings of birds that have not been alerted to an immobile observer. The use by researchers of observation points placed above the ground, for example on raised platforms or in a low tree-fork, offers some hope of observing the normal behaviour of wild buttonquails in areas where they are common. They will respond readily to imitation of the booming call by approaching the source of the sound.

Buttonquails are active by day and night. They do most of their foraging by day, often early and late or crepuscularly, and they roost on the ground at night during sedentary phases of their life cycle. Some species of arid or semi-arid zones are suspected to be mainly nocturnal, which would assist in thermoregulation and moisture conservation. Many buttonquails also travel on migration at night, at such times frequently being attracted to bright artificial lights (see Movements). On their breeding territories, females often give their advertising calls at night, as well as during the day.

Buttonquails variously occur singly, in pairs or in small coveys. The latter are family groups consisting of a male, sometimes also with a female, and usually about four dependent young. Breeding adult *Turnix* of both sexes are solitary and aggressive towards others of their own sex, and form temporary, monogamous pair-bonds (see Breeding). However, in some species, notably the smaller ones in dry regions, post-breeding aggregations of more than one family group may occur. These amount to loose flocks numbering tens or, during irruptions of the Australian Little Buttonquail, hundreds or thousands of birds in a small area. It is unlikely that large aggregations have a coherent social structure; they may simply represent concentrations of birds in favourable habitat. Adult Lark Buttonquails occur singly or in pairs.

Buttonquails roost in circular scrapes made in the soil, often beneath a tussock or some other form of shelter, such as a clump of shrubs. Members of a family group or a mated pair roost together, often in bodily contact, by clumping side by side, and roost-sites may be used repeatedly if undisturbed. Roosts are used at night and also during the middle of the day in warm weather. In some of the smaller, more sociable species, two or more adult pairs sometimes clump together to roost.

Buttonquails sun-bathe and dust-bathe. When sun-bathing, they stretch out flat on the ground with one or both wings spread and sometimes with their plumage ruffled and their eyes closed. They may also preen beneath a spread wing. For dust-bathing, a bird first prepares a site by scratching a circular scrape with its feet and sometimes pecking at the soil. Then it squats in the scrape, wipes its head in the soil, and performs a dust-tossing movement which is different from that used by true quails. A buttonquail simultaneously loosens soil with its feet as it shuffles its body rapidly from side to side, feathers fluffed, and it thus envelops itself in a cloud of dust.

At least the smaller species of buttonquail allopreen, in the breeding season. The members of a pair preen each other's head feathers, this activity being most intense during the courtship and mating phases of the cycle. Buttonquails perform stretching exercises by simultaneously extending a wing and leg out and down on the same side, or by momentarily arching both wings above the back. They also perform jumping and fluttering exercises, one member of a pair occasionally stimulating the other to follow suit. These exercises punctuate or end periods of loafing and preening in the birds' day-time roosting scrapes.

Buttonquails drink rapidly with a continuous sucking or "bibbling" action, by immersing the bill for several seconds. In this respect they resemble the pigeons and some other birds, rather than those species that drink by repeatedly scooping and swallowing individual beakfuls. Buttonquails thus minimize the time spent in a vulnerable position and activity, at sites such as waterholes in dry country where predators may abound.

Most buttonquail aggression is related to aspects of the breeding cycle, such as defence of the territory and young (see Breeding). However, in at least the larger and more solitary species, adults are generally aggressive to members of their own sex, and females are also aggressive to males that are not their current mates. A buttonquail will chase the recipient of its aggression, and deliver pecks to the head, neck and back, sometimes grasping the nape feathers. In female Black-breasted Buttonquails, this may escalate to a short pursuit flight. In the Common Buttonquail, and perhaps others, males have a prostrate submissive posture which inhibits further aggression by a female. In small species, aggressive chases may be preceded by the aggressor approaching with "Rocking" gait and tail flicking up and down.

Voice

The characteristic buttonquail vocalization is the resonant booming, through closed bill, of female *Turnix* species which have specialized vocal organs (see Morphological Aspects). In small species the notes have a hooting or cooing quality, sometimes given in couplets by the Australian Little Buttonquail. In larger species the notes have a bovine or moaning quality, like the distant lowing of cattle. In the Black-breasted Buttonquail, each tremulous boom is really a series of drumming notes. In sympatric species, the calls of each differ in pitch or tempo, or both.

The booming calls are loud and far-carrying, an obvious advantage for such small and inconspicuous birds living at rather low densities. The calls are also ventriloquial and hence difficult to pinpoint, which would hinder attempts by a predator to locate the caller.

The booming call seems to be mainly an advertisement call to attract a male, although in the larger, more solitary species at least, it may also serve to ward off other females. A female responds aggressively to another female booming in or near her territory. In the advertisement phase, the booming notes are given deliberately from a standing position with the body upright, the bill pointing down, the abdomen drawn in and the breast and upper back inflated and pulsating in rhythm. In the Painted Buttonquail, if a male approaches a female she gives the notes explosively, in excited courtship behaviour (see Breeding). Despite the ventriloquial nature of the booming calls, prospective mates are probably able to locate each other because the male answers with soft calls; the female can turn about to project the sound towards the male when she sees or hears him, and at close range the female enhances the booms with visual signals (see Breeding). Excited individuals run and sometimes flutter about erratically, perhaps trying to locate the source of the booming.

Female *Turnix* species also give rapid purring or drumming series, with the same resonant quality as the booming calls. In the Painted Buttonquail, drumming is given softly by the female during courtship feeding (see Breeding).

Buttonquails of both sexes utter a variety of soft clucking, crooning, chattering, churring, rattling and whistling calls, through the open bill, in the normal avian manner. These are short range signals between members of a pair or family. Some small species utter a few squeaking alarm notes on being flushed. Chicks make soft peeping notes which may become more rapid and staccato if the chicks are distressed. Adult Lark Buttonquails are only known to utter soft whistling notes.

Food and Feeding

Buttonquails are rather opportunistic and generalized feeders, taking a variety of seeds, invertebrates and plant matter, which they find by walking over the ground, gleaning and scratching. A broad and flexible diet may have enabled the buttonquails to occupy most dryland habitats within the family's range, although only in Australia is there a species living entirely within rain forest (see Habitat).

There are virtually no detailed dietary studies of any buttonquail, the limited information having come almost entirely from casual observations of a few species and the stomach contents of a few individuals of most species. Seeds eaten are small, for instance those of grasses, weeds, clover, cereal crops, legumes and *Acacia* trees, many apparently taken as fallen seed in the soil and litter. Invertebrates taken are mainly small insects, such as ants, flies, bugs, weevils, beetles, cockroaches, grasshoppers, moths and their larvae, pecked from the ground or low plants within reach or seized after a short chase of a few steps. In arid regions, termites may be important food, partly for their moisture content, as desert buttonquails may not have access to surface water. Plant material taken, also probably important for its moisture content, includes seedlings, soft green shoots, buds and small berries. Buttonquails swallow sand, grit or fine pebbles according to their body size, probably to assist in the grinding up of hard food items in the gizzard.

Some species, such as the slender-billed Common and Red-backed Buttonquails, appear to take seeds and invertebrates in similar proportions, whereas others, such as the stout-billed Australian Little and Red-chested Buttonquails, take mostly seeds including fallen grain. The large, but rather slender-billed, Black-breasted Buttonquail appears to be mainly insectivorous, living as it does on the moist rain forest floor where invertebrates abound in the deep litter. A recent study of the diet of this species, based on the microscopic analysis of faecal pellets, showed this species to take many beetles and ants, as well as spiders, whereas centipedes, millipedes and snails were also present, but were scarce in the pellets; soft-bodied prey items are most unlikely to be detected using this technique. In general, buttonquail chicks are fed mainly on small insects, although they start to cope with tiny seeds within a few days of hatching.

Buttonquails have a unique method of uncovering food on the soil surface, beneath accumulated litter. They scratch with one foot while pivoting on the other, turning a half or complete circle before changing feet and reversing direction. This method differs markedly from the alternate scratching of galliform birds. A feeding group of buttonquails presents a scene of busily "spinning" and pecking birds, which leave characteristic circular scrapes, or "platelets", as wide as the bird's body length, and numbering up to 250 platelets/5 m^2 in the abundant leaf litter of wooded habitats. Black-breasted Buttonquails briefly shade their scrapes with spread wings after scratching, presumably to delay the retreat of exposed prey. This spinning technique is also used to construct roost-sites, dust-bathing sites and nesting scrapes.

Buttonquails forage singly, in pairs and in family groups of an adult or two with a brood of young. Some species, such as the smaller ones, or those of dry regions, also forage in post-breed-

Highly terrestrial birds, buttonquails, such as this Barred Buttonquail, find all of their food on the ground. Whether in search of seeds or invertebrates, they forage by walking along in a rather furtive manner, scratching as they go and making curious circular scrapes in the ground by a strange spinning action in order to uncover prey.

[*Turnix suscitator fasciata*, Philippines. Photo: Brian J. Coates]

ing coveys or small flocks which consist of more than one family.

Buttonquails drink when water is available, but those of arid regions apparently do not need to do so, because they occur in areas lacking surface water. They probably obtain and conserve sufficient moisture from their food, but detailed physiological studies are required to prove this. They may also conserve moisture by behavioural strategies such as nocturnal activity (see General Habits).

Breeding

The mating system of the *Turnix* buttonquails has been deduced largely from captive birds, with very little information available on wild birds, although general conclusions have been confirmed in wild Painted Buttonquails from ringing studies. The usual breeding strategy is sequential polyandry with male parental care, although monogamy with limited female parental care also occurs in the Common Buttonquail and probably some other species. Perhaps food abundance determines the female's breeding condition, and hence her drive to produce multiple clutches quickly, with different mates, in a single season. Conversely, in poor seasons the chance of rearing a few young may be increased if females stay and help to rear a single brood.

The little known Lark Buttonquail is apparently monogamous, breeding solitarily in simple pairs, although male incubation would suggest the possibility of polyandry. In most *Turnix* species for which information is available, temporary monogamous pair-bonds are formed, lasting at least up to the early incubation stage and perhaps beyond, with mated females chasing away other males as well as rival females. Having presented a male with a clutch of eggs, the female then finds a new mate, if one is available, and in turn leaves him with a clutch of eggs. As already noted, in some species monogamy also occurs, at least for the duration of a breeding season. Pairs nest solitarily, with males defending their nesting territories against other males.

It follows from the mating system that the home range of a particular female, as well as covering that of her current partner, may partly overlap those of neighbouring males, although evidence is lacking. Another consequence is that males alone incubate the eggs and rear the chicks, although in some species the female may at times assist with incubation, at least in the early stages, and occasionally with the care of the young. The Black-breasted Buttonquail is puzzling, in that a wild female has been seen caring for juveniles apparently from two amalgamated broods.

In temperate regions, buttonquails usually breed in spring and summer. In the tropics and subtropics they can breed opportunistically at any time, with clutches recorded in all months, although locally breeding is episodic or seasonal in response to conditions. In areas with pronounced wet and dry seasons, they breed during or after the rains when food is most abundant. Polyandrous females lay another clutch, with a new male, in as little as two weeks after the preceding clutch. Even monogamous females can present their mate with a new clutch within two months, after the first brood has become independent. Polyandrous females can produce up to seven clutches in a season.

Female *Turnix* in breeding condition defend exclusive territories and boom frequently to attract a male. In the Painted Buttonquail, when a male appears, the female becomes excited, puffing out her breast and lowering it to the ground, cocking her tail and delivering the notes explosively as she runs around him, stopping to stamp her feet and scratch the ground. The female of the Black-breasted and Barred Buttonquails sometimes spreads her wings when drumming to a male. A courting female Common Buttonquail also makes the circular scratching motions when a male arrives, and she may be aggressive towards him at first until he stands his ground and is accepted.

In the smaller species, ensuing pairing behaviour includes the "Rocking" display by both birds, increasing synchronization of activities, male sidling up to roost or dust-bathe in bodily contact with the female, "Mutual Bowing", and allopreening. Imminent nesting is marked by the female frequently squatting in an incubating position with the tail cocked and breast puffed out.

Courtship proceeds with a "Tidbitting" display, in which the female calls the male to take an item of food from her bill or the ground, and the performance of the "Scrape Ceremony" by one or both birds. The "Scrape Ceremony" consists of elements of nest-site preparation and nest construction: either bird or both, singly or together, scratches a circular scrape, squats in it with the tail cocked, and pecks the soil or pulls grass into the site, while making soft calls. At first, "reversed" false copulation may occur, the female mounting the male, but true copulation soon ensues with the male approaching and allopreening the crouching female, or the male following the female and grasping her nape feathers.

Both sexes search for a nest-site, testing several by the "Scrape Ceremony", with the female selecting the final site. The nest is a depression on the ground amongst grass, often under or

The Yellow-legged Buttonquail breeds amid grassland. The nest, a shallow depression in the ground, is lined with dry grass. Sometimes blades of grass are bent over it to form a kind of canopy and a side entrance is made. The clutch consists of four or five cryptically coloured eggs. Both incubation and rearing of the chicks is undertaken by the male, a reversal of the normal sex roles in birds, and a feature common to all species of the Turnicidae.

[*Turnix tanki blanfordii*, Russian Far East. Photo: Yuri Shibnev/ Planet Earth]

within a tussock, lined and sometimes hooded over with grass stems. Some are domed grass structures with a side entrance, and in dense cover they may have a runway leading to them. Both sexes, but mostly the female, prepare the site either by pivoting and scratching, or by using elements of the "Scrape Ceremony": pecking the soil, squatting and shuffling the body. They then pull grass stems in on themselves, moulding a compact structure by pushing, shuffling and turning, with the female again doing most of the work. The result is that the nest and incubating bird are invisible, the cryptic situation further enhanced by the adults adopting a very cautious attitude when entering and leaving. The nest of the Lark Buttonquail is a simpler structure in sparser cover; it is often rimmed by small pebbles.

Buttonquail eggs are oval to almost pyriform, and are smooth and glossy, measuring about 18 x 15 mm in the Lark Buttonquail to 29 x 24 mm in the largest *Turnix* species. They are cryptically coloured, white to buff with dark freckles, spots and blotches, particularly near the larger end. The usual clutch size is four or five, though it is only two in the Lark Buttonquail and sometimes reaches seven in some small *Turnix*. Eggs are laid at daily intervals, and incubation starts with the last egg so that hatching is synchronous. Incubation takes around 12 to 15 days, the shortest of all similarly precocial species, and little longer than in the smallest passerines. Male Common Buttonquails leave the nest about eight times per day for stints of up to 15 minutes of feeding.

Buttonquail chicks hatch downy and mobile, and desert the nest to follow the male about. They are cryptically coloured in browns and greys with dark and pale dorsal stripes. At about two grams, they are among the smallest of precocial chicks. For the first week or so they are brooded and fed by the male, which calls them, with "Tidbitting" behaviour, to take food from the tip of his bill. When threatened, they lie "frozen" with closed eyes, while the male performs an injury-feigning distraction display. If this fails and the chicks utter distress calls, the male may charge at the intruder with his wings spread, or even fly at the intruder, such as a human, with buffeting wings. The main enemies of buttonquails include raptors, mammalian carnivores and humans, and, in Australia, introduced predators such as cats and foxes.

The chicks start to feed themselves within a week, and by the second week require brooding only at night. They fend for themselves in the third week, and become fully independent in the fourth week. They perform adult behaviour such as pivoting and female booming motions, though with immature voices and anatomy, in the first week, and full maintenance behaviour and the "Rocking" gait by two weeks old.

Buttonquail chicks grow very rapidly, sprouting wing feathers on the second day, fluttering in a week and flying properly in two weeks. Body feathers quickly follow suit, with juvenile plumage attained in the third week. A post-juvenile primary moult, beginning with the innermost primary, starts at only three weeks of age, while the outermost juvenile primaries are still growing. At about this stage, when still only half-sized, chicks begin a complete moult of the juvenile plumage. Adult size is achieved in a month, adult-like plumage within two months and sexual maturity within three months of age in the smallest species.

Rapid growth and early maturity, coupled with polyandry, multiple broods per season and short breeding cycles, permit enormous potential increase in the populations of the smaller species. This is particularly the case where young hatched early in the season are themselves able to breed later in that same season when less than four months old. This capacity permits buttonquails to take full advantage of prolonged favourable conditions in climatically unpredictable semi-arid regions. However, mortality may be very high, with life expectancy in the wild perhaps only two or three years, although captive individuals have lived for up to nine years. The short generation time and rapid population turnover has apparently facilitated rapid genetic evolution in the family (see Systematics).

Movements

The movements of buttonquails are poorly understood and apparently complex, with most evidence in the form of observed fluctuations in abundance at given localities, and occasional records of buttonquails appearing in unlikely places, such as cities. In warmer temperate regions such as the Mediterranean or eastern Australia they are often considered to be resident; that is, they are always present in an area, although evidence from ringing suggests a high turnover of individuals. Conversely, some ringing data also reveal that individuals are sedentary for up to eight months at a time. In cooler temperate regions, for instance at higher latitudes and altitudes in southern Australia or east Asia, buttonquails appear to behave as spring and summer breeding migrants, wintering at lower latitudes and altitudes.

Continental populations of the smaller species make seasonal movements in those parts of the tropics and subtropics with pronounced wet and dry seasons. Generally, it appears that they are well dispersed during the wet season, when they breed, taking advantage of the abundant food supply after rains, but they then

The male Common Buttonquail incubates, admirably concealed amid tussocks of grass. Buttonquail chicks hatch after 12 to 15 days, the shortest incubation period amongst those species with precocial chicks. They develop rapidly and by the fourth week are completely independent. This short breeding cycle and the polyandrous nature of the mating system in Turnicidae can lead to multiple clutches and consequently, in good years, sizeable population increases in the smaller species.

[*Turnix sylvatica*. Photo: W. R. Tarboton]

The nest of the Painted Buttonquail is a slight cup lined with grass and forest litter, often under a tussock of grass, near a rock, or in the shelter of a small bush. The cryptic pattern and coloration of the dorsal plumage ensures that the incubating male remains virtually invisible to any inquisitive marauder.

[*Turnix varia varia*, Dryandra, West Australia. Photo: Babs & Bert Wells/ Oxford Scientific Films]

retreat to refuge areas during the dry, non-breeding season. The Australian Little Buttonquail migrates south in spring to the winter-rainfall zone of temperate regions, and north in autumn to the summer-rainfall zone of the deserts and subtropics. By doing so, this arid-adapted species follows the flush of plant growth and hence food. Buttonquails on tropical and subtropical islands, and in the more climatically stable parts of the tropics, appear to be sedentary. Even those populations in the subtropics display a tendency to extend their stay or be resident where conditions permit. On the other hand, their movements may be erratic or irruptive in response to climatic fluctuations. It is possible that some apparent "irruptions" are at least partly attributable to explosive local population growth in exceptionally favourable conditions (see Breeding).

Evidence for movement in the tropics and subtropics has come partly from a ringing station in north-eastern Australia, where there is a high turnover of individuals with none recaptured. There, and in Africa and Asia, evidence for migration has come in the form of many birds being attracted to, and sometimes colliding with, artificial lights, windows and lighthouses at night, particularly in fog after heavy rain. Nothing is known of migrating behaviour, routes or staging areas, except that many Red-backed Buttonquails "island hop" across the Torres Strait between Australia and New Guinea, with biannual movement pulses early in the wet and dry seasons. With their rather long, almost shorebird-like wings (see Morphological Aspects), it is apparent that buttonquails are capable of long-distance movements by night, and that they are stronger fliers than the gallinaceous quails.

During sedentary phases of their life cycle, buttonquails move about their home range on foot, foraging, and frequently retreat to their regular roosting scrapes to rest. Females, at least of the larger, more solitary and territorial species, also regularly patrol their territory boundaries by walking rapidly along them. The female Black-breasted Buttonquail, sometimes with her mate in tow, stops frequently to drum.

Relationship with Man

The buttonquails are secretive, cryptic and little known, and present few opportunities to observe their behaviour in the field, hence there is little raw material to form the basis of extensive folklore. They are heard, particularly with the booming call, much more often than they are seen. A mistaken belief among African tribespeople is that the booming call is made by a snake, the puff adder *Bitis arietans*. The "very human-like and heart-rending moans" of the female Yellow-legged Buttonquail must inevitably have given rise to folklore among Asian tribal peoples, but details are difficult to ascertain; rather less poetic is the comparison of the voices of both the Barred and the Yellow-legged Buttonquails to the sound of a distant two-stroke motorcycle engine!

Limited evidence suggests that buttonquails were probably significant in the ceremonial life of Aborigines in central Australia, but precise details are lacking. An Aboriginal legend from northern Australia makes possible reference to buttonquails, which a translator probably did not distinguish from the true quails. In a story explaining the long neck of the Emu (*Dromaius novaehollandiae*), Quail was one of several spirit men who changed into birds as they ate a meal obtained by trickery. Quail took the remains of the meal into long grass to eat it. An old spirit woman, who had been tricked out of her food, thought Quail's voice was coming from the sky. She threw a stick straight up, trying to hit Quail, but it fell down and lodged in her throat as she peered up. She changed into an Emu with a long neck. In this story, Quail's voice in the sky may refer to the ventriloquial booming quality of a buttonquail's call.

The buttonquails' predominant relationship with man concerns their palatability. They have long been hunted and eaten as gamebirds, although they are now not legal gamebirds in most Western countries. In developing countries, particularly in Asia, they are trapped for the pot and sold in markets. Caged or tethered females are used as decoys, and wild birds' trails, or faithful human copies, are used as sites for snares. Also in Asia, females are kept and used in "hen-fights" just as the males of galliform birds are used in cock-fights. The Australian Aborigines hunted buttonquails by means of nets set at water-holes; women and children gathered their eggs and young, and youths hunted them on drives by hurling their throwing-sticks at flushed birds.

In recent decades there has been much avicultural interest in buttonquails, with several species being bred in captivity by zoos and private individuals. This may have generated some pressure on remaining wild populations of rare species, such as the Black-breasted Buttonquail, but that particular species breeds well in aviaries. Once captive stock is established, the birds' high reproductive potential should obviate the need for further trapping of wild birds for the avicultural trade. The buttonquails have not

Long highly appreciated as tasty gamebirds, buttonquails are still snared and sold in markets in Asia. This Barred Buttonquail behind bars, hung outside a house by the entrance to a "protected area" in Sumatra, may have been kept as a pet, or perhaps for use as a decoy to trap other buttonquails.

[*Turnix suscitator suscitator*, Harau Gorge, Payakumbu, West Sumatra. Photo: Isabel Martínez]

been truly domesticated, in the sense that no domestic strains or mutants have been developed, as has happened in the true quails.

Status and Conservation

As a family, the buttonquails seem secure, with most species adapted to, and occurring in, human pastoral and agricultural landscapes; their high reproductive output is sufficient to compensate for human predation. This is particularly the case in developing countries of the tropics and subtropics, where traditional agriculture leaves rough areas, fallow fields, forest clearings and secondary growth, and traditional pastoralism leaves sufficient grass cover. Most of the species of Africa and Asia seem to be holding their own, with the Lark Buttonquail perhaps increasing with expanding deserts. The tropical island endemics, notably the Spotted, Worcester's and Sumba Buttonquails, give cause for concern, but this may be largely because they are so poorly known. Worcester's and the Sumba Buttonquails are classified as Vulnerable, while the Spotted is considered to be near-threatened. It is difficult to foresee any real threats to these species, other than large-scale conversion to Western agricultural methods and consequent loss of habitat. The other three species currently believed to be threatened are the Black-breasted, Chestnut-backed and Buff-breasted Buttonquails, all of tropical Australia.

By contrast, the buttonquails have fared less well under highly Westernized agriculture. The Common Buttonquail has all but disappeared from Europe, under modern intensive farming methods which leave little room for wildlife, combined with at least a certain degree of hunting pressure. It is still common in sub-Saharan Africa and Asia. Similarly, several Australian species in southern, intensively farmed regions are retreating from the conversion of native grassland and grassy woodland or forest to cropland and heavily grazed pasture. These are the Painted, Red-chested and Australian Little Buttonquails. However, much habitat remains for them in northern and inland Australia where the main land use is rough grazing on native pasture. Similarly, the Red-backed Buttonquail has declined at the south-eastern periphery of its Australian range, following habitat destruction and urbanization, but it remains common in the tropics. The New Caledonian Painted Buttonquail, possibly a full species, may now even be extinct. Significantly, its habitat has been altered by Western colonists with their attendant impacts.

Australia is home to no fewer than seven buttonquail species which persist there with varying degrees of success. Among those in decline, the most at risk is the Black-breasted Buttonquail, now classed as Endangered. Its distribution in coastal eastern Australia was never extensive and of recent years its favoured habitat, dry rain forest, is under the ever-increasing threat of clearance for conversion to pastures and forestry plantations.

[*Turnix melanogaster*, near Brisbane, Australia. Photo: Roger Brown, Auscape]

Two tropical Australian species, the Chestnut-backed and Buff-breasted Buttonquails, may be affected by the European grazing and fire regime in the monsoonal grassy woodlands, with some evidence that the Chestnut-backed Buttonquail's range has contracted. Frequent hot fires, late in the dry season, may be causing a decline in habitat quality and food supply. However, the biology of these species, and likewise the effects of human impact on them, are poorly known. The two species are classified, respectively, as Vulnerable and Endangered, and a strategy to redress the lack of knowledge about them has been formulated, though not yet implemented.

The most seriously threatened species is the Black-breasted Buttonquail, which is now classed as Endangered. It always had a restricted distribution, in coastal eastern Australia. Its range and numbers have seriously declined, owing to clearance of its habitat for agriculture, grazing and intensive plantation forestry. It is largely restricted to dry rain forest, although it may be adapting to native *Araucaria* plantations with an understorey of introduced *Lantana*, which forms prickly thickets. Its preferred habitat has been decimated and fragmented into small pockets, and adjoining grassy forest is frequently burnt, a process which removes the litter on which it depends. As is often the case when a rather spectacular species becomes rare, the Black-breasted Buttonquail is prone to attract the attention of illegal egg-collectors and bird-trappers; their activities have the potential to affect remnant populations seriously.

Surveys and research are being conducted in order to gather the necessary knowledge for conserving the Black-breasted Buttonquail. The emphasis of such research is mainly on the potential impact of timber harvesting in public forest, although recent surveys have located the birds also in habitat remnants within farmland. Ironically, these findings come at a time when the remnants are threatened with clearance.

The Black-breasted Buttonquail has been found recently on a large offshore island, Fraser Island, which is partly a national park. However, there is no reason to believe that this represents a recent range extension. Rather, the species was probably always present, but simply passed undetected. Extralimital reports of the species are unconfirmed, those from northern Queensland being unsupported by adequate details, and those from Victoria probably referring to the Stubble Quail (*Coturnix pectoralis*), a species that was formerly known as the "Black-breasted Quail".

On the positive side, the Black-breasted Buttonquail appears to be little affected by introduced predators, such as cats and foxes; indeed, it is not known whether the total population of any Australian buttonquail species is seriously affected by the cat or the fox, although it is suspected that they may kill many individuals. Another slightly more optimistic sign for this species lies in the fact that it has been found to respond well to the exclusion of fire from the grassy forest fringing its rain forest refuges. The main hope for its survival hangs on the preservation of all surviving remnants of its habitat, and appropriate management of wood-production forests that contain populations of the species. A fairly large captive-bred stock exists, should reintroduction become an appropriate measure.

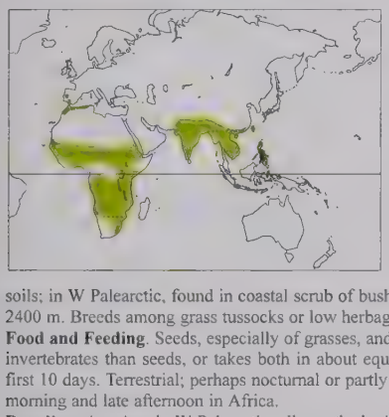
PLATE 3

inches 4

cm 10



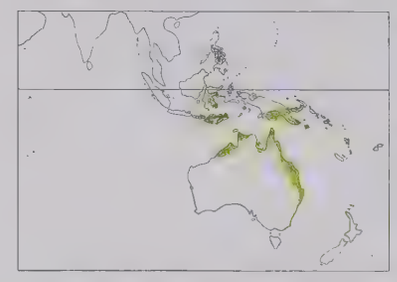
Genus *TURNIX* Bonnaterre, 1791

1. Common Buttonquail

Turnix sylvatica

French: Turnix d'Andalousie **German**: Laufhühnchen **Spanish**: Torillo Andaluz
Other common names: Striped/Small/Little(!)/Kurrichane Buttonquail, Andalusian Hemipode, Bustard Quail

Taxonomy. *Tetrao sylvaticus* Desfontaines, 1787, near Algiers.
May form superspecies with *T. maculosa*, with which formerly considered conspecific, but differs in colour of plumage, bill and legs. Internal taxonomy rather complex and still somewhat provisional. Race *celestinoi* of SE Philippines sometimes referred to *T. maculosa*: Mindanao claimed to hold two sympatric forms, *celestinoi* and *masaaki*, of which former referred to *T. maculosa* and latter to present species; however, it is not at all clear that "true" *celestinoi*-type birds actually occur on Mindanao, nor that *celestinoi* and *masaaki* are indeed distinct; thus, as sympatry of two distinct forms is not demonstrated, on current evidence it appears safer to retain both forms in present species, and amalgamate *masaaki* with *celestinoi*. Several formerly recognized races now considered indistinguishable: *alleni* and *arenaria* merged into single African race *lepurana*; *mikado* merged into E Asian *davidi*. Nine subspecies normally recognized.
Subspecies and Distribution.
T. s. sylvatica (Desfontaines, 1787) - relictual in S Spain and NW African coast.
T. s. lepurana (A. Smith, 1836) - sub-Saharan Africa, except forests and deserts.
T. s. dussumier (Temminck, 1828) - W parts of SE Asia, from India to Myanmar; possibly E Iran (unconfirmed).
T. s. davidi Delacour & Jabouille, 1930 - E parts of SE Asia, from Indochina through S China to Taiwan.
T. s. whiteheadi Ogilvie-Grant, 1897 - Luzon (N Philippines).
T. s. nigrorum DuPont, 1976 - Negros (SE Philippines).
T. s. celestinoi McGregor, 1907 - Bohol and Mindanao (SE Philippines).
T. s. suluensis Mearns, 1905 - Sulu Is (SW of Mindanao).
T. s. bartelsorum Neumann, 1929 - Java and Bali.



Descriptive notes. 15-16 cm; male 32-44 g, female 39-54 g; female larger. Small, largely chestnut *Turnix* with pale eyebrow, rusty breast and innerwings, scalloped upperparts, spotted flanks, pale eyes, and slender blue-grey bill. Female slightly darker and more brightly coloured than male. Non-breeding birds have duller plumage. Juvenile smaller, more heavily spotted, with dark eyes. Races differ in size and in colouring of upperparts and sides of breast; birds of SE Asia much smaller.
Habitat. Scrub, thickets, tussocky or rank grassland, crops, stubble and weedy fallow fields, sometimes near water but always on warm dry soils; in W Palearctic, found in coastal scrub of bushes and dwarf palms; occurs from sea-level up to 2400 m. Breeds among grass tussocks or low herbage.
Food and Feeding. Seeds, especially of grasses, and invertebrates including ants; usually takes more invertebrates than seeds, or takes both in about equal proportions. Chicks entirely insectivorous for first 10 days. Terrestrial; perhaps nocturnal or partly so in W Palearctic, whereas most active in early morning and late afternoon in Africa.
Breeding. Apr-Aug in W Palearctic; all months in Africa and Asia but locally only during rainy seasons. Solitary breeder; in general, females sequentially polyandrous, but locally monogamous. Nest is shallow, well concealed scrape lined with grass, under grass tussock or low vegetation; standing grass stems often pulled over to form loose canopy. Usually 4 eggs (2-5) in Palearctic, 3-4 eggs (2-7) in Africa, and 4 eggs (4-5) in Asia; incubation 12-15 days. Incubation and chick-care by male alone, except in cases of local monogamy. Chicks rufous brown with dark and pale dorsal stripes; fly at 7-11 days, independent at 18-20 days before fully-grown; first breeding within 4 months. Longevity in captivity 9 years.
Movements. Poorly understood, but seemingly rather complex. Apparently sedentary in W Palearctic. Resident and intra-tropical migrant in Africa: resident with some local movements in Nigeria, Ethiopia, E Africa, Malawi, Zambia, Zimbabwe, South Africa, and probably also in Gambia and Ghana; wet season breeding visitor to drier areas of N tropics (Chad, Sudan, Kenya) and parts of S subtropics (Namibia, Botswana); dry season non-breeding visitor to Zaire, and to Zimbabwe, Zambia and South Africa where these numbers swell resident populations. Resident and locally seasonally nomadic or semi-migratory in Asia; wet season breeding visitor to NW India. Irregular visitor or vagrant to N Yemen, SW Saudi Arabia, S Oman and Iran; formerly occurred regularly in winter in S Yemen. Migrates at night.
Status and Conservation. Not globally threatened. Nominate *sylvatica* rare and declining towards extinction in W Palearctic; now surviving locally in SW Spain and along coast of NW Africa, and perhaps also in S Portugal; extinct in Sicily not later than 1920, probably due to hunting and conversion of garigue habitat. Scarce to locally abundant in Africa: widespread W Africa, and common in Nigeria; moderately common in Sudan and Ethiopia; widespread and locally common in E Africa; common to abundant in Zambia, Zimbabwe and Malawi, and common in Kalahari zone. Uncommon to common throughout Asian range. Most widespread *Turnix* species, adapted to a variety of primary and secondary vegetation types, therefore probably secure.
Bibliography. Ali & Ripley (1980), Baker (1928b), Beaman (1994), Benson & Benson (1975), Cramp & Simmons (1980), Crouther (1994), Dickinson *et al.* (1991), Dowsett & Forbes-Watson (1993), DuPont (1971), Elgood *et al.* (1994), Étchécopar & Hüe (1964, 1978), Ginn *et al.* (1989), Gonzales & Rees (1988), Grimes (1987), Hoesch (1959, 1960), Hollom *et al.* (1988), King *et al.* (1975), Lekagul & Round (1991), MacKinnon (1988), MacKinnon & Phillipps (1993), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Newby (1980), Niethammer (1961), Pakenham (1979), Pinto (1983), Rahmani (1988), Roberts, T.J. 2. Red-backed Buttonquail

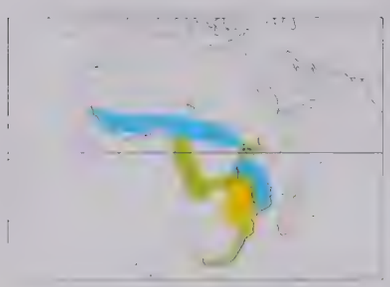
Turnix maculosa

French: Turnix moucheté **German**: Fleckenlaufhühnchen **Spanish**: Torillo Moteado
Other common names: Black-backed/Black-spotted/Orange-breasted/Red-collared/Spotted(!) Buttonquail

Taxonomy. *Hemipodius maculosus* Temminck, 1815, Timor.
May form superspecies with *T. sylvatica*, with which formerly considered conspecific, but differs in colouring of plumage, bill and legs. Alternatively, may be closely related to *T. tanki*, although this seems less likely. Formerly recognized races *yorki* (NE Australia) and *pseutes* (NW Australia) now considered inseparable from *melanota*; *mayri* sometimes merged with similar *horsbrughi* (New Guinea). Race *T. sylvatica celestinoi* of SE Philippines often referred to present species, on grounds of sympatry of two distinct *Turnix* forms on Mindanao; however, this sympatry remains to be demonstrated, and stronger evidence required to justify range extension of present species to include Philippines. Fourteen subspecies normally recognized.
Subspecies and Distribution.
T. m. beccarii Salvadori, 1875 - Sulawesi, Muna and Tukangbesi Is.
T. m. kinneari Neumann, 1939 - Peleng (Banggai Is).
T. m. obiensis Sutter, 1955 - Obi and Kai Is (Moluccas), Babar (Lesser Sundas).
T. m. sumbana Sutter, 1955 - Sumba (Lesser Sundas).
T. m. floresiana Sutter, 1955 - Sumbawa, Komodo, Padar, Flores, Alor (Lesser Sundas).
T. m. maculosa (Temminck, 1815) - Timor, Wetar, Kisar, Moa (Lesser Sundas).
T. m. savuensis Sutter, 1955 - Sawu (Lesser Sundas).
T. m. saturata Forbes, 1882 - New Britain and Duke of York I (Bismarck Archipelago).
T. m. furva Parkes, 1949 - Huon Peninsula (NE New Guinea).
T. m. giluwensis Sims, 1954 - CE New Guinea.
T. m. horsbrughi Ingram, 1909 - S New Guinea.
T. m. mayri Sutter, 1955 - Louisiade Archipelago.
T. m. salamonis Mayr, 1938 - Guadalcanal (Solomon Is).
T. m. melanota (Gould, 1837) - N & E Australia.

Descriptive notes. 12-16 cm; male 23-39 g, female 32-51 g; female larger. Small *Turnix* with darkish upperparts, slender yellow bill, pale eyes and yellow legs. Female brighter and more rufous than male. Non-breeding birds duller; also some individual variation in brightness. Juvenile smaller, darker, more mottled and scalloped, with dark eyes. Races vary in size and colour, some much darker overall; extent of rufous collar on hindneck varies with races, absent in some.
Habitat. Rank grassland, crops and sedgeland; also grassy ground cover in woodland, often moist or seasonally flooded; from sea-level up to 2400 m. Breeds in dense grass near water.
Food and Feeding. Seeds, e.g. of grasses, *Vicia*, *Swainsona*, *Polygonum aviculare*, *Rumex*; also green shoots and invertebrates; species more insectivorous than most *Turnix*. Swallows grit and sand, presumably to aid mechanical breakdown of seeds in gizzard, as is probably norm for family. Terrestrial, nocturnal and crepuscular; gleans and scratches in litter.
Breeding. Season Oct-Jun. Solitary breeder; females sequentially polyandrous. Nest is shallow depression on ground under grass tussock, herbage or shrub, lined with grass; surrounding grass stems bent and woven to form canopy or dome with side entrance. Usually 4 eggs (2-4); incubation 14 days. Incubation and chick-care by male alone. Chicks dusky with only traces of pale markings; self-feeding at 10 days, fully-feathered at 6 weeks, adult size at 7 weeks, adult-like plumage at 4 months.
Movements. Poorly known; apparently some populations resident, others migratory or dispersive, with some coastal concentration in dry season in Australian tropics and fluctuations in SE of Australian range. Migrates at night.
Status and Conservation. Not globally threatened. Uncommon in E Australia and has disappeared from SE extremity of Australian range, but common in N Australia. Still common in remaining habitat in Solomon Is, but most of habitat there now destroyed and race *salamonis* may now be threatened. Elsewhere, species apparently still secure, but presumably subject to habitat destruction and human predation in many areas.
Bibliography. Andrew, P. (1992), Beehler *et al.* (1986), Blaber & Milton (1991), Coates (1985), Crouther (1994), Dickinson *et al.* (1991), DuPont (1971), Gonzales & Rees (1988), Lindsey (1992), Macdonald (1988), Marchant & Higgins (1993), Mayr (1944), Olsen *et al.* (1993), Pendleton (1947), Pizzey & Doyle (1980), Rand & Gilliard (1967), Schodde & Tidemann (1986), Shephard (1989), Simpson & Day (1994), Slater *et al.* (1989), Stokes (1983), Sutter (1955), Trounson (1987), White & Bruce (1986).



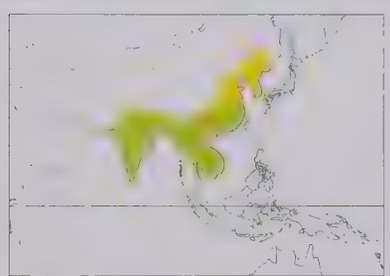
3. Black-rumped Buttonquail

Turnix hottentotta

French: Turnix hottentot **German**: Hottentottenlaufhühnchen **Spanish**: Torillo Hotentote
Other common names: Dwarf/African Buttonquail; Natal Buttonquail (*nana*); Hottentott South African Buttonquail (*hottentotta*)

Taxonomy. *Turnix hottentottus* Temminck, 1815, Cape of Good Hope.
Race *nana* often considered separate species, mainly on account of differences in eye colour and migratory habits; no intergradation reported in zone of contact, but very few recent records. Possible northern races *luciana* and *insolata* now considered inseparable from *nana*. Two subspecies normally recognized.
Subspecies and Distribution.
T. h. nana (Sundevall, 1851) - irregularly and locally in sub-Saharan Africa, mainly from Nigeria E to Uganda and Kenya, S to Angola and E South Africa; status and limits of range particularly uncertain in W Africa.
T. h. hottentotta Temminck, 1815 - mountains of S South Africa, in winter rainfall area of S Cape Province.
Descriptive notes. 14-15 cm; male 40 g, female 58-62 g; female larger. Small, rather dark *Turnix* with slender bill and orange-rufous face and breast; prominent barring on sides of breast and spotting on

On following pages: 4. Yellow-legged Buttonquail (*Turnix tanki*); 5. Spotted Buttonquail (*Turnix ocellata*); 6. Barred Buttonquail (*Turnix suscitator*).



flanks; pale yellow eyes. Female has very slightly brighter red underparts. Darker, browner and generally less scalloped dorsally than partially sympatric *T. sylvatica*; calls differ. Juvenile smaller, less rufous and more heavily marked. Race *nana* has pale blue to whitish eyes, darker upperparts, richer rufous breast with less extensive black markings on sides; male much duller and more heavily marked than female.
Habitat. Short and fairly open grassland and savanna, often in moist zones; also found in fallow fields, native gardens, scrubland, areas of short herbage, and edges of thickets; occurs from sea-level up to 1800 m. Breeds in moist, open tussocky grassland; occasionally in somewhat marshy, harvested fields of sugar cane.
Food and Feeding. Little specific information available. Seeds of grasses and weeds; invertebrates including insects and their larvae. Food taken on ground.
Breeding. Laying occurs in most months, but locally during or at end of rainy seasons; nominate *hottentotta* recorded laying in Feb. Solitary breeder; females possibly polyandrous. Nest is shallow scrape, lined with grass, under grass tussock with standing stems bent to form loose canopy, or under sheaf of fallen grass without canopy. Usually 3 eggs (2-6); incubation 12-14 days. Incubation by male.
Movements. Poorly understood. Resident and local intra-African migrant; apparently itinerant over most of range, where tends to be breeding migrant during rains. Nominate race exclusively resident. Race *nana* resident in Kenya, Uganda and (formerly?) South Africa; breeding visitor to Malawi, Zimbabwe and Zambia; probably only vagrant to Nigeria, although breeding recorded; erratic appearances in Cameroon. Migrates at night.
Status and Conservation. Not globally threatened. Uncommon or locally common, but cryptic in plumage and behaviour and easily overlooked; less numerous than partially sympatric *T. sylvatica*. Nominate *hottentotta* very poorly known and restricted in range; uncommon and local, and possibly even extinct, with last breeding record in 1968. Species as a whole very rare in South Africa, where range has undergone major contraction, probably due, at least in part, to overgrazing, trampling and excessive burning of habitat; may no longer breed. Locally common in Zaire, Uganda and Kenya; widespread but local in Zambia and Malawi; uncommon and local in Mozambique and Zimbabwe, and apparently also in W Africa. Association with dry and heavily grazed grasslands, and attraction to areas disturbed by cattle, suggest that species is likely to be secure; however, overgrazing could be a threat in some areas.
Bibliography. Anon. (1995g), Benson & Benson (1975), Britton, P.L. (1980), Brooke (1984a), Brown & Britton (1980), Clancey (1967, 1970), Cyrus & Robson (1980), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Flieg (1973), Ginn *et al.* (1989), Kemp (1980), Lippens & Wille (1976), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Masterson (1969, 1973), Newman (1980), Pinto (1983), Short *et al.* (1990), Skead, C.J. (1967), Urban *et al.* (1986), Winterbottom (1968).

4. Yellow-legged Buttonquail

Turnix tanki

French: Turnix indien **German**: Rotnacken-Laufhühnchen **Spanish**: Torillo Tanki

Taxonomy. *Turnix tanki* Blyth, 1843, Bengal.
May be closely related to *T. maculosa*, although this proposal has not been widely accepted. Two subspecies recognized.
Subspecies and Distribution.
T. t. tanki Blyth, 1843 - Indian Subcontinent, Andaman and Nicobar Is.
T. t. blanfordii Blyth, 1863 - Myanmar through Indochina to E China, breeding N to Korea and extreme SE of Soviet Far East (S Amurland and Ussuriland).

Descriptive notes. 17 cm; male 35-78 g, female 93-113 g; female larger. Fairly large, greyish *Turnix*; rather pale underparts with bold black spotting; bright yellow bill and legs. Female brighter than male, with rufous collar on hindneck. Non-breeding birds duller, female lacking rufous collar. Juvenile smaller, with more rufous mottling and more densely spotted. Race *blanfordii* slightly larger, with more distinct dorsal barring.
Habitat. Grassland, crops, secondary growth on deserted cultivation, bamboo thickets with grassy undergrowth, and scrub; occurs from sea-level up to 2200 m. Breeds in grass.
Food and Feeding. Grain, seeds, green shoots and invertebrates (ants, small beetles and grasshoppers); feeds mostly on seeds. Chicks fed mainly on minute insects, though seeds also eaten. Terrestrial forager, like congeners.
Breeding. Mar-Nov, occasionally other months; usually in rainy season Jun-Oct. Solitary breeder; females sequentially polyandrous. Nest is shallow depression on ground, lined with grass, sometimes with surrounding stems arched over to form rough dome with side entrance. Usually 4 eggs; incubation 12 days. Incubation and chick-care by male alone. Chicks can fly at 10 days, attain adult plumage at 7 weeks.
Movements. Apparently resident most areas, but nomadic or migratory in dry regions of India and Pakistan, where is breeding visitor during rainy season; summer breeding migrant in NE of range, with birds wintering in SE of range. Migrates at night.
Status and Conservation. Not globally threatened. Status and trends very poorly known. Species widespread and apparently common in much of range, e.g. in Thailand; frequent in Pakistan. Preference for disturbed and cultivated areas suggests that its future is secure.
Bibliography. Ali & Ripley (1980), Austin (1948), Baker (1928b, 1930), Beaman (1994), Deignan (1945), Étchécopar & Hüe (1978), Flint *et al.* (1984), Inskipp & Inskipp (1991), King *et al.* (1975), Knystautas (1993), Lekagul & Round (1991), Liang Qihui (1986), Meyer de Schaunsee (1984), Potapov & Flint (1987), Rahmani (1988), Ripley (1982), Roberts, T.J. (1991), Rutgers & Norris (1970), Seth-Smith (1903), Smythies (1986), Zhang Weigong & Chen Zuoping (1985).

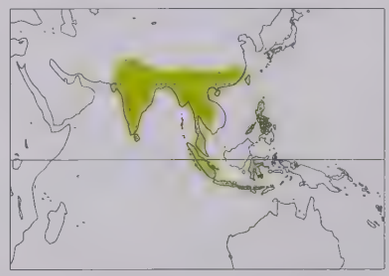
5. Spotted Buttonquail

Turnix ocellata

French: Turnix de Luçon **German**: Riesenlaufhühnchen **Spanish**: Torillo Ocelado

Other common names: Ocellated/Philippine/Chestnut-breasted(!) Buttonquail

Taxonomy. *Oriolus ocellatus* Scopoli, 1786, Manila.
Generally regarded as polytypic, but population of Luzon may be monotypic with clinal variation in size; racial diagnosis based on few specimens. Taxonomic status of Negros population unknown. Two subspecies currently recognized.
Subspecies and Distribution.
T. o. benguetensis Parkes, 1968 - montane N Luzon; intermediate form in lowland NE Luzon (Philippines).
T. o. ocellata (Scopoli, 1786) - lowland C Luzon (Philippines).
Also occurs on Negros, but subspecies uncertain.



Descriptive notes. 17 cm; female larger. Fairly large, brown *Turnix* with strongly patterned head, plain rufous breast and boldly spotted wings. Female brighter, with much more boldly marked head and more prominent rufous collar. Juvenile smaller, more spotted on foreparts. Geographical or possibly altitudinal variation in size: race *benguetensis* has slightly smaller wings and bill, but intermediate specimen known; rufous of underparts also slightly brighter and often somewhat more extensive; more white markings on sides of head.
Habitat. Poorly known. Brushy grassland, ravine edges, rice fields and rarely open grassland; recorded from sea-level up to 2200 m.
Food and Feeding. No information available.
Breeding. Season Feb (chick) and May-Aug; no further information available.
Movements. No information available. Presumably sedentary, as inferred from isolation and possible subspeciation; no records outside normal range.
Status and Conservation. Not globally threatened. Currently considered near-threatened. No specific information available on status; seldom encountered by ornithologists, biology unknown. Restricted range, but apparently common as suggested by frequent capture; subject to certain amount of human predation.
Bibliography. Collar *et al.* (1994), Dickinson *et al.* (1991), DuPont (1971), Gonzales & Rees (1988), Hachisuka (1931), Hornbuckle (1994), Parkes (1968), Rabor (1955).

6. Barred Buttonquail

Turnix suscitator

French: Turnix combattant **German**: Bindenlaufhühnchen **Spanish**: Torillo Batallador
Other common names: Common(!)/Dusky/Indian/Philippine(!) Buttonquail

Taxonomy. *Tetrao Suscitator* Gmelin, 1789, Java.
Race *powelli* has on occasion been considered sufficiently distinct to merit separate species status, and is undoubtedly the most distinctive subspecies. Race *interrumpens* doubtfully distinct from *blakistoni*; validity of race *baweanus* sometimes questioned, due to similarity with Javan *suscitator*. Birds of Sumatran zone sometimes receive different subspecific designations: those of N Sumatra have been placed in race *atrogularis*; those of C Sumatra have been awarded separate race, *machetes*; and those of Belitung I sometimes awarded separate race, *kuiperi*; however, no clear patterns of geographical variation, and all three populations probably best retained in nominate *suscitator*. Eighteen subspecies recognized.
Subspecies and Distribution.
T. s. taigoor (Sykes, 1832) - India.
T. s. leggei Stuart Baker, 1920 - Sri Lanka.
T. s. plumbipes (Hodgson, 1837) - Nepal, Sikkim, Bangladesh and Assam E to NE Myanmar.
T. s. bengalensis Blyth, 1852 - lower W Bengal (India).
T. s. okinavensis Phillips, 1947 - S Kyushu and Makenoshima I (Japan) S to Ryukyu Is.
T. s. rostrata Swinhoe, 1865 - Taiwan.
T. s. blakistoni (Swinhoe, 1871) - Myanmar and N Vietnam to S China and Hainan.
T. s. pallescens Robinson & Stuart Baker, 1928 - SC Myanmar.
T. s. thai Deignan, 1946 - C Thailand.
T. s. interrumpens Robinson & Stuart Baker, 1928 - peninsular Myanmar and Thailand.
T. s. atrogularis (Eyton, 1839) - Malay Peninsula.
T. s. suscitator (Gmelin, 1789) - Sumatra, Belitung I and Bangka I to Java and Bali.
T. s. baweanus Hoogerwerf, 1962 - Bawean I (Java).
T. s. fasciata Temminck, 1815 - Luzon S to Mindoro, Sibuyan and Masbate (N Philippines).
T. s. haynaldi Blasius, 1888 - Palawan and Calamian Group (W Philippines).
T. s. nigrescens Tweeddale, 1878 - Panay and nearby islands S to Negros and Cebu (CE Philippines).
T. s. rufilata Wallace, 1865 - Sulawesi.
T. s. powelli Guillemard, 1885 - Lombok, Sumbawa, Sangeang, Flores, Lomblen and Alor (Lesser Sundas).
Contrary to some recent sources, no evidence of occurrence in Pakistan.

Descriptive notes. 15-17 cm; male 35-52 g, female 47-68 g; female larger. Fairly large, russet brown *Turnix* with boldly patterned head, barred underparts and greyish legs and feet. Female brighter than male, with black throat and rufous collar in some races. Non-breeding birds duller. Juvenile smaller and more buff-coloured, with underparts spotted. Races vary in size, and in patterns and coloration of plumage; sexes alike in some races; race *powelli* very different, essentially lacking rufous tones throughout plumage, and with greyish brown upperparts largely unmarked; female of race *rufilata* has throat barred black and white, rather than solid black; race *nigrescens* particularly dark rufous collar on hindneck varies considerably in extent, being totally absent in some races.
Habitat. Grassland, crops, deserted fields, secondary growth, scrub, bamboo thickets and forest edge habitats, on sandy soil, often near water; occurs from sea-level up to 2500 m. Breeds in rank ground vegetation, often near margin of more open ground.

Food and Feeding. Grass and weed seeds, invertebrates and green shoots. Terrestrial; forages among grass and leaf litter, where makes circular scrapes in mulch. Commutes to foraging sites via well defined trails, marked by footprints.

Breeding. Laying recorded in all months, but with local peaks according to seasonal conditions and possible gaps at height of rains or in driest months. Solitary breeder; females sequentially polyandrous. Nest is pad of grass in shallow depression, often in grass tuft; stems bent to form overhead dome with side entrance. Usually 4 eggs (3-6); incubation 12-14 days. Incubation and chick-care by male alone. Chicks reach adult size in 40-60 days.

Movements. Poorly known. Apparently resident in most areas, but some continental populations may be locally nomadic or migratory, according to rains.

Status and Conservation. Not globally threatened. Appears to be widespread and common in India, Sri Lanka and most parts of SE Asian range, so far as is known; very common in Thailand. Ability to live near humans and to benefit from cutting, grazing and cropping suggests that species is likely to be secure.

Bibliography. Ali & Ripley (1980), Baker (1928b), Beaman (1994), Brazil (1991), Deignan (1945), Dickinson *et al* (1991), DuPont (1971), Étchécopar & Hüe (1978), Gonzales & Rees (1988), Henry (1971), Inskipp & Inskipp (1991), King *et al*. 7. Madagascar Buttonquail

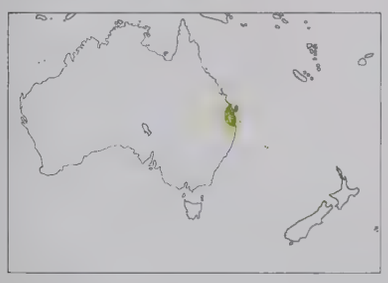
Turnix nigricollis

French: Turnix de Madagascar **German**: Schwarzkehl-Laufhühnchen **Spanish**: Torillo Malgache
Other common names: Black-necked Buttonquail

Taxonomy. *Tetrao nigricollis* Gmelin, 1789, Madagascar.
Monotypic.
Distribution. Madagascar; also Mauritius, Reunion and Glorieuses Is, but possibly introduced to all of these, though may have colonized them, e.g. introduced to Reunion, but an indigenous population may have existed there already.



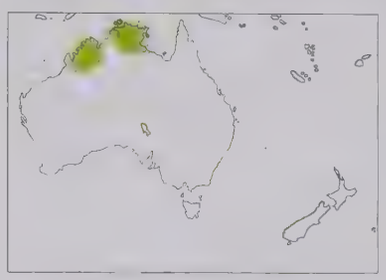
Descriptive notes. 14-16 cm; female 67-84 g; female larger. Smallish *Turnix* with blackish forehead; male has black and white barred breast; female considerably brighter, with solid black breast and deep rufous shoulder path; no congeners within range. Juvenile smaller, with wings more rufous and more heavily spotted.
Habitat. Typically found in grassland, crops, savanna, woodland, brush and dry forest, including disturbed forest; occurs from sea-level up to 1900 m. Breeds in grassy glades in secondary growth, and among brush and tall weeds in open grassland.
Food and Feeding. Recorded as taking seeds and insects. Terrestrial and diurnal; scratches and pivots in leaf litter to form characteristic circular feeding scrapes.
Breeding. Late Aug-Feb. Solitary breeder. Nest is shallow depression or scrape, lined with grass, under grass tussock or in midst of grass beneath small tree; grasses often domed over to form canopy with side entrance, sometimes with tunnel or runway to nest. 3-5 eggs; incubation 13-16 days. Incubation by male alone. Chick brown with pale dorsal stripes; chicks self-feeding at 2 weeks, fully-feathered and flying at 3 weeks, independent in 4th week.
Movements. No specific information available, but apparently sedentary. Perhaps locally dispersive, if populations on offshore islands were self-introduced.
Status and Conservation. Not globally threatened. Common in N, W and S Madagascar, less so in E and on High Plateau. Occurs in a variety of disturbed, cultivated and secondary habitats including forest clearings, therefore probably secure. Possibly introduced population on Mauritius now extinct.
Bibliography. Appert (1972), Benson, Beamish *et al.* (1975), Benson, Colebrook-Robjent & Williams (1976-1977), Berlioz (1946), Cheke (1987), Dee (1986), Delacour (1932), Dowsett & Forbes-Watson (1993), Diamond (1987), Langrand (1990), Lever (1987), Milon (1951), Milon *et al.* (1973), Penny (1974), Rand (1936), Rutgers & Norris (1970), Salvan (1972b), Staub (1976), Watson *et al.* (1963).

8. Black-breasted Buttonquail

Turnix melanogaster

French: Turnix à poitrine noire **German**: Schwarzbrust-Laufhühnchen **Spanish**: Torillo Pechinegro

Taxonomy. *Hemipodius melanogaster* Gould, 1837, Moreton Bay, Queensland, Australia.
Variously considered to be similar to, and possibly related to, either *T. nigricollis* and *T. ocellata*, or *T. suscitator*; but affinities more likely to be with *T. varia* group, and males of *melanogaster* and *varia* resemble each other. Proposed race *goweri* (Queensland) no longer recognized because based on individual variation. Monotypic.
Distribution. Coastal E Australia, in SE Queensland and extreme NE New South Wales; recently found to occur on offshore Fraser I.



Descriptive notes. 17-19 cm; male 50-87 g, female 80-119 g; female larger. Fairly large, robust *Turnix* with relatively slender bill and pale eyes. Female, with mostly black head and breast, unmistakable. Juvenile smaller, duller, foreparts more mottled. Male and juvenile similar to those of *T. varia*, from which distinguished by details of plumage and eye colour.
Habitat. Rain forest, other moist forest, vine thicket and grassy edges, with deep leaf litter; also introduced *Lantana* thickets; sometimes found in *Araucaria* and pine plantations, rarely in grass or stubble away from forest. Occurs from sea-level up to 800 m. Breeds within rain forest or under *Lantana*.
Food and Feeding. Apparently feeds mainly on invertebrates, though seeds, including grain, also reported. In one study, commonest items were: beetles, including weevils; ants; and spiders, probably including a jumping spider (Salticidae) and a brown trapdoor (*Arbanitis variabilis*) reckoned to measure 1·5-2 cm; other items included centipedes, millipedes and land snail *Nitor pudibundus*. Terrestrial, feeding both diurnally and nocturnally. Gleans, scratches and pecks at litter; creates characteristic circular feeding scrapes by pivoting on one foot while raking with the other (see page 47), sometimes reversing direction. Sometimes shades litter with outstretched wings while scratching.
Breeding. In wild, recorded in Oct-Feb or Mar; all year but mainly Sept-Apr in captivity, if conditions sufficiently warm. Solitary breeder; females sequentially polyandrous. Nest is scrape, lined with grass and leaves, under low bush or coarse grass tussock, often with grass stems forming hood or even substantial dome with side entrance. Usually 3-4 eggs; incubation 15-16 days. Incubation and chick-care by male alone. Chicks brown with black and white dorsal stripes; start to self-feed at 8 days, but fed by male for 2 weeks; attain sexually diagnostic plumage at 8-12 weeks, breeding at 4-5 months.
Movements. Apparently mostly sedentary, with no evidence of seasonal or long distance movements, though occasional local irruptions.
Status and Conservation. ENDANGERED. CITES II. Range and numbers greatly reduced by habitat clearance for agriculture and silviculture, and remaining populations threatened by frequent fire and further habitat clearance; species now rarely seen despite searches by ornithologists. May be adapting to pine plantations and *Lantana*, but not known if these are very suitable for breeding. Extensive research required on species, especially in terms of habitat requirements, home range size, breeding biology and post-breeding dispersal, and the impact of forestry and fire; inventory and management of dry rain forest remnants also required. Some of this work has been initiated, including survey of the species and the conservation status of its habitat remnants, as well as research on impact of forestry.
Bibliography. Bennett (1985), Blakers *et al.* (1984), Brouwer & Garnett (1990), Collar & Andrew (1988), Collar *et al.* (1994), Erritzoe (1993), Garnett (1992, 1993), Hermes (1980), Holmes (1987), Hughes & Hughes (1991), Lindsey (1992), Macdonald (1988), Marchant & Higgins (1993), Olsen *et al.* (1993), Phipps (1976), Pizzey & Doyle (1980), Schodde & Tidemann (1986), Shephard (1989), Simpson & Day (1994), Slater *et al.* (1989), Trounson (1987).

9. Chestnut-backed Buttonquail

Turnix castanota

French: Turnix castanote **German**: Rotrücken-Laufhühnchen **Spanish**: Torillo Dorsicastaño

Taxonomy. *Hemipodius castanotus* Gould, 1840, Port Essington, Northern Territory.
Forms superspecies with *T. olivii* and *T. varia*; sometimes considered conspecific with former, but differs in bill size and details of plumage. Invalid races *magnifica* (NW Australia), *melvillensis* (Melville I) and *alligator* (N Australia) no longer recognized, because based on individual rather than geographical variation. Monotypic.
Distribution. NW & NC Australia and offshore islands.

Descriptive notes. 14-20 cm; male 68-69 g, female 87-124 g; female larger. Fairly large, rufous *Turnix* with stout bill and orange-yellow eyes. Female brighter, with plainer pattern than male on upperparts. Smaller, duller and more heavily patterned than *T. olivii*. Juvenile unknown.
Habitat. Short grass in open, dry savanna woodland, often on lightly wooded, stony and litter-strewn hillsides and sandy ridges; occurs from sea-level up to at least 500 m.
Food and Feeding. Little specific information available. Takes seeds (including grass *Triodia*) and insects (beetles, ants and their eggs). Swallows grit and sand, presumably to assist mechanical breakdown in gizzard, as is probably norm for congeners. Terrestrial; nocturnal and crepuscular. Gleans and scratches in litter.
Breeding. Little known. Breeding reported to occur Dec-May, in wet season; eggs recorded Jan. Solitary breeder. Nest is depression in grass, at base of shrub or grass clump, often near water; lined with grass and leaves; sometimes domed with side entrance. Usually 4 eggs (3-4); incubation reportedly 14-15 days. Chicks rufous brown with cream dorsal stripes.
Movements. Unknown; presumably sedentary or locally nomadic, with no evidence of dispersal into other habitats nor seasonal fluctuations.
Status and Conservation. VULNERABLE. Shows cryptic behaviour and inhabits remote areas; seldom encountered by ornithologists, and biology poorly known. Has disappeared from SE extremity of range; possibly threatened by grazing and associated regular fires. Research is required on distribution, status, biology and impact of pastoralism and fire.
Bibliography. Andrew, D. (1992), Blakers *et al.* (1984), Christidis & Boles (1994), Collar *et al.* (1994), Garnett (1992, 1993), Lindsey (1992), Macdonald (1988), Marchant & Higgins (1993), Olsen *et al.* (1993), Pizzey & Doyle (1980), Rogers, D. (1995a, 1995b), Schodde & Tidemann (1986), Simpson & Day (1994), Slater *et al.* (1989), Squire (1990), Trounson (1987).

10. Buff-breasted Buttonquail

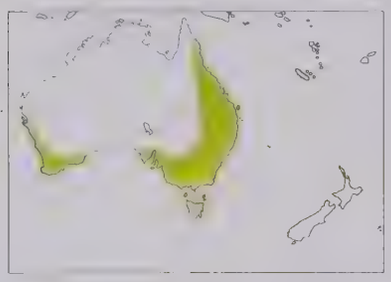
Turnix olivii

French: Turnix de Robinson **German**: Ockerbrust-Laufhühnchen **Spanish**: Torillo de Robinson
Other common names: Buff-backed/Olive's/Robinson's Buttonquail

Taxonomy. *Turnix olivii* Robinson, 1900, Cooktown, Queensland.
Forms superspecies with *T. castanota* and *T. varia*; sometimes considered conspecific with former, but differs in bill size and plainer plumage. Specific name sometimes misspelt *olivei*, but original spelling is *olivii*. Proposed race *coenensis* (from N of range) no longer recognized, because based on individual variation. Monotypic.
Distribution. Cape York Peninsula, N Queensland, Australia.

Descriptive notes. 18-22 cm; female larger. Large, rufous *Turnix* with large bill and yellow eyes. Female brighter than male, with plainer pattern. Juvenile unknown.
Habitat. Normally found in wooded grasslands and grassy fringes of forests and swamps; often on stony hillsides or ridges with sparse grass cover, within woodland or rain forest; occurs from sea-level up to 400 m. Breeds in grassy woodland.
Food and Feeding. Little known; seeds and insects recorded. Like congeners, swallows coarse sand, presumably to assist mechanical breakdown in gizzard. Terrestrial.
Breeding. Little known. Season Jan-Mar. Solitary breeder. Nest is domed structure of grass stems with side entrance, in shallow depression lined with grass and a few leaves; well hidden among grass stalks or low shrubs or under grass tussock. Usually 3-4 eggs (2-4); incubation period unknown but presumably similar to that of *T. varia*. Incubation and probably chick-care by male alone. Chicks not described.
Movements. None known; southerly expansion of range may occur during wet years.

On following pages: 11. Painted Buttonquail (*Turnix varia*); 12. Worcester's Buttonquail (*Turnix worcesteri*); 13. Sumba Buttonquail (*Turnix everetti*); 14. Red-chested Buttonquail (*Turnix pyrrhothorax*); 15. Australian Little Buttonquail (*Turnix velox*); 16. Lark Buttonquail (*Ortyxelos meiffrenii*).



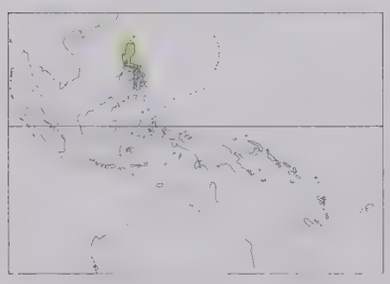
Status and Conservation. ENDANGERED. Scarcely distributed in remote area, with cryptic behaviour typical of congeners; seldom encountered by ornithologists, and biology poorly known. Possibly threatened by grazing and associated frequent fires. Extensive survey and research work on ecology required.
Bibliography. Blakers *et al.* (1984), Brouwer & Garnett (1990), Christidis & Boles (1994), Collar & Andrew (1988), Collar *et al.* (1994), Garnett (1992, 1993), Lindsey (1992), Macdonald (1971, 1988), Marchant & Higgins (1993), Olsen *et al.* (1993), Pizzey & Doyle (1980), Rogers, D. (1995a, 1995b), Schodde & Tidemann (1986), Simpson & Day (1994), Slater *et al.* (1989), Squire (1990), Trounson (1987), White (1922a, 1922b).

11. Painted Buttonquail

Turnix varia

French: Turnix bariolé **German**: Buntlaufhühnchen **Spanish**: Torillo Pintojo
Other common names: Varied Buttonquail

Taxonomy. *Perdix varia* Latham, 1801, Sydney, New South Wales.
Forms superspecies with *T. olivii* and *T. castanota*. Proposed races *stirlingi* (SW Australia) and *subminuta* (NE Australia) no longer recognized, because based on individual rather than geographical variation. Race *novaecaledoniae* very distinct, and may be separate species. Three subspecies normally recognized.
Subspecies and Distribution.
T. v. novaecaledoniae Ogilvie-Grant, 1893 - New Caledonia.
T. v. scintillans (Gould, 1845) - Abrolhos Is (SW Australia).
T. v. varia (Latham, 1801) - SW, E & SE Australia; Tasmania.



Descriptive notes. 17-23 cm; male 53-94 g, female 72-134 g; female larger. Large, rather rufous *Turnix* with fine bill and red eyes. Female brighter, more rufous than male. Juvenile smaller, more mottled and greyer, with no rufous; eyes pale. Races vary in size, and in intensity of colour and spotting: race *scintillans* smaller, browner and more boldly marked; *novaecaledoniae* small and dark with mostly black upperparts.
Habitat. Scrub, grassy forest and woodland, heath, grassy clearings within dense forest, particularly with abundant litter, and tussocky grass on stony ridges or slopes; occurs from sea-level up to at least 1500 m. Breeds in scrub, forest, woodland or rarely grassland, in sites affording extensive litter, fallen timber, saplings and clumps of grass tussocks.
Food and Feeding. Seeds (grasses, *Avena*, Fabaceae, *Trifolium*, *Erodium*, *Acacia*), fruits (*Solanum* and other wild berries), green shoots and invertebrates (fly pupae, grasshoppers, ants, beetles, weevils, bugs, moths, larvae, aquatic insects). Foraging nocturnal and crepuscular, but also diurnal; terrestrial. Like congeners, swallows grit and sand, presumably to assist mechanical breakdown in gizzard. Scratches and gleans; forms characteristic circular scrapes in litter by pivoting on one foot while raking with the other, sometimes changing feet and reversing direction.
Breeding. Aug-Mar in S, extending to May in E; all months according to local conditions in tropical N of range. Solitary breeder; females sequentially polyandrous, but monogamous bonds can be maintained for several months. Nest is cup of grass and fine litter, at least partly hooded and walled by grass stems, in scrape, sometimes with runway to entrance; normally at base of grass tussock, sapling or rock, or under small shrub. Usually 3-4 eggs (3-5); incubation 13-14 days. Incubation and chick-care by male alone. Chicks grey-brown with black and white dorsal stripes; fed by male for 7-10 days; can fly at 10 days, fully-feathered at 16 days, adult size at 23 days. For 60 eggs in 16 successful nests, 3·7 young raised per successful nest, and 2·6 young per clutch started; mean brood size 3·5 in first week, 2·3 at flying age.
Movements. Poorly understood. Mostly resident, though with high turnover of individuals and some local fluctuations in numbers. Apparently a summer breeding migrant in S of range, particularly in highlands. Migrates at night.
Status and Conservation. Not globally threatened. Generally uncommon to locally common; declining in S, particularly Tasmania where now rare. Subject to habitat clearance and degradation by urbanization, agriculture, grazing and fire. Small island population of race *scintillans* vulnerable. Poorly known on New Caledonia, where endemic race *novaecaledoniae* (possibly full species) rare, or perhaps even extinct.
Bibliography. Beruldsen (1980), Blakers *et al.* (1984), Bourne (1982), Christidis & Boles (1994), Crouther (1994), Frith (1969), Garnett (1992, 1993), Hannecart & Létocart (1980), Hobbs (1981), How & Dell (1990), Lindsey (1992), Macdonald (1971, 1988), Marchant & Higgins (1993), Mather & Rounsevell (1991), Olsen *et al.* (1993), Pedler (1982b), Pizzey & Doyle (1980), Roberts (1979), Rogers, D. (1995a, 1995b), Schodde & Tidemann (1986), Serventy & Whittell (1976), Shephard (1989), Simpson & Day (1989), Slater *et al.* (1989), Storr & Johnstone (1984), Trounson (1987), Whinray (1978).

12. Worcester's Buttonquail

Turnix worcesteri

French: Turnix de Worcester **German**: Worcesterlaufhühnchen **Spanish**: Torillo de Worcester

Taxonomy. *Turnix worcesteri* McGregor, 1904, probably Parañaque, Luzon.
Usually considered a separate species or conspecific with *T. everetti*, but both taxa recently proposed as races of *T. pyrrhothorax*; distinguished from latter by plumage and size. Monotypic.
Distribution. Luzon, N Philippines.

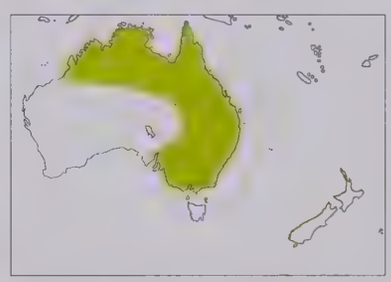
Descriptive notes. c. 14 cm; female larger. Small, stout-billed *Turnix* closely resembling allopatric *T. everetti*, which is slightly darker above; *T. pyrrhothorax* is somewhat paler dorsally, duller ventrally and normally rather larger.
Habitat. Grasslands; recorded from sea-level up to 1000 m, though perhaps mainly in the highlands.
Food and Feeding. No information available.
Breeding. No information available.
Movements. Unknown; no records outside normal range. It has been suggested that a record from a mountain pass may represent an intra-island migration point.
Status and Conservation. VULNERABLE. No specific information available; species rare and probably threatened. Restricted in range, rarely encountered by ornithologists, and biology unknown. Known from few specimens. Subject to certain degree of human predation. Populations may await discovery on other islands. Extensive research required.
Bibliography. Alonzo-Pasicolan (1992), Amadon & DuPont (1970), Christidis & Boles (1994), Collar & Andrew (1988), Collar *et al.* (1994), Dickinson *et al.* (1991), DuPont (1971), Gonzales & Rees (1988), Hornbuckle (1994), Poulsen (1995), Sutter (1955).

13. Sumba Buttonquail

Turnix everetti

French: Turnix de Sumba **German**: Sumbalaufhühnchen **Spanish**: Torillo de Sumba
Other common names: Everett's Buttonquail

Taxonomy. *Turnix everetti* Hartert, 1898, Waingapo, Sumba.
Usually considered a separate species or conspecific with *T. worcesteri*, but both taxa recently proposed as races of *T. pyrrhothorax*; distinguished from latter by plumage and size. In past, was considered race of *T. sylvatica*. Monotypic.
Distribution. Sumba (Lesser Sundas).



Descriptive notes. c. 14 cm; juvenile male and female 28 g; female larger. Small, stout-billed *Turnix* closely resembling allopatric *T. worcesteri*, which is slightly paler above; *T. pyrrhothorax* is paler yet dorsally, possibly slightly duller ventrally and generally somewhat larger.
Habitat. Inhabits scrubby and mostly uncultivated fields mixed with grassland; sparse grassland with scattered bushes inland from mangrove belt. Recent records were in areas of grassland with sward height of 50-70 cm, with areas of short grass interspersed. Basis of ecological separation from sympatric *T. maculosa sumbana* uncertain.
Food and Feeding. Forages on the ground, in pairs; no further information available.
Breeding. No information available.
Movements. Unknown; no records outside normal range.
Status and Conservation. VULNERABLE. Little specific information available; species apparently uncommon and considered threatened, although occurs in man-made grassland and may reach high densities (2 birds per hectare) in suitable habitat; instability of habitat combines with limited range to make species vulnerable. Repeated burning of vegetation to provide land for grazing and cultivation may have increased the area of suitable habitat. Restricted in range, rarely encountered by ornithologists, and biology unknown. Known from very few specimens. Presumably subject to some degree of human predation. Populations might await discovery on other islands. Extensive research required.
Bibliography. Andrew, P. (1992), Christidis & Boles (1994), Collar & Andrew (1988), Collar *et al.* (1994), Jones, M.J., Juhaeni *et al.* (1994), Jones, M.J., Linsley & Marsden (1995), Marsden & Peters (1992), Mayr (1944), Sutter (1955), White & Bruce (1986).

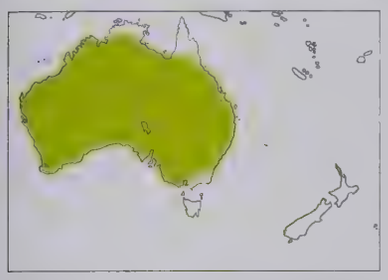
14. Red-chested Buttonquail

Turnix pyrrhothorax

French: Turnix à poitrine rousse **German**: Rotbrust-Laufhühnchen **Spanish**: Torillo Pechirrufo
Other common names: Chestnut-breasted/Red-breasted/Rufous-breasted/Yellow Buttonquail

Taxonomy. *Hemipodius pyrrhothorax* Gould, 1841, Aberdeen, New South Wales.
Usually regarded as monotypic, but recent proposal to treat *T. worcesteri* and *T. everetti* as races of present species. Proposed races *berneyi* (NW Australia) and *intermedia* (Queensland) no longer recognized, because based on individual rather than geographical variation. Monotypic.
Distribution. N & E Australia.

Descriptive notes. 12-16 cm; male 27-46 g, female 43-76 g; female larger. Small to medium-sized, grey and rufous *Turnix* with stout bill and pale eyes. Female brighter than male, with scalloping rarely extending onto breast. Juvenile smaller, browner and more mottled, with breast scalloped.
Habitat. Normally recorded in grassland and grassy woodland; also crops, stubble and weedy fields with dense ground cover; occurs from coastal plains around sea-level up to 1000 m. Generally found in moister, denser cover than *T. velox*, but inhabits semi-arid zones. Breeds in tussock grasslands, pastures of native grass, standing crops and stubble.
Food and Feeding. Seeds (grasses, *Triticum*, *Panicum*, Malvaceae) and insects (cockroaches, ants, flies, larvae). Terrestrial; nocturnal and crepuscular, but also diurnal. Gleans and scratches in litter; makes circular scrapes by pivoting on one foot while raking with the other.
Breeding. Little known. Eggs recorded in Feb-Jul and Sept in N, Sept-Feb in S. Solitary breeder; females sequentially polyandrous. Nest is depression lined with grass, hooded, and sheltered by grass tussock. Usually 4 eggs (2-5); incubation 13-18 days. Incubation and chick-care by male alone. Chicks grey-brown with dark and pale dorsal stripes; reach adult size in 6-8 weeks, adult-like plumage at 2-3 months.
Movements. Poorly known. Local populations variously resident, erratic or migratory. Apparently a spring-summer migrant to parts of S, and dry season (austral winter) migrant to tropical N. Migrates at night.
Status and Conservation. Not globally threatened. Generally ranges from uncommon to locally common, but cryptic behaviour makes it easily overlooked. Declining or suspected to be declining in S of range; attributed to conversion of native grasslands to agriculture.
Bibliography. Bourne (1982), Christidis & Boles (1994), Crouther (1994), Frith (1969), Fulgenhauer (1980), Lindsey (1992), Macdonald (1988), Marchant & Higgins (1993), Morris (1971), Morris & Kurtz (1977), Olsen *et al.* (1993),



Pizzey & Doyle (1980), Schodde & Tidemann (1986), Simpson & Day (1994), Slater *et al.* (1989), Sutter (1955), Trounson (1987).

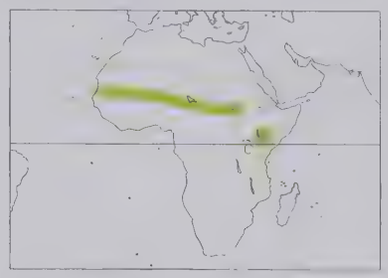
15. **Australian Little Buttonquail**

Turnix velox

French: Petit Turnix **German**: Zwerglaufhühnchen **Spanish**: Torillo Veloz

Taxonomy. *Hemipodius velox* Gould, 1841, Yarrundi, New South Wales.
Proposed races *picturata* and *vinotincta* (NW Australia) and *leucogaster* (C Australia) no longer recognized, because based on individual variation. Monotypic.
Distribution. Continental Australia, mainly inland.

Descriptive notes. 12-16 cm; male 28-44 g, female 39-64 g; female larger. Rather small, rufous and white *Turnix* with very stout bill and pale eyes. Female brighter than male, with somewhat plainer pattern; sides of breast less scalloped. Non-breeding birds duller, and more mottled. Juvenile smaller, browner and more mottled.
Habitat. Dry grassland, grassy woodland, shrub-steppe, crops, stubble and pastures in arid and semi-arid zones; occurs from sea-level up to 1000 m. Breeds in native grasslands and crop fields.
Food and Feeding. Mostly grass seeds, including grain (*Triticum*, *Triodia*, *Danthonia*, *Chloris*, *Eragrostis*, *Panicum*, *Stipa*, Juncaceae, *Sida*, *Rumex*, *Portulaca*); some green shoots (*Citrullus* and *Cucumis* seedlings) and insects (crickets, grasshoppers, bugs, beetles, ants, moth larvae). Like congeners, swallows grit, presumably to assist mechanical breakdown in gizzard. Mainly nocturnal; also diurnal and crepuscular. Terrestrial; gleans and scratches in litter.
Breeding. Poorly known. Sept-Mar in S, Mar-Dec (usually Aug-Nov) in N; recorded in almost all months but varies locally according to rains. Solitary breeder; females sequentially polyandrous. Nest is scrape lined and sometimes hooded over with grass, or domed grass structure with runway to side entrance, under grass tussock, small shrub or fallen branch, or in dense grass or crops. 3-4 eggs; incubation 15 days. Incubation and chick-care by male alone. Chicks brown with dark and pale dorsal stripes; start to self-feed at 3 days; sexually mature at 3 months.
Movements. Poorly known. Resident, migratory and dispersive populations apparently exist; erratic or irruptive in some regions according to local rains and plant growth. General southward and coastward shift in spring-summer to regions of winter rainfall, and northward and inland in winter to regions of summer rainfall. Migrates at night.
Status and Conservation. Not globally threatened. Generally uncommon to common, but may be locally abundant during irruptions. Has declined in some intensively cultivated areas in S, but has also colonized areas where forest and scrub have been converted to pasture. Farm machinery causes much mortality during harvesting, with birds crushed or sucked in; others may catch in barbed wire, when trying to escape. Some predation by cats recorded.
Bibliography. Bourne (1982), Crouther (1994), Eckert (1972), Frith (1969), Lendon (1938), Lindsey (1992), Macdonald (1988), Marchant & Higgins (1993), Morris & Kurtz (1977), Olsen *et al.* (1993), Pizzey & Doyle (1980), Roberts (1979), Schodde & Tidemann (1986), Shephard (1989), Simpson & Day (1994), Slater *et al.* (1989), Trounson (1987).



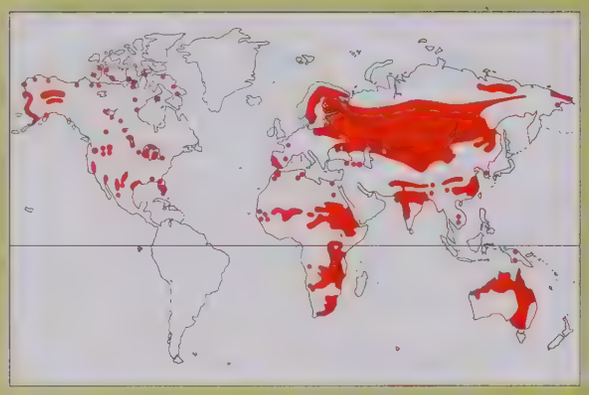
Genus *ORTYXELOS* Vieillot, 1825

16. **Lark Buttonquail**

Ortyxelos meiffrenii

French: Turnix à ailes blanches **German**: Lerchenlaufhühnchen **Spanish**: Torillo Alaudino
Other common names: Lark-quail, Quail-plover

Taxonomy. *Turnix Meiffrenii* Vieillot, 1819, Senegal.
Differs from *Turnix* in morphology, ecology and behaviour (see page 44); shape and structure, especially of wings and tail, and colour pattern of upperwing quite different. Monotypic.
Distribution. Tropical Africa, from Senegal E to Sudan and Kenya; breeds in S Ghana and possibly elsewhere in W Africa.



Descriptive notes. 10-13 cm; male 16-20 g; female larger. Distinctive tiny, courser-like buttonquail, with longer wings and tail than *Turnix*; shows conspicuous white wing flashes and also narrow pale tail tip. Female has slightly more rufous brown breast, and more whitish in tail. Juvenile duller and paler; more mottled and scalloped.
Habitat. Arid to semi-arid and coastal grassland; also savanna and sparse scrub to dense shrubland; occurs from sea-level up to 2000 m. In Sudan, closely associated with grass *Cenchrus catharticus*; in Chad, with grass *Aristida papposa*. Breeds on ground among sparse vegetation. Does not require access to water.
Food and Feeding. Little specific information available. Recorded taking grass seeds and insects, including termites. Terrestrial.
Breeding. Little known. Egg-laying Sept-Mar, in cool dry season. Solitary breeder; possibly monogamous. Nest is scrape in bare ground, lined with leaves and stalks, near base of plant, and often rimmed with small pebbles. 2 eggs; incubation by male alone. No further information available.
Movements. Poorly understood. Resident in some areas, elsewhere intra-African migrant, with some birds apparently breeding on coast in cool dry season; variously present only in wet season or only in dry season in some parts of range. Resident in E (Sudan, Ethiopia, Kenya) and possibly parts of W Africa; breeding visitor to S Ghana.
Status and Conservation. Not globally threatened. Uncommon to locally common; expanding range in some parts, and possibly favoured by expanding deserts. Uncommon and local in Mauritania, Niger, Ghana, Nigeria, Cameroon, Ethiopia, Uganda and Kenya; in Senegal, may have become less common since 1930's; locally common in Mali, Chad and Sudan; spreading southwards in Kenya. No threats currently known.
Bibliography. Britton, P.L. (1980), Brown & Britton (1980), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Glen (1994), Gore (1990), Grimes (1987), Lack (1975), Lamarche (1988), Lamm & Horwood (1958), Lynes (1925), Mackworth-Praed & Grant (1957, 1970), Newby (1980), Nikolaus (1987), Pearson (1986), Short *et al.* (1990), Snow (1978), Urban *et al.* (1986).

Class AVES

Order GRUIFORMES

Suborder GRUES

Family GRUIDAE (CRANES)

- Large, graceful wading and terrestrial birds, with long neck and legs, and mainly grey or white plumage.
- 90-176 cm.

- All regions except Antarctic, but only marginal in Neotropical; greatest diversity of genera in Africa, of species in Asia.
- Wide expanses of shallow wetlands and grasslands from the Arctic to the tropics.
- 4 genera, 15 species, 24 taxa.
- 7 species threatened; none extinct since 1600.

Systematics

The crane family is divided into two subfamilies, the crowned cranes (Balearicinae) and the "typical" cranes (Gruinae). Crowned cranes date back in the fossil record to the Eocene, 54-37 million years before the present, and as many as eleven species of crowned cranes are known to have existed in Europe and North America over the last 50 million years. The two species that survive are found exclusively in Africa. Modern crowned cranes can not withstand extreme cold, and it is conjectured that as the earth cooled these cranes died out on the northern continents and held on only in Africa, where tropical conditions were maintained throughout the ice ages. The typical cranes, by contrast, are more cold hardy. They first appear in the fossil record in the Miocene, 24-5 million years ago, the age of grasslands, and it was during this period that the thirteen surviving species of Gruinae evolved. At least seven other species of Gruinae cranes are known to have become extinct during this period.

Although there is no convincing evidence, it is generally agreed that the order Gruiformes is probably most closely related to Charadriiformes and Galliformes. This degree of uncertainty is not too surprising as Gruiformes itself is a rather heterogeneous assemblage of families, most of which do not appear to be very closely related to one another, an impression commonly reflected by the division of the order into anything from six to ten suborders. However, a number of common morphological features, mainly of the skeleton, the musculature, the digestive tract and the circulatory system, can be considered to link these different families, and the evidence of DNA supports the grouping together of virtually all of the families traditionally placed in Gruiformes.

Within the Gruiformes, cranes appear to be closely related to the Limpkin (Aramidae), which has similar flight patterns and loud calls; the trumpeters (Psophiidae), which resemble crowned cranes in their dances and plumage; and the bustards (Otididae), which are also large, long-legged, long-necked birds of open lands. Recent studies of morphology, ethology and DNA have confirmed these relationships. Also traditionally linked with the Gruidae are the Rallidae, and these two families have frequently been considered the main "core" families of the order.

Crowned cranes are distinguished from the typical cranes by their lack of a coiled trachea, their loose body plumage and their inability to withstand severe cold. They retain the ability to roost in trees, and indeed are the only cranes able to do so. Their calls are also simpler than those of the typical cranes. There are two species, the Grey Crowned Crane (*Balearica regulorum*) of savannas from Uganda and Kenya to South Africa, and the Black Crowned Crane (*Balearica pavonina*) of the Sahel zone from Senegal to Ethiopia and Kenya. Until recently, the two were considered conspecific, but recent research suggests that it is probably better to consider them as two closely related species.

The typical cranes are divided into three genera, *Anthropoides*, *Bugeranus*, and *Grus*. The Demoiselle Crane (*Anthropoides virgo*) and the Blue Crane (*Anthropoides paradisea*) have bustard-like short toes and bills, and like the bustards live in grasslands. Although the morphological features of the *Anthropoides* species and the larger Wattled Crane (*Bugeranus carunculatus*) are dramatically different, studies of their behaviour and DNA indicate a close relationship between them. The Wattled Crane is a much more aquatic species, and

Subdivision of the Gruidae.

[Figure: Hilary Burn]

Cranes usually take off into the wind, from a running start, both of which are means of helping them lift their considerable bulk off the ground. This elegant Florida Sandhill Crane demonstrates the essential features of the crane family: the slender, elongated neck, body and legs, the fairly long bill and toes, the rather plain pale plumage, and the contrasting colour pattern on the head.

[*Grus canadensis pratensis*, Florida, USA. Photo: Tom Vezo]

undoubtedly its large size is an evolutionarily convergent feature that it shares with many of the *Grus* species that also are primarily aquatic.

The ten species of the genus *Grus* can be placed in four natural groups: the Siberian Crane (*Grus leucogeranus*) stands alone; likewise the Sandhill Crane (*Grus canadensis*); the "Group of Three" includes the Sarus Crane (*Grus antigone*), the Brolga (*Grus rubicunda*) and the White-naped Crane (*Grus vipio*); and the "Group of Five" is comprised of the Eurasian Crane (*Grus grus*), the Hooded Crane (*Grus monacha*), the Whooping Crane (*Grus americana*), the Black-necked Crane (*Grus nigricollis*) and the Red-crowned Crane (*Grus japonensis*).

The differences between the Siberian Crane and the other *Grus* species are greater than those that separate the remaining nine species. In fact, there are some morphological and ethological similarities between the Siberian Crane and the Wattled Crane, but DNA evidence suggests that these are due to convergent evolution, and several authors hold that the Siberian Crane should be placed within its own distinct genus, *Sarcogeranus*. The Sandhill Crane has features in common with both the Group of Three and the Group of Five, which suggests that it might be, or might resemble, the common ancestor of the two groups. Although the Sarus Crane and the Brolga are similar morphologically, DNA analysis suggests that the Brolga and White-naped Crane are actually more closely related. Despite the accepted sequence of species, the Eurasian Crane is probably closest to the Whooping Crane, and the Hooded Crane closest to the Black-necked Crane. Within the Group of Five, the Red-crowned Crane is the species most distantly related to the others.

At the infraspecific level, cranes show relatively little diversification, and only four species are normally considered polytypic (only three, if one considers the two crowned cranes conspecific). Again, the subspecies that are recognized do not tend to be particularly well marked, and, while four distinct forms of crowned crane are relatively apparent, with two races accepted for each species, the six generally recognized races of Sandhill Crane differ little in size and colour. Likewise, of the three extant races normally considered valid in the Sarus Crane, two differ primarily in size, while there is insufficient information to determine whether the probably extinct Philippine form was really a distinct race. The Eurasian Crane and the Brolga have at times been divided into two subspecies, but these divisions are not now usually deemed valid.

Morphological Aspects

Cranes are large to very large birds with long necks and legs, streamlined bodies and long, rounded wings. They are readily recognized by their imposing size and graceful proportions. Cranes are among the world's tallest birds, ranging in length from 90 to more than 150 cm. The shortest is the Demoiselle Crane, while the tallest is the Sarus Crane. The Indian race of the Sarus, which can stand as high as 176 cm, is the world's tallest flying bird. The Red-crowned Crane is the heaviest crane, weighing up to 12 kg when fat deposits peak in the autumn. Male and female cranes of all species are identical in their external features, although males are usually somewhat larger than females. Compared to the other tall wading birds, cranes generally have longer legs and hold their necks straighter than the day-herons; have proportionately larger bodies than the egrets; and have longer legs, lighter bodies and smaller bills than the storks.

Distinctive features within the family reflect the varied evolutionary history and ecological niches of the cranes. Crowned cranes have a long, prehensile hallux, or hind toe, that allows them to roost in trees. Demoiselle and Blue Cranes have short, bustard-like toes that are adapted for rapid running in their grassland habitats. The relatively short bills of these cranes allow them to forage more efficiently for seeds, insects and other food items in upland habitats. All the other cranes display adaptations to more aquatic conditions: elongated necks and bills, long bare legs and broader feet. The Siberian Crane, the most aquatic of all cranes, has the longest bill and toes, adaptations for probing and walking in mud. The Brolga, which uses salt-marshes and other saline wetlands more extensively than the other species, has specialized salt glands near the eyes, through which it is able to secrete concentrated salts.

The length and positioning of the trachea are critical features of crane anatomy, and shape the distinctive voices of the various species. The two Balearicinae cranes have shorter tracheas that are, at most, impressed only slightly against the sternum, whereas in Gruinae cranes the trachea penetrates the

The Sandhill Crane is the most abundant of the 15 crane species. Its population of over 500,000 individuals is equivalent to those of all the other crane species put together. It also has the most races, six, the northern ones migrating considerable distances through North America. The dark pigment in the primary feathers serves to strengthen them structurally, so aiding long distance flight in migration. Cranes use thermal soaring when they can, but most flight is muscle-powered, with the birds often travelling in V-formation.

[*Grus canadensis*, Bosque del Apache, New Mexico, USA. Photo: Günter Ziesler]

sternum to varying degrees. On the sternum of the Siberian and Wattled Cranes the trachea makes a slight indentation that is twice as deep as that found in the *Anthropoides* cranes. With the exception of the Siberian Crane, the trachea of all *Grus* species actually coils on the vertical plane within the sternum. In the Brolga and the Sandhill and Sarus Cranes, the coiled trachea fills most of the anterior half of the sternum, while in the White-naped, Eurasian, Hooded, Whooping, Black-necked and Red-crowned Cranes the trachea penetrates the entire sternum. The bony rings of the trachea fuse with the sternum to create thin plates, and when the cranes vocalize, the plates vibrate. This produces the cranes' amplified calls, which can carry several kilometres (see Voice).

The varied features on the heads of the fifteen species are distinctive and diagnostic. Crowned cranes have elaborate tawny crests, bare cheeks and a gular wattle; unlike any of the typical cranes, mated crowned cranes preen one another's head plumage. Demoiselle and Blue Cranes have completely feathered heads, and during display they elongate the plumes on the sides of the head. This show is especially pronounced in the Blue Crane, and gives this species its unusual "cobra-like" appearance. The Wattled Crane is similarly able to raise the feathers on the sides of its head. The Wattled and Siberian Cranes have bare red skin on the front of the face that extends down the upper mandible to the nares, and in the Wattled Crane continues further down the front of the two fleshy dewlaps that hang from its cheeks. The Siberian Crane can expand the dorsal portion of its mask backward when displaying, whereas the Wattled Crane can elongate its wattles downwards. The White-naped Crane has a red comb, which in this species covers the face to a point behind the ear. In the Brolga the red skin surrounds the back of the head, while in the Sarus Crane it covers the sides and back of the head and continues several centimetres down the neck. In sharp contrast, the red comb in the remaining species is on the top of the head and expands down the back of the head only during display.

The cranes that dwell in vast open wetlands, where they are generally able to avoid undue pressure from terrestrial predators, are either entirely white, as in the Siberian, Whooping and Red-crowned, or partially white, as in the White-naped and Wattled, and they are generally larger birds. Their size and bright white plumage makes them conspicuous to conspecifics, and presumably facilitates defence of the breeding territory. The cranes that nest in smaller or forested wetlands are generally smaller and coloured various shades of grey. Their size and colour may help them to keep a low profile on their nests. At the onset of the breeding season, Sandhill and Eurasian Cranes "paint" their feathers with mud, staining them russet brown, which makes them much more difficult to see on their nests than unpainted cranes. At the onset of its breeding period, the Siberian Crane paints dark mud on the base of its neck, but this behaviour is part of the species' sexual display rather than a camouflaging exercise.

Juvenile Demoiselle, Blue, and Wattled Cranes and Brolgas are, for reasons unknown, predominantly grey at the time of fledging. Juveniles of all the other species are russet brown, providing them with cryptic coloration as a defence against predation. This is of particular importance to young Siberian, Whooping and Red-crowned Cranes, which are destined to be primarily white as adults. During the second year of growth, adult plumage gradually replaces the juvenile plumage, and by the end of their second year many juvenile cranes are difficult to distinguish from adults.

Cranes have ten functional primary feathers, and in most species a vestigial eleventh, and 18-25 secondaries. With the exception of the Red-crowned Crane, which has white primary flight-feathers, all species have black or dark grey primaries, including the mostly white Siberian and Whooping Cranes. The dark pigment apparently strengthens the feathers structurally, thereby improving their effectiveness on long migrations. Red-crowned Cranes may once have been predominantly non-migratory, as they are today in northern Japan, and they could thus "afford" to sacrifice durability for display. The inner secondaries of many species are elongated, and when the wings are folded produce the impression of a prominent "tail" or "bustle". This "tail" is most pronounced in the Blue, Demoiselle, Wattled and White-naped Cranes, while the "bustle" is most conspicuous in the Eurasian, Hooded and Black-necked. In most species, adults moult annually during the post-breeding period. The main flight-feathers are lost at this time, rendering the birds flightless. Moulting patterns, however, vary among and within species. The wing moult in Brolgas, Demoiselle and crowned cranes occurs gradually, so that these species do not actually experience an extended flightless period.

Cranes take flight with a running start, usually into the wind, quickly gaining speed before lifting into the air with a push of the wings. When flap-flying, cranes flick their wings with a distinctive rhythm, pushing deliberately on the downstroke and rising rapidly on the upstroke. This rhythm is especially apparent

when cranes are disturbed or otherwise eager to gain height quickly. Cranes, like storks, flamingos, geese and swans, and unlike the larger herons, fly with their necks stretched straight forward. With their long legs trailing directly behind them along the same axis as their bills, necks and bodies, cranes in flight present an elegant silhouette, resembling perhaps most closely that of the flamingos. When flying in cold weather, birds sometimes pull their legs in against their bodies. When landing, they approach the ground with the head semi-erect, the wings extended and the legs dangling. They descend with the wings and tail spread out and down, and, with a final flapping of the wings, alight in a normal standing stance.

Habitat

Cranes are cosmopolitan in their distribution, occurring from the North American and Asian tundra to Southern North America and the Asian, Australian and African tropics. East Asia, with eight species, has the highest level of species diversity. Five species occur at some point in the year in the Indian Subcontinent. Africa supports four species all year round; resident and wintering populations of a fifth, the Demoiselle; and wintering populations of a sixth, the Eurasian. Why cranes never colonized South America remains a mystery.

Most of the cranes prefer relatively open spaces and require territories with a wide range of visibility. Space and solitude are especially important requirements during the breeding season. Most of the species nest in shallow wetlands, where they meet both their feeding and nest building needs. The crowned cranes roost in trees, nest in wetlands and forage predominantly in grasslands. At sundown, adult crowned cranes may hide their chicks in the wetlands, and then go to roost safely in nearby trees. The *Anthropoides* species usually nest, and almost invariably feed, in expanses of open grassland, but they tend to roost in wetlands. In Central Asia, the Demoiselle Crane will nest in arid grasslands, and even in true deserts, as long as water is available.

The degree to which cranes use and require wetlands varies widely among, and within, species. The Cuban race *nesiotes* of the Sandhill Crane lives in pine and palm savanna, and nests and rears its young on dry ground. Other Sandhill Cranes and the Sarus, Brolga, White-naped, Eurasian and Black-necked Cranes nest in wetlands; however, soon after the chicks hatch they are led to neighbouring uplands to forage, returning to the wetlands to spend the night. Wattled Cranes, in the enormous floodplains of Central Africa, nest when water levels peak during the annual floods, but they remain in the wetlands throughout much of the year. In the montane wetlands of South Africa, Zimbabwe and Ethiopia the same species nests at the end of the dry season on small wetlands bordered by grassland. The large white cranes, the Siberian, Whooping and Red-crowned, remain in wetlands throughout the nesting and rearing periods, as may the Hooded Crane, which nests in isolated larch (*Larix*) swamps.

In the migratory species, family groups join together into flocks at pre-migration staging areas, soon after the chicks fledge. A staging area usually contains safe roosting sites as well as a dependable source of food. The number of cranes using a staging area continues to increase over the days until inclement weather forces the birds to move south and join even larger pre-staging congregations. Then the major portion of the migration flight is initiated, along which there are no traditional staging areas. Most species of migratory cranes remain in large flocks throughout the winter non-breeding period, roosting at night in shallow wetlands and foraging during the day in wetlands and upland areas, including agricultural fields.

Non-migratory cranes also gather in groups during the non-breeding season. They are somewhat opportunistic and nomadic in choosing habitats, moving from area to area in search of food and security. Although the availability of food is always of paramount importance during these times, social needs, such as pairing and the introduction of juveniles to flocks, also contribute to habitat choice and flocking behaviour in the non-migratory cranes.

The Red-crowned Crane, also known as the Japanese or Manchurian Crane, is the heaviest species, with birds weighing up to 12 kg in the autumn when their subcutaneous fat deposits are at their maximum. The larger cranes are wetland specialists: they require shallow wetland areas for both feeding and nesting. These more aquatic species have longer toes and bills, adapting them well for walking in soft, muddy substrates and for probing under water for food.

[*Grus japonensis*. Photo: Orion Service and Trading Co. Inc./ Bruce Coleman]

The smaller crane species tend to be more terrestrial than most of the larger ones. They have shorter toes and are better runners. They have shorter bills too, another adaptation associated with obtaining food in grasslands rather than in wetlands. They tend also to be rather more attractively coloured, with more ornate feathers. The exquisite Blue Crane, South Africa's national bird, has longish plumes on the sides of the head, which can be enlarged to surprising effect during display.

[*Anthropoides paradisea*, Stanford-Napier, South-western Cape, South Africa. Photo: Albert Masó/ VISION]

Cranes generally try to maintain a distance of at least several kilometres between themselves and areas of human activity. If, however, they are not harmed or disturbed, they can quickly become accustomed to the presence of people. Thus, Sarus Cranes in India have adapted to the high human population density in the country, and commonly nest and roost in small village ponds and *jheels*. The recovering populations of Eurasian Cranes in Europe and Sandhill Cranes in North America have in recent decades taken to using smaller, less isolated, and lower quality wetlands that are closer to human settlements. In parts of Kazakhstan and the Ukraine, the Demoiselle Crane has been able to continue breeding in steppes that have been converted to agriculture, as long as farming operations are timed so as to minimize disturbance.

The advent of agriculture has had varying consequences on cranes and their habitats. Drainage of wetlands for agriculture has negatively affected the habitat of most cranes to one degree or another, with the greatest impact on the more wetland dependent species, the Wattled, Siberian, Whooping and Red-crowned Cranes. Other species have adapted to, and even benefited from, agriculture. For some cranes, wetlands bordered by agricultural fields often provide better breeding habitat than pristine regions where wetlands are surrounded by forests. In general, cranes that subsist on gleanings of waste grain in agricultural fields during migration and in their wintering grounds are currently faring better than those species that depend exclusively upon wetlands throughout the year (see Status and Conservation).

General Habits

In general, cranes are isolated on their territories during the breeding season and gregarious during the non-breeding period. Among the migratory species during winter, those that feed primarily on abundant sedge tubers and other aquatic vegetation, such as the Sandhill, White-naped and Siberian Cranes, tend to forage in flocks, while those that feed mainly on animals, for example the Whooping and the Red-crowned, are territorial and forage in family groups.

All cranes are basically diurnal in their habits. During the day they forage, rest and preen, attend to their young during the breeding season, and socialize within flocks in the non-breeding season. At night during the breeding season, most cranes stay on or near their nests, brooding their chicks and standing guard against predators and other sources of disturbance. In the non-breeding season, they roost at night in more or less large flocks at traditional roosting sites.

The non-breeding season pattern of feeding by day and roosting by night is universal. Roosting provides security for the flock and offers juvenile and "single" birds opportunities for pair formation. Crowned cranes roost in trees (see Morphological Aspects), whereas the other species usually roost in shallow water, but occasionally use dry ground, mudflats or sandbars. Within roosting flocks, each crane stands about a "peck distance" apart from its neighbours. At night, cranes rest with the head and neck tucked on or under a shoulder. They stand on one leg, though during the course of a night they may switch from one leg to the other several times. They defecate at regular intervals. One unfamiliar sound or alarm call from a flock member is all that is required for the birds to become alert and ready to fly.

At dawn the cranes awaken, stretch, preen and drink, before beginning the day's activity. They fly off in small groups to an open upland area near the evening's roost, the post-roosting staging area, where they land and continue to preen. Cranes from several roosting sites may join together at the same staging area. From there, initially in small groups but then in larger congregations, they will move on to the day's feeding areas. Perhaps those cranes that located a good feeding spot the previous day will be the first to depart, and will thus lead the others to that area.

Depending on the availability of food, cranes feed for extended periods in the early morning, and then move to loafing areas. In these areas they drink, preen and engage in social displays to facilitate the pairing of unmated birds and to establish a pecking order among families. If temperatures are unusually hot,

the birds may escape the heat by spiralling skyward on rising thermals, eventually disappearing from view. Later in the day they return to feeding or watering areas, where they again forage, before moving to pre-roosting staging areas. Here they may again engage in social displays before flying to the evening's roost, where they remain silent and still unless disturbed.

The behaviour of individual cranes can be divided into those activities that are self-directed and those that are undertaken in response to other cranes and other external stimuli. In addition to such fundamental activities as eating, drinking, sleeping, walking and flying, self-directed activities include preening, bathing, shaking, stretching, ruffling, scratching and feather painting. Behavioural studies of cranes have revealed some 90 more specific behavioural patterns within these categories.

The social behaviour of cranes includes a wide array of visual displays. These ritualized displays serve many intra- and interspecific functions, and are often accompanied by vocal displays (see Voice). Among the thirteen species that have bare red skin in the region of the head, this skin too plays an important role in communication. Cranes can vary the extent of skin displayed by contracting or relaxing the subcutaneous muscles, and can change the intensity of the colour of the skin by engorging it. The colour and exposure of the skin change in response to various stimuli, often in association with other behavioural displays.

When cranes are aggressive, they assume an upright posture with their body feathers sleeked, thighs protruding and head features expanded. They walk in a stilted manner that has been likened to the goose-step of parading soldiers. They will follow this threatening posture with a variety of flaps, ruffles, bows, bouts of false preening, stomps, nasal snorts and growls. If a crane takes to the air in this excited state, it will fly with rigid flaps in narrow arcs, with its feet and neck arched upward.

Cranes also engage in a variety of more circumscribed threat gestures. In the "Crouch Threat", the crane bends its legs, lowers itself to the ground, folds its wings loosely against its body and the ground, and places its head forward with the red patch prominent. In the "Ruffle Threat", the bird raises the feathers of its neck, wings and back, partially opens and lowers its wings, ruffles them alternately, and then lowers its bill to its lower breast or leg in a preening movement, often concluding this sequence with a low growl. In a "Charge", the bird points its neck and head straight down and lifts the feathers along its neck and back, holding this stance for several seconds. In all such threat displays, the patch of red skin appears bright and conspicuous.

A crane that is frightened, for example when confronting a predator, spreads its wings, arches forward as if ready to strike, and approaches the feared animal. A submissive crane, by contrast, lowers its neck, elevates its body feathers, and diminishes the threatening display of its head features by lowering the feathers and decreasing the comb size. In this state of deference, the crane walks loosely and warily.

Of all forms of behaviour exhibited by cranes, none is as spectacular or as well known as their elaborate and enthusiastic dancing. Cranes are not the only birds known to dance; trumpeters and egrets, for example, engage in somewhat similar displays, although not so habitually. All species of crane dance. It is apparently an ancient and complex form of behaviour within the family, and serves a variety of functions. Dancing is undertaken by even very young birds, as a part of their behavioural and physical development. Unpaired subadult birds probably dance more than any other age group, and for these birds, dancing facilitates the processes of socialization and pair formation. In adults, dancing can be a form of displacement activity when they are nervous. Within pairs, it may serve to maintain pair-bonds and synchronize sexual response prior to breeding: new pairs dance during courtship; well established pairs, on the other hand, have less need to synchronize their behaviour or to ward off rivals, and hence dance less often. Cranes do not always dance in response to readily apparent stimuli. Within flocks, it is often a contagious activity that spreads easily among the excited birds.

The pattern and intensity of dancing vary somewhat among the crane species, but the dances of all cranes consist of long, intricate sequences of co-ordinated bows, leaps, runs and short flights. In the course of dancing, cranes pick up in their bills whatever small objects, sticks, moss, grass or feathers, happen to be in the area, randomly tossing them into the air. Dancing tends to be most energetic in the smaller species, such as the Demoiselle and the two crowned cranes. Crowned cranes perhaps dance most distinctively, bobbing their heads up and down prior to bowing, spreading their wings, leaping and flapping their wings, then often landing and circling one another. The sequence

Outside the breeding season, most cranes are gregarious. After roosting in quite large flocks, they spread out a little to feed, and may then gather in loafing areas where they preen, drink, bathe, rest and interact with other conspecifics, as can be seen in this group of Eurasian Cranes. Really large concentrations may be encountered, for example, at pre-migratory staging areas, but also in winter, when hierarchies among families become established, and unmated birds go about the business of attempting to pair up.

[*Grus grus*, Lake Hornborga, Västergötland, Sweden. Photo: Francisco Márquez]

Measuring up to 176 cm, the Sarus Crane is the world's tallest flying bird. It demonstrates its size during some of its displays. The huge spread wings, sometimes spanning almost three metres, combine effectively with the forward arching posture and the pointing bill, and may serve to deter some predators, as well as indicating a degree of ambivalence in the bird itself. The degree of vividness of the red skin on the head of most crane species varies with the bird's motivation, and helps to communicate its intentions to others of its species.

[*Grus antigone antigone*, Keoladeo National Park, Bharatpur, India. Photo: Günter Ziesler]

of courtship dancing in Blue Cranes has been observed to last for as long as four hours. The dance of the Demoiselle Crane has been described as "more ballet-like" than those of the *Grus* species, with fewer, less theatrical, jumps. In the *Grus* cranes, dancing is slightly more deliberate, and is punctuated frequently with high, flapping leaps.

Bathing helps to keep the plumage in good condition, but in order for it to be effective, the bird must ruffle up its feathers and shake itself vigorously in the water. Mutual preening is also indulged in by crowned cranes, reaching those parts that are inaccessible to a bird's own bill. Grey Crowned Cranes forage in grassland and agriculture, nest at wetland edges, and, unlike other cranes, roost in trees. This species is the national bird of Uganda.

Voice

Cranes have evolved elaborate vocal displays to help them communicate with one another. From barely audible contact calls to trumpet-like notes that can carry out across their extensive territories, cranes employ a variety of calls with different meanings. The typical volume and tone likewise varies widely from species to species: the crowned cranes have soft honks; the voices of *Anthropoides* are low and raspy; and those of *Grus* are high-pitched and extremely loud. The Sandhill Crane has a distinctive low-pitched rattle, while the Siberian Crane's voice is noted for its clear, flute-like quality.

The "languages" of the various cranes develop differently, depending on the nature of the adult voice, but in all cases the "vocabulary" begins to emerge early in life. Hatching chicks emit high-pitched peeps that will subsequently persist through the first year of life. Newly-hatched chicks quickly acquire a low, purring contact call to maintain regular contact with their parents and a louder, more insistent stress call to draw their more immediate attention. Within a day or so of hatching, chicks develop a food-begging call, a soft peeping that signals the parents to provide food, and within their first year of life, the young birds also learn the "Flight-intention" and alarm calls.

By the end of a bird's first year, the voice deepens and gains strength and volume. The contact, "Flight-intention", and alarm calls are retained, while additional new ones develop: the "Guard Call" is generally given as an intraspecific threat; the "Location Call" allows a newly mobile bird to gain its bearings, if visual contact is and the "Pre-copulatory Call" begins to be heard at about the age of 24 months. Fully adult cranes augment these calls with an assortment of other specialized vocalizations.

The most penetrating of all the calls in the vocal repertoire of cranes, and among the most spectacular of all avian sounds, are the special duets of mated pairs. The duets, known as "Unison Calls", can last from a few seconds to as long as one minute, and may be repeated regularly through the course of a day; they are most commonly heard prior to the breeding season. Unison calling begins to develop in the second or third year of a bird's life. It serves a variety of important functions in the individual and social lives of cranes. First and foremost, it plays a critical role in the initiation, development and maintenance of pair-bonds.

Grey Crowned Cranes are local residents, and share their marshes with a wide variety of herons, egrets, storks and waterfowl, as well as other cranes on occasion. Feeding ranges are not generally defended, but other species even as large as cattle may be ousted from the proximity of a nest. In this photo an Abdim's Stork (Ciconia abdimii) *is being displaced from a feeding spot, while European White Storks* (Ciconia ciconia) *forage in the background.*

[*Balearica regulorum*. Photo: Ferrero-Labat/ Ardea]

The unison calls of recently formed pairs are typically loosely co-ordinated, in comparison with the highly synchronous calls of well established pairs. Unison calling perhaps helps partners to come into breeding condition at the same time. The call is also used more generally to demarcate territories, to ward off potential intruders and to respond to other threats.

Unison calls vary among the species. During sexual displays, crowned cranes lower their heads to shoulder level, inflate their gular sacs, and emit a long sequence of low booming calls. The unison calls of Gruinae species can be used by researchers to determine the sex of individual cranes: the female usually has the higher-pitched voice. In the case of the Siberian Crane, the pitch of the call is the only outward diagnostic feature that allows one to distinguish males from females. In *Anthropoides* and the Wattled Crane, the male and female assume distinct postures during the unison call: the female Demoiselle Crane calls with her bill pointing upward, while the male calls with the bill held horizontal; male Blue and Wattled Cranes elevate their wings at the conclusion of the unison call. All *Grus* species, except the Siberian Crane, have sexually distinct voices during the unison call, with the female emitting two or three calls for every call produced by the male. Male Sarus, Brolga and White-naped Cranes always raise their wings over their backs and droop their primaries during the unison call. In the Eurasian, Hooded, Whooping, Black-necked and Red-crowned Cranes, the amount of wing-posturing depends on the intensity of the aggression associated with the display.

A Sandhill Crane utters its loud unison call, made usually by pairs of adult birds as duets in synchrony with one another. The female's voice is usually higher-pitched, as is to be expected with a slightly smaller bird. Particularly in the typical cranes (Gruinae), the trachea is considerably elongated and is coiled within the sternum. As a result, cranes are capable of producing a variety of calls which can carry over enormous distances. A. Leopold described an approaching flock of Sandhill Cranes as sounding like first "a tinkling of little bells", then, as they came nearer, the "baying of some sweet-throated hound", and eventually "a pandemonium of trumpets, rattles, croaks and cries".

[*Grus canadensis pratensis*, St Cloud, Florida, USA. Photo: A. & E. Morris/ Windrush]

Food and Feeding

Although some species are more specialized than others, most cranes are generalists and opportunists, feeding on a remarkably wide variety of plant and animal foods. Among cranes that use upland areas, the diet includes seeds, leaves, acorns, nuts, berries, fruits, waste grains, worms, snails, grasshoppers, beetles and other insects, snakes, lizards, rodents and other small mammals, and even small birds. Wetland food items include the roots, bulbs, rhizomes, tubers, sprouts, stems and seeds of submergent and emergent plants, as well as molluscs, aquatic insects, crustaceans, small fish and frogs. Cranes readily shift their feeding strategies on a daily or seasonal basis to take advantage of available food items. For example, Eurasian Cranes wintering in the Iberian Peninsula subsist primarily on cereal grains in the early part of the winter, switch to acorns of the holm oak in mid-winter, and may turn again to germinating cereals and legumes in the late winter.

Cranes are catholic, flexible and busy feeders. A wide diversity of animal and plant food is consumed as available. Animal food includes amphibians, fish, molluscs, crustaceans and other aquatic invertebrates when foraging in wetlands, and rodents, reptiles, worms, snails and insects from grasslands. Plant matter include roots and tubers, leaves and stems, and a range of seeds, berries, nuts and fruits. The long, powerful bill of the Brolga is particularly suited to digging for submerged foods in wetland mud. Crops grown by humans comprise a food resource sometimes abundantly available and sometimes, therefore, heavily used. Cranes may spend half to three quarters of their daylight hours feeding.

[*Grus rubicunda*, Australia. Photo: Harald Lange/ Bruce Coleman]

The anatomy of cranes reveals much about their feeding preferences. Those species with shorter bills usually feed in the dry uplands, while those with longer bills usually feed in wetlands. Crowned cranes stamp the ground to scare up insects, which they then grasp in their short bills. These cranes, together with the two *Anthropoides* species, and the Sandhill, Eurasian, Hooded and Black-necked Cranes, also use their shorter bills for grazing in a goose-like manner. The taller cranes with the largest and longest bills, the Wattled, Siberian, Sarus, Brolga and White-naped, are diggers, and use their powerful mandibles to excavate tubers and roots from the muddy soils of wetlands. The long-billed Whooping and Red-crowned Cranes use their bills to probe gently in the bottom of shallow wetlands for mudfish and crustaceans.

The foraging behaviour of cranes reflects their varied strategies, niches and food items. The diggers usually stay in the same area for extended periods of time, excavating holes that are continually enlarged to expose the tubers that proliferate in certain types of wetland soil. Unlike herons, which stand motionless and wait for the moment to strike at prey, hunting cranes walk slowly through the water searching and probing for prey to grab. The upland feeders usually walk with their heads lowered, hunting and pecking at the ground for insects, seeds and other morsels. The generalist feeders will use different strategies in different circumstances. Sarus Cranes, for example, often dig for tubers and other sub-surface plant materials, but they are effective upland foragers and hunters, and have also been observed stripping grains of rice from their stalks.

Where several crane species occur together, the varied feeding strategies and adaptations tend to minimize the degree of niche overlap. This occurs most noticeably in wintering areas in China, where four species may co-exist in the same area. Thus, at Poyang Lake in Jiangxi Province, Siberian Cranes will feed in the shallow water and on mudflats, White-naped Cranes along the wetland borders, Hooded Cranes in adjacent dry sedge meadows, and White-naped, Hooded and Eurasian Cranes in agricultural fields. When Sarus and Siberian Cranes have occurred together at Keoladeo National Park (Bharatpur) in India, the Siberians have foraged for sedge tubers in deeper waters while the Sarus fed on a broader variety of plants and animals in shallower waters. A somewhat analogous situation has been observed in parts of Australia where Brolgas and Sarus Cranes are sympatric, the former tending to restrict themselves to lowland sedge marshes and the latter tending to use drier habitats.

Many species of cranes benefit from the food provided by agricultural fields during either the breeding or the non-breeding phases of their annual cycle, or in some cases both. At one time or another, most cranes forage in cropland and pastures that border wetlands where they nest or roost. At migration stopovers and on wintering grounds, those species that feed on gleanings from agricultural fields usually find an abundance of food, and interfere minimally with farming operations. For example, the great spring congregations of migrating Sandhill Cranes along the Platte River, in the central USA, subsist largely on waste corn gleaned from nearby fields. In some parts of the world, however, crop damage can be a serious problem. This usually occurs during autumn migration or early in winter, when crops are being harvested, or in early spring, when new crops are germinating. During these times, not only are the crops available as food, but the cranes are usually present in large flocks.

For several species, artificial feeding has come to play an important role not only in their annual cycle, but in the very survival and recovery of the species. Some 80% of the world's Hooded Cranes, and about 40% of all White-naped Cranes, are sustained by artificial feeding at Izumi on the Japanese island of Kyushu, a programme that was initiated in 1952. The Hokkaido population of Red-crowned Cranes, about one third of the total world population, has also used feeding stations since 1952. In both cases, artificial feeding has contributed to rapid growth of the small remnant populations. Again, in both cases, the challenge is now to avoid problems associated with overconcentration

of the populations, by dispersing the birds and diversifying their feeding opportunities.

Breeding

Cranes are monogamous. Mated birds stay together throughout the year, and generally remain paired until one bird dies. The age of sexual maturity has been studied in Sandhill and Whooping Cranes. In these species, birds begin to establish pairs in their second or third years, with successful breeding usually occurring in the fourth or fifth year. Pair-bonds may be formed at any time, but many, if not most, pairs fail to breed successfully in their initial attempts. In the Sandhill Crane, the species most extensively studied, it has been shown that pairs that are unsuccessful in their first attempts to breed often dissolve, while successful pairs remain together. A strong pair-bond is maintained as long as the pair successfully reproduces. However, if breeding efforts continually fail, the pair-bond weakens and new mates are eventually taken. Most studies of this species indicate that individuals do not successfully reproduce until they are between four and eight years old. Other species may share this general pattern.

Securing a breeding territory is a prerequisite of reproduction, and in areas where all the available territories are occupied, the young birds may need to wait in order to breed. Cranes of the northern temperate and Arctic zones begin to establish breeding territories soon after their arrival from the wintering grounds, usually between mid-April and mid-June. The breeding seasons of cranes in the tropical and subtropical zones are much more variable, but generally coincide with the local rainy seasons. In the Brolga and the Sarus Crane breeding is closely associated with the distinct monsoons of south-east Asia and Australia. By contrast, Sarus Cranes in India and Wattled Cranes and Grey Crowned Cranes in southern Africa may breed throughout the year, although breeding usually peaks in response to localized conditions. Such variability is evident even within species: Sandhill Cranes breeding in Alaska produce almost all of their eggs in June; the breeding season for Florida Sandhill Cranes extends from December to June, with most eggs produced from February to April.

Breeding density and territory size are highly variable depending on food availability and topography. In India, for example, nesting territories as small as one hectare are sufficient for Sarus Cranes, if the quality of the water and vegetation is adequate and human disturbance is minimized. In Cambodia, on the other hand, Sarus Cranes have larger nesting territories in remote, isolated wetlands. A pair of Red-crowned Cranes may successfully breed on relatively small, isolated wetlands of perhaps 500 hectares, but on a larger wetland with excellent visibility they might defend several thousand hectares. Similarly, Eurasian and Sandhill Cranes have both adapted to human presence by establishing breeding territories in smaller, less natural wetlands. Once territories are established, pairs defend them through unison calls (see Voice), threat postures and attacks. The male is primarily responsible for defence, while the female is more involved in looking after the nest.

New pairs engage in long bouts of dancing before attempting copulation, whereas established pairs copulate with facility and without tension. The copulatory sequence can be initiated by either sex. One member of the pair will elevate its bill, arch slightly forward and emit a low purr-like call. If its mate reciprocates with similar behaviour, one bird, usually the male, will circle the other with exaggerated steps. The female then spreads her wings and the male approaches. With wings flapping, he jumps on her back and crouches down. The female elevates her tail as the male lowers his, and their cloacae meet. The male then jumps forward over his mate's head, and performs threat displays for a few seconds. Both members of the pair then engage in a long sequence of preening. Cranes copulate repeatedly for

A great many social interactions take place within wintering crane groups, as birds strive to impress and select potential mates, support existing mates, and establish or reinforce positions in fluid hierarchies. In migratory species, such as the Eurasian Crane, flock size diminishes once the birds have returned north in the spring to breed, but aggressive encounters are frequent as birds stake out their claims. The prominent "bustles" of this species are typically raised in threat displays, as the challenging bird cranes its neck forward at its opponent; the "bustles" are simply elongated inner secondary feathers.

[*Grus grus*, Lake Hornborga, Västergötland, Sweden. Photo: Sture Traneving]

A male Wattled Crane displays to his mate, with his facial wattles elongated and the bare red skin on his face flushed. During courtship in this species, spreading the huge wings is often the prelude to a short run followed by a jump into the air. As usual in cranes, the male is a little larger than the female. From the colour rings, it is known that the birds were ringed as chicks in 1987. They were not seen again until in 1994 they turned up as a breeding pair, 12 and 217 miles from where they had been raised, the female having dispersed farther and, interestingly, from a population previously thought to be genetically isolated.

[*Bugeranus carunculatus*. Photo: W. R. Tarboton]

several weeks in advance of laying. Copulation usually occurs before sunrise, although it can take place at any time during the daylight hours.

Both sexes participate in nest building. They select a secluded spot within their territory and unison call from that spot. Walking away from the selected spot, they take nesting materials, mainly the stems and leaves of sedges, cat-tails and other wetland plants, and toss them over their shoulders. They return to the nest-site and pull in the material within their reach, before walking slowly away from the nest and throwing more material behind them. As they repeat this sequence many times, large quantities of nesting material accumulate at the low, platform nest, while a "moat" of water forms around the platform.

This nest building behaviour holds for those species that nest within wetlands, but two species, the Blue and Demoiselle Cranes, nest on dry ground. In both species, the eggs are usually laid directly on the ground; the birds may gather together some small stones or vegetation to provide protection and camouflage, but otherwise the nests show little preparation, if any. In some parts of its range, the Sandhill Crane also nests on dry sites. On rare occasions, Grey Crowned Cranes will nest in trees, and they have even been observed using the abandoned nests of other large tree-nesting species.

Cranes almost invariably lay two eggs. The exceptions are the crowned cranes, which regularly lay three and sometimes four eggs, and the Wattled Crane, which usually lays only one. Eggs are ovule-pointed and in most species are heavily pigmented. The species that inhabit tropical and subtropical areas lay either pale bluish eggs, as in the case of the crowned cranes, or white eggs, as in the case of the Sarus and the Brolga. In contrast, those inhabiting the coldest regions, the Siberian, Black-necked and Lesser Sandhill (*G. c. canadensis*) Cranes, produce darker eggs. This tendency for eggs to be pale in warmer climates and dark in colder climates is undoubtedly an adaptation to environmental conditions, allowing the eggs to reflect heat in the former case and absorb heat in the latter. Red-crowned Cranes lay both white and pigmented eggs, an indication that the species may have evolved under warmer climatic conditions.

The extent to which multiple clutching can or does occur in cranes is little known. Repeat clutches have, however, been reported for Grey Crowned, Blue, Wattled, Sandhill, Eurasian, White-naped and Red-crowned Cranes, while Florida Sandhill Cranes (*G. c. pratensis*) have been known to lay third, and in one case even fourth, clutches. Cranes of the northern latitudes, including the Whooping and Siberian Cranes, experience such short growing seasons that even if they did produce second clutches, it would be very difficult for them to fledge the young in time to undertake migration. In captivity, however, females of these and other species have been induced to lay repeatedly through the removal of the eggs, either one at a time or as whole clutches. In this manner, females have regularly produced up to ten or more eggs in a single breeding season.

In the crowned cranes, incubation begins after the clutch is complete, but in the remaining species, incubation begins after the first egg is laid, lasting an average of 28-32 days in most species. The Wattled Crane, at 33-36 days, has the longest incubation period, whereas species breeding in higher latitudes and altitudes tend to have the shortest periods, of under 30 days. The female usually incubates at night, but during the day the sexes exchange incubation duties several times. Once relieved, the off-duty member of the pair normally flies to a favourite feeding area far from the nest.

In accordance with the respective patterns of incubation, crowned crane chicks hatch synchronously, whereas those of Gruinae do so asynchronously. Wattled and Siberian Cranes have been observed to leave the nest after only the first egg has hatched, and typically only a single chick is raised in these species. In other species, the parents frequently rear two chicks, but one of these soon becomes dominant, and, if food is scarce, the weaker chick often dies.

The chicks of most crane species are predominantly brown. The exceptions are the Demoiselle and Blue Cranes and the Brolga, which all have silvery grey chicks. The egg tooth drops off within a few days, and the initial coat of down is replaced by a second down, which, in turn, is replaced by feathers. The rate of chick growth is astonishing, especially in chicks of the northernmost species. The legs grow rapidly during the first six weeks, followed by more rapid development of the wings.

Crane parents begin to feed their chicks almost immediately after hatching occurs, and both parents contribute to the feeding of young. The adults carry small food items to the chicks and either present the food directly to them by holding it at the tip of

Cranes are famous for their dancing, which is performed by all species. Some other bird groups dance too, but none do so as extensively, nor, simply because of their smaller size, as beautifully to human eyes. Dancing in cranes has a number of separate components in different combinations. There are elements of jerky bouncing, of graceful leaping up in the air, and of wild running with wings outstretched. Bowing, with bent legs and raised wings, is frequent, and is often followed by a jump. Stick-tossing is often incorporated, the bird seizing a piece of stick or vegetation and tossing it up in the air as the bill is flung upwards and opened. Dancing is most frequent in unpaired, young adult birds, but is by no means confined to them. Indeed, even chicks less than two days old have been seen to dance. Dancing may strengthen the pair-bond or helps to synchronize or stimulate reproductive condition, and it may, of course, have different functions at different ages. Thus it may be largely exercise and play for chicks but communicatory in adults, perhaps particulary in stifling aggression. Established breeding pairs do not dance much: their aggression towards one another is probably slight, and their breeding synchronization already good. Dancing can also be a displacement activity in situations of anxiety. Whatever its motivation, it is a delight to observe.

Gregarious out of the breeding season, pairs of cranes separate from others to reproduce. Grey Crowned Cranes will sometimes display within the flock, when the activity of one pair can act as a stimulus to other pairs to follow suit, and up to 60 have been observed displaying simultaneously. All crane species are monogamous. They apparently remain paired for life as long as they breed successfully, but failure may precipitate a change of mate.

[*Balearica regulorum*. Photo: Günter Ziesler]

the bill or by dropping it before them. The chicks eventually begin to follow their parents to nearby food sources, although in some cases adults will continue to bring food until the chicks are several months old. Demoiselle Crane are especially noted for the high degree of mobility that young birds quickly exhibit.

Adults care for their chicks continuously through the pre-fledging period. The length of the fledging period varies widely. It is shortest in those species that inhabit upland areas, such as the Grey Crowned, Black Crowned, Demoiselle and Blue, and those that nest in the high Arctic, namely the Siberian and the Lesser Sandhill. In general, chicks of these species fledge at 50-90 days, and the Demoiselle Crane has the shortest average fledging period, usually 55-60 days. The species that inhabit permanent wetlands in warmer climates, the Wattled and Sarus Cranes and the Brolga, have the longest fledging periods, usually lasting 85-100 days, or more; the Wattled Crane has the longest fledging period at about 90-130 days.

The productivity of a given crane population can be measured in several ways, but is most easily determined by counting the number of juveniles in the flocks during the non-breeding period. In general, about 10-15% of a healthy population will consist of non-breeding juveniles.

The juvenile cranes remain with their parents throughout the non-breeding period, but at its conclusion they either leave their parents voluntarily or are driven off by the adults, after the family has returned to the breeding territory. Unpaired juvenile birds gather in non-breeding flocks and are often nomadic throughout the breeding period. By the end of their second year, juvenile birds have usually initiated their own attempts to form pair-bonds.

Movements

In terms of their movements, cranes can be divided into two groups: migratory and non-migratory. Non-migratory cranes move relatively short distances between their breeding and non-breeding areas, and also gather in large flocks prior to the onset of the breeding period. Local and seasonal movements of varying lengths are typical of the lower latitude species, the crowned cranes, the Blue, Wattled and Sarus Cranes, and the Brolga of Australia and New Guinea. In most cases, their breeding seasons, and hence their movements, are tied to, and vary with, the duration and intensity of the local rainy seasons. Local and seasonal movements are also characteristic of southern, non-migratory populations of some of the northern migratory species. This may be seen among populations of the Demoiselle Crane in north-

Copulation starts a few weeks before the first egg is laid. It requires good co-ordination between the two birds, the female adopting a solicitation posture with open wings, and the male maintaining his balance by flapping his wings. After a copulation lasting 4-5 seconds, the male dismounts forwards, and both birds ruffle their feathers. Displays often precede and follow copulation. Eurasian Cranes reach sexual maturity at about five years old.

[*Grus grus*, Lake Hornborga, Västergötland, Sweden. Photo: Francisco Márquez]

Both sexes build the nest, pulling at the vegetation nearby, tossing it towards the nest-site, and subsequently collecting it in to form a thick mat. In typical cranes, such as the White-naped Crane, two eggs make up a normal clutch. In captivity this species will readily lay again about ten days later if the clutch is removed, and will do so several times over, thus producing a fair number of eggs over a single season. Crane eggs weigh 130-240 g, and, although the larger species produce eggs that are larger in absolute terms they are relatively smaller in comparison with the weight of the adult bird. The two eggs are laid two or three days apart, incubation beginning with the laying of the first. Both sexes play a part in incubation, changing over several times a day, with the off-duty bird usually away feeding. The bird on the nest rises to adjust the nest or roll the eggs at intervals averaging 30 to 80 minutes. Incubation lasts 30-33 days in White-naped Cranes, and 27-36 days in the Gruidae as a whole. The birds at this nest are in the process of delivering a unison call.

[*Grus vipio*, Zhalong Crane Sanctuary, Heilongkiang, China. Photo: Sture Traneving]

Sarus Cranes, like Brolgas (Grus rubicunda), *lay white eggs, and it has sometimes been remarked that the tropical members of the family show a tendency to lay paler eggs than their higher latitude counterparts. After a period of 31-34 days of incubation, the two Sarus chicks hatch asynchronously, two or three days apart. The chicks are very weak when they hatch, and they remain in the nest for a couple of days; by that stage they can walk quite well and swim very well, and they leave the nest accompanied by the adults. Unlike the sibling young of some bird families, notably birds of prey, the two chicks are not aggressive towards one another. However, the second hatched tends to be subordinate, and may well die if food is not abundant.*

ern Africa and also in Sandhill Cranes in Cuba, Florida and Mississippi.

Such limited and seasonal movements are modest in comparison with the epic migrations of the northern cranes. Some of the migration routes stretch thousands of kilometres, during which the cranes must confront broad deserts, high mountain ranges and other formidable obstacles. This achievement is even more remarkable for the northernmost species, the Siberian and Sandhill Cranes breeding in the Arctic latitudes of Eurasia and North America. In these populations, the young of the year must in one short growing season gain the size, strength and endurance to join their adult companions on the long journey south.

Migratory cranes spend several days or weeks at pre-migration staging areas, building up their fat reserves and integrating into the life of the flock. Then they begin their migration. After feeding for several hours in the early morning, on a clear day with breezes gusting, they start to climb. Flap-flying in wide circles and lifted by thermals, they rise into the sky. After climbing as high as 2000 metres, they stop flapping, extend their wings, assume a V-formation and glide southwards, propelled by gravity and the wind. After losing a certain amount of altitude, they repeat the cycle, again spiralling skyward and gliding south. While flying over land, they follow this pattern throughout the day. However, when forced to fly over water, where they can not rely on thermals to gain height, they flap-fly in V-formation. Young birds fly close to their parents, and during their first migration south learn the migration route. While migrating, cranes call constantly; their voices can often be heard even before the birds are spotted as tiny specks against the blue sky.

Migratory movements have been studied closely in several species. Whooping Cranes, for example, have been shown to migrate as far as 800 km in a single day, although 300 km is more typical. In one study, Sandhill Cranes flew 575 km without stopping, over a period of nine and a half hours. Flight speeds in most estimates average 60-80 km/h.

Several crane migrations stand out as especially impressive. Eurasian Cranes from central Eurasia fly over the Himalayas at altitudes approaching 10,000 metres, while Demoiselle Cranes also negotiate the passes between these highest of all mountains. Other Demoiselles migrate across the wide deserts of the Middle East and northern Africa to wintering grounds in the upper reaches of the Nile Basin. Lesser Sandhill Cranes from eastern Siberia undertake the longest of all crane migrations, moving east across the Bering Sea into North America and continuing south to as far as northern Mexico.

An understanding of crane migratory patterns and behaviour is critically important in assessing the conservation status and needs of the different species. The problems cranes face during migration often constitute the weak links in the chain of conservation actions. Even if the cranes are secure in their breeding and wintering areas, they may be vulnerable to habitat changes at traditional staging and resting areas, and often face other dangers associated with human activity along the migration routes. Historically, for example, collisions with utility lines and accidental shooting have been important mortality factors along the Whooping Crane's narrow migration corridor. For this reason, biologists have in recent years devoted much time and effort to the study of crane migration through ringing, radio telemetry and satellite tracking programmes. Such studies have been especially important in developing recovery and reintroduction plans for the Siberian and Whooping Cranes. Because the knowledge of migration routes is passed along to new generations of cranes by experienced older birds, conservation programmes for these most threatened species must emphasize the maintenance of existing routes and the development of new techniques for teaching migration. Perhaps most significant, the conservation needs of cranes during migration have necessitated extensive co-operation across national boundaries, sometimes among countries otherwise in conflict with one another.

Relationship with Man

Since time immemorial, cranes have evoked strong emotional responses in people. Their size, behaviour, social relations, unique calls, graceful movements and stately appearance have inspired expression through human art, artifacts, mythology and legend in cultures around the world. This appreciation of cranes was first conveyed in prehistoric cave paintings in Africa, Australia and Europe.

In the western tradition, evidence of cranes dates to the ancient Egyptians, whose tombs were adorned with Demoiselle Cranes. The ancient Greeks are known to have domesticated cranes, and according to myth the flight of cranes inspired the god Hermes to invent the Greek alphabet. Throughout the classical period, cranes provided symbolic meaning in allegories and stories. They frequently appear in the literature of the ancient Greeks and Romans, for instance in the works of Homer, Aristotle, Cicero, Pliny and Plutarch. The Latin word for crane, *grues*, is thought to have been an imitation of their call. In later Christian expressions, cranes came to signify watchfulness, steadiness and mutual aid.

In the east, cranes have for millennia occupied a prominent place in religious traditions and mythology. In China, cranes have long symbolized longevity, and often appear in artwork carrying the souls of the departed to heaven after death. Similar spiritual and symbolic associations appear in various forms in many parts of Asia. In China, Korea and Japan, the Red-crowned Crane symbolizes happiness, good luck, long life and marital bliss, and appears regularly in paintings, ceramics and other decorative arts. The Emperor's throne in Beijing's Forbidden City is flanked by statues of cranes. Cranes are featured on bridal kimonos in Japan, and one of Japan's most popular folk tales concerns a crane that transforms itself into a lady.

In the New World, cranes begin to appear in pictographs, petroglyphs and ceramics from what is now the North American South-west after the year AD 900. Modified crane bones also first

Chicks of the Sandhill Crane have been rather thoroughly studied. The adult feeds small pieces of the eggshell to the newly hatched chicks, and subsequently offers them food, either held in the bill or dropped in front of them. Right from the start the chicks grow fast. They may leave the nest when only six hours old, perhaps even swimming at that very early age. Rapid growth and elongation of the legs and bill take place in the first six weeks, and the young are fully feathered by about three months old.

[*Grus canadensis pratensis*, Alachua County, Florida, USA. Photo: Stephen A. Nesbitt]

appear from middens of this era in other parts of North America. Crane clans developed among the Hopis and Zunis in the Southwest, while cranes served as totems for the Ojibwa and other tribal groups. Warriors of the Crow and Cheyenne made small whistles from the wing bones of Sandhill Cranes, and blew upon them in preparing for battle.

Crane-associated dances have been recorded in many parts of the world, including the Mediterranean, China, Siberia and Australia. A "dance of the white cranes" is known from 500 BC in China. Aboriginal Australians named the Brolga after a young woman whose exquisite dancing drew attention from numerous suitors, all of whose proposals of marriage she refused. Among these was an evil magician who, in his rage, transformed her into a crane.

Cranes continue to be used in new symbolic ways around the world. Crowned cranes are the national birds of Nigeria and Uganda, as are Blue Cranes of South Africa. The coins and stamps of many countries have borne cranes. In part, perhaps, because of their beauty in flight, cranes have also been selected as the corporate logos for several commercial airlines. The emergence of the conservation movement, and in particular the near demise of the Whooping Crane, invested cranes with added symbolic value as emblems of civilization's changing relationship with nature. Perhaps the best known, and most poignant, example of the enduring symbolic significance of cranes emerged from the ashes of the Second World War. A young Japanese girl who had lived through the bombing of Hiroshima, but who was fatally stricken during its impact, resolved to fold a thousand paper cranes during her effort to recover. Although she was not able to complete the task, other children soon took up the challenge. Since then, children have annually prepared paper cranes to symbolize the hope for peace.

The human relationship with cranes extends beyond the symbolic. Cranes have occasionally been used as a source of food, although this has rarely been a widespread custom. Historically, crane hunting was a leading factor behind the Eurasian Crane's extirpation from much of Europe, but hunting of cranes is now illegal in most countries where they occur. In areas, however, where hunger is a persistent problem, cranes and other large birds are seen as an excellent source of food, and are still occasionally taken.

Cranes have long been popular birds in private collections and, more recently, in zoos. Records of cranes being kept in captivity by the Chinese nobility date back more than two thousand years. Marco Polo described Kublai Khan's efforts at crane "management" in the thirteenth century. Several of the species had already bred in captivity by the late nineteenth century; all fifteen have now been bred under artificial conditions. In general, most species breed readily in captivity if they are provided with space, privacy and a balanced diet. This facility for captive propagation is now an important conservation tool for the threatened cranes, and many techniques first developed for cranes have subsequently been employed for other threatened species.

The relationship between cranes and people is by no means idyllic. Throughout the world, crane populations have been profoundly affected by development and degradation of their wetland and grassland habitats, and by other, more direct threats (see Status and Conservation).

Status and Conservation

The cranes are among the most severely threatened of all bird families. Seven of the fifteen species are now considered to be threatened; four more may shortly be added in accordance with new classification criteria of the World Conservation Union (IUCN). In addition, several subspecies are also threatened.

The loss and degradation of wetlands and grasslands have been the leading factors behind the decline of cranes around the world. In particular, the drainage and conversion of wetlands to agriculture and other human uses has deprived the birds of extensive portions of their ancestral habitat. Direct exploitation in the form of hunting and trapping, and other anthropogenic threats, including poisoning and disturbance, have also taken their toll. Populations of crowned, Sarus and Demoiselle Cranes have been affected, in some cases seriously, by the trade in live birds. Those species that face growing pressures on their natural habitats have in some cases turned to using cultivated lands. In most circumstances there is little conflict with farmers' interests, but in some situations, especially when cranes gather in large flocks during migration and in winter, they can inflict serious damage on crops.

The Demoiselle Crane is the smallest species of crane. Most Demoiselle populations are migratory, moving from breeding grounds right across eastern Euorpe and Asia to wintering grounds in North Africa and India. In travelling between these zones they pass over high mountain ranges, at altitudes up to 8000 m, and they also cross arid desert regions. The numbers that assemble for such journeys can be rather impressive, for example, many thousands of birds together.

[*Anthropoides virgo*, Blue Nile, El Kamlin, near Khartoum, Sudan. Photo: Sture Traneving]

In response, cranes have sometimes been intentionally poisoned or shot.

Even as the world's cranes have declined in response to these multiple threats, their cultural value, conspicuousness extraordinary beauty, dramatic migrations and striking behaviour have inspired widespread conservation efforts. The special characteristics of cranes have provided conservationists with unique opportunities for action. Because cranes require large territories and are among the most prominent inhabitants of wetlands, they have served as important symbols for wetland protection, and conservation activities undertaken on their behalf have benefited a wide range of other plant and animal species. Because most crane species have extensive ranges, they have been responsible for stimulating many innovative conservation measures at the international level. These same qualities also make them effective vehicles for conveying lessons in conservation education and environmental awareness. In addition, captive propagation and reintroduction programmes have been undertaken for several species, providing important experience in the combining of *in situ* and *ex situ* conservation methods for other threatened species.

Of the many conservation sagas associated with cranes, none is more dramatic than that of the Whooping Crane. The story of the species' decline, near extinction, and slow recovery is among the best known and most closely followed chapters in the annals of wildlife conservation. The Whooping Crane once frequented the vast prairie wetlands of the north central USA and south central Canada, from present day Chicago to Alberta, a region that has now been largely converted to intensive agricultural production. Beginning in the mid-1800's, European settlers drained the wetlands to build farms and cities and hunted the great white birds for their meat. As Whooping Cranes became scarce, oologists contributed to their decline by collecting eggs from the known nesting areas. Were it not for a tiny remnant flock nesting in the impenetrable muskeg in the remote Northwest Territories of Canada, the species would undoubtedly have become extinct early in the 1900's.

The Whooping Crane and its habitats continued to disappear through the early decades of the twentieth century. The population of migratory Whooping Cranes reached its historical low in 1941, when only 15 birds were counted at the wintering grounds along the Gulf Coast of Texas in the southern USA. A separate, non-migratory flock existed in Louisiana until 1950, when the last lone individual was taken into captivity. The precarious state of the species stimulated intensive efforts, beginning in the late 1930's, to protect the species' wintering grounds and to locate its breeding grounds. Since then, the establishment of refuges, the development of careful monitoring and protection programmes, and education of hunters along the narrow migration route have permitted the number of Whooping Cranes in the traditional flock to increase slowly to its current size of approximately 150 birds. This population, however, remains highly vulnerable to pollution, storms and other potentially catastrophic events in its winter range, and to genetic and demographic problems associated with the small population size.

More intensive steps have also been taken in efforts to speed the recovery of the species. Whooping Cranes lay two eggs but seldom rear two chicks. By removing second eggs and hatching them elsewhere, crane conservationists have been able to establish a captive population of more than 100 birds. If eggs are collected from the captive birds, one pair may produce several clutches in a single breeding season. Using the available "surplus" eggs from the wild and captive flocks, conservationists have attempted to establish new wild populations of Whooping Cranes. Between 1976 and 1989, in the north-western state of Idaho, USA, 289 Whooping Crane eggs were substituted into the nests of wild Greater Sandhill Cranes (*G. c. tabida*). From these eggs, 84 juveniles were fledged, and these birds accompanied their foster-parents along a 1300 km migration route to New Mexico. The Whooping Cranes learned to feed in the niche of the Sandhill, and they learned a new migration route. Unfortunately, however, they also learned to be sexually attracted to Sandhill Cranes through the process of sexual imprinting. As a result, conspecific pairs did not form and the experiment was discontinued in the late 1980's.

Since 1992, an experiment has been under way in central Florida to establish a non-migratory flock of Whooping Cranes using captive-reared birds. Through a technique known as "isolation rearing", chicks are reared in enclosures by people in crane costumes, using hand puppets that resemble the heads and necks of adult cranes. In an adjacent area, adult Whooping Cranes provide "imprint models" for the chicks; the chicks are exposed to

What with their northern breeding grounds, their intermediate staging posts, and their southern wintering areas, Eurasian Cranes are in effect distributed over the whole of Europe and Asia. Spain lies towards the northern limits of the species' wintering zone, and even here, where they escape the worst of a European winter, winter temperatures can drop quite low. One of the major sites for both passage migrants and winterers of this species in Spain is the lake at Gallocanta, where up to 54,000 birds have been seen together.

[*Grus grus*, Laguna de Gallocanta, Aragón, Spain. Photo: Francisco Márquez]

uncostumed people only to condition them to be afraid of humans. Chicks fledged using these methods have then been released on the Kissimmee Prairie in Florida, where scattered wetlands amidst grazed fields provide prime habitat for Florida Sandhill Cranes. As of 1994, this new experimental flock of Whooping Cranes contained approximately 25 birds.

The Florida project was undertaken in part because no artificial technique has yet been developed for teaching cranes to migrate. In the future, Whooping Crane recovery projects will have to overcome this barrier if new migratory populations are to be established. Research to develop such techniques is now under way. One promising method, already used successfully to teach migration to young Canada Geese, is to teach chicks to follow an ultralight aeroplane, which can then be used to guide the fledged young along a new migration route. However, the development of such techniques is highly intensive in terms of time, labour and money, and the focus in recovery programmes for this and other crane species has been on maintaining the existing migratory populations, with their ancestral knowledge of migration routes.

The Red-crowned Crane, with between 1600 and 1900 birds in the wild, is the second rarest crane. It is divided into two allopatric populations: 1100-1400 in a migratory flock on mainland Asia; and 600 in a non-migratory flock in Japan. It is estimated that as much as 90% of the species' wetland breeding habitat in northern China has been destroyed through drainage for agriculture since the 1950's. China views the vast wetlands of former Manchuria as its "great northern food basket", and development of these areas has proceeded on a massive scale. Although several nature reserves have been established to protect the nesting habitat of the Red-crowned Cranes in China, the reserves are seriously affected by changes in hydrology due to development of neighbouring areas. Reintroduction of captive-reared Red-crowned Cranes has taken place on a limited basis at three natural breeding sites: at Kushiro Natural Crane Park in Hokkaido; at the Zhalong Nature Reserve in northern China; and at the Khinganski Reserve in south-eastern Russia. For the species as a whole, however, the critical need is to protect the existing habitats against looming threats.

A large portion of the Red-crowned Crane's mainland population winters along the delta of the River Yangtze, where several hundred metres of "new" land are created each year by the deposit of sediments. However, the world's largest power dam is being planned for construction across the Yangtze at the Three Gorges. If, as a result of the dam, the deposit of sediments downstream is insufficient to overcome erosion losses on the delta, there could be a net annual loss in wetland area, and thus rapid loss of prime winter habitat for as many as 800 Red-crowned Cranes.

Another portion of the mainland population of Red-crowned Cranes breeds in south-eastern Russia and neighbouring areas of China, and winters in the Cholewon Basin of the Korean Demilitarized Zone. If North and South Korea are united, plans to build factories in the Demilitarized Zone, using capital from the South and labour from the North, will likely move forward at a rapid pace, thus destroying the winter habitat of about 300 Red-crowned Cranes. The impact would be all the greater as the Demilitarized Zone also provides important migratory and wintering habitat for the threatened White-naped Crane.

The Red-crowned Cranes in northern Japan are much more secure that those on the mainland. Considered extirpated from Japan for half a century, a tiny population of about 30 birds was discovered in 1924 in south-eastern Hokkaido. They fed along streams and near hot springs throughout the winter, and their failure to migrate turned out to be their salvation. In 1952, however, severe cold covered their feeding areas in ice. Seeing that the cranes might starve, school children in the area scattered corn on the ice. The cranes readily accepted the food and the tradition of feeding cranes thus had its beginning in Japan. Today, three major crane feeding stations and several smaller stations are sponsored by the Japanese government. The number of cranes has increased to approximately 600 and thousands of tourists visit the feeding stations each winter to observe and photograph the Red-crowned Cranes. This concentration of the population, however, brings with it an increased risk of disastrous mortality, should a disease break out during the winter.

Although not the rarest of the cranes, the Siberian Crane is perhaps the most seriously threatened. Unlike Whooping and Red-crowned Cranes, which during the non-breeding period can feed in upland habitats alongside their more abundant cousins, such as Sandhill and Eurasian Cranes, Siberian Cranes are restricted to wetlands, where they dig in the mud for roots and

tubers. Thus, the challenge for Siberian Crane conservationists in southern Asia, a region heavily populated and intensively used by people, is to protect, manage and restore vital wetland habitats. Siberian Cranes are also highly vulnerable to hunting along their migration routes.

There are three major wintering areas for Siberian Cranes: the Caspian lowlands of Iran; the Gangetic Plains of northern India; and the Yangtze lowlands of China. The wintering flock in Iran has been reduced to 9-12 birds, the Indian flock is nearly extinct, and the China flock amounts to perhaps 3000 birds; the breeding grounds of the Iranian flock remains a mystery. The Indian flock has probably been decimated by sport hunters in Afghanistan and Pakistan. The fragile wetlands used by wintering Siberian Cranes, as well as White-naped and other cranes, in China may be seriously affected by the proposed dam across the Yangtze.

Since 1977, when the collecting of "second" eggs from wild Siberian Cranes in eastern Siberia began, captive flocks have been established in Germany, Russia and the USA. These flocks now form a "species bank" to provide insurance, should the wild cranes be lost, and to supplement the dwindling wild populations. Experiments are now under way to use captive-raised birds to bolster the Iranian flock and to revive the Indian population.

The intensive conservation work undertaken for the Whooping, Red-crowned and Siberian Cranes reflects the vulnerability of their small populations and their restricted habitats. Three other threatened species, the Wattled, White-naped and Black-necked Cranes, still exist in the low thousands, while a fourth, the Blue Crane, may still be slightly more numerous, but appears to be declining rapidly. Unless these birds and their habitats are protected, they could easily follow the path of the Whooping Crane and the western flocks of Siberian Cranes.

The Wattled Crane, with a total estimated population of 13,000-15,000 birds, is the rarest of the six crane species occurring in Africa. The population of the species has been declining throughout its range over the last several decades. The Wattled Crane is the most wetland dependent of the African cranes, preferring in particular the expansive riparian marshes of the Zambezi, Okavango and other large river systems in southern Africa. The species has thus suffered disproportionately from the loss of wetlands to development and the disruption of floodplain hydrological cycles due to dam construction and other water development projects. In areas where Wattled Cranes use smaller wetlands, as in the highlands of Ethiopia and South Africa, human disturbance also constitutes an important threat. Since the early 1980's, conservation measures involving Wattled Cranes have expanded throughout the species' range, most extensively in South Africa. These measures include regular counts and surveys in many portions of the range, marking and relocation of utility lines, adoption of habitat conservation practices by private landowners, initiation of a limited release programme, and development of special education schemes. Reserves have also been established to protect several key wetland complexes used by the species in Zambia, Namibia and Botswana.

The population of the White-naped Crane reached its historic low in the years immediately following the Second World War, and has since recovered to a current estimated total of about 5000 birds. However, the species may be declining again in parts of its Russian and Chinese breeding grounds, due largely to agricultural expansion in the Amur Basin and elsewhere in northern China. The preferred habitat of the White-naped Crane, wetland margins and adjacent grassland, are especially attractive for conversion to agriculture. Other threats include the potential development of non-breeding habitat in the Korean Demilitarized Zone, proposed dams along the Amur and Yangtze Rivers, and an elevated risk of disease due to the concentration of wintering cranes at Izumi, in southern Japan. Along with the other east Asian cranes, the White-naped has benefited in recent years from expanded international co-operation, involving legal protection, research, surveys, and establishment of

Young cranes grow remarkably quickly, on the varied food that their parents help them to acquire. Those 57-97% of young that survive are able to fly by the age of about three months. The young birds learn the traditional migration routes from their parents, whom they accompany for almost a year. After their first return journey back to the breeding grounds, they leave their parents' territory, or are expelled from it. Thereafter, in often nomadic non-breeding groups, they will initiate the process of forming their own pair-bonds.

Perhaps the least studied crane, the Black-necked is, nonetheless, known to be in difficulty. In general, the species has been protected in its breeding grounds, both by legislation recently and by Buddhist respect for wildlife for centuries beforehand. In its wintering grounds in areas where fire-arms are more numerous, hunting has become a significant problem. In addition, the wetlands themselves are under threat through drainage, conversion and pollution. The lake of Cao Hai (meaning "Sea of Grass") in China was unsuccessfully drained for agriculture in 1971, but reflooded and made into a Nature Reserve in 1985.

[*Grus nigricollis*, Cao Hai Nature Reserve, China. Photo Sue Earle/ Planet Earth]

protected areas. In particular, the combined efforts of Chinese, Mongolian and Russian conservationists have provided greater protection for the species on its breeding grounds. Captive-raised White-naped Cranes have been released on a limited basis at the Zhalong Nature Reserve in China and the Khinganski Reserve in Russia.

The Black-necked Crane population, estimated at 5600-6000 birds, seems to have stabilized since the 1970's, after many decades of decline. Local Buddhist traditions of respect for wildlife have played an important role in safeguarding the species across much of its breeding range in the Tibet-Qinghai Plateau in China and adjacent parts of Bhutan and India. The major threats to the species occur at the lower altitudes where the birds winter. In these areas, wetlands have been extensively lost or degraded due to drainage, dam construction, river canalization and other environmental modifications. The species' main winter food, surplus barley and wheat, is increasingly scarce due to widespread changes in traditional agricultural practices. At the same time, hunting of Black-necked Cranes has increased, as formerly remote areas have become accessible, and firearms more available. Since the late 1970's, the species has drawn closer attention from conservationists. Key wintering habitats have been protected in reserves in China and Bhutan. Regular surveys have been carried out, especially in the wintering areas, allowing for much more accurate estimates of the population. Field research on the species in general has expanded dramatically in these years. Although these measures have done much to safeguard the species, it remains highly vulnerable to poaching, changing land uses, and habitat deterioration, especially in its wintering grounds.

South Africa's endemic Blue Crane, with a population estimated at 21,000 birds, is still relatively abundant in some portions of its range. However, since 1980 its numbers have declined significantly in many portions of its range due to intentional and unintentional poisoning, as well as the extensive loss of its grassland habitat to afforestation. As a result of these alarming trends, and in the absence of accurate total population estimates, the Blue Crane has been added to the list of globally threatened species. Since the mid-1980's, conservation efforts for this species have increased, and it is to be hoped that the decline can be halted before numbers slump much further.

The Hooded Crane's total population, estimated at about 9400-9600 birds, is probably as high as it has been at any point since the 1920's. The species is somewhat more secure than the other rare endemic cranes of eastern Asia, due mainly to the relative inaccessibility and low development potential of its boggy breeding grounds in south-eastern Russia and northern China. However, even these areas are subject to increased economic pressures. At the same time, wintering habitats in Korea and China are subject to intensified agricultural and commercial development. Some 80% of the total Hooded Crane population winters at Izumi, on the Japanese island of Kyushu. Sustained by artificial feeding, these birds, along with White-naped Cranes, are densely concentrated, and thus highly sus-

Since 1971, the Hooded Crane has been considered a National Monument in South Korea. Its fortunes have fluctuated over the past 70 years. Three quarters of the world population of around 10,000 birds are sustained by artificial winter feeding at Izumi in Japan; with such numbers close together there is clearly a risk of disease. There is an international studbook and captive breeding programme in the world zoo community, containing about 100 birds.

[*Grus monacha*, Fuji, Japan. Photo: T. Shimba/VIREO]

Siberian Cranes provide a fine illustration of varied conservation problems. Their long migrations across international borders, the existence of tiny populations, together with our lack of knowledge about them and the difficulties in enforcing protection measures all combine to produce an uncertain future for the species in the wild. The three wild populations are faring very differently. The western population, which winters in the Caspian lowlands of Iran, is apparently down to only about 10 individuals; where they breed in northern Russia is unknown, but this might soon be revealed by satellite radio tracking. The central population breeds in an apparently secure remote region of northern Russia, and winters at Bharatpur and other Indian wetlands where it is protected. But in between, its staging posts are being disturbed, and the birds are often shot at in Afghanistan and Pakistan. This minute population was believed extinct when none showed up in 1994 or 1995, but four birds reappeared at Bharatpur in 1996. The eastern population was discovered only in the 1980's, wintering at Lake Poyang in China. It numbers about 3000 birds, which breed in Yakutia and Siberian Arctic regions. The huge Three Gorges dam being constructed on the River Yangtze may well damage the wintering wetlands on which the birds depend.

[*Grus leucogeranus*, Keoladeo National Park, Bharatpur, India. Photo: Jean-Paul Ferrero/ Auscape

Grus leucogeranus, Lake Poyang, Jiangxi Province, China. Photo: Sture Traneving]

The Whooping Crane has come pretty well as close to extinction as any species can: no more than 16 individuals remained in the early 1940's. Careful protection and management of both wild and captive populations brought world numbers up to 330 birds by August 1995, including some 150 wild birds, a success story that can be put down, in large part, to the management practice of removing second eggs for incubation and rearing elsewhere. Reintroduction attempts are under way and have met with some success, but one particularly exasperating problem is how to teach the migration routes to the inexperienced birds.

[*Grus americana*, Aransas National Wildlife Refuge, Texas, USA. Photo: Jeff Foott/ Bruce Coleman]

ceptible to outbreaks of disease. Like the White-naped Crane, the Hooded has benefited from international agreements and co-operative conservation actions. At present, however, the long-term security of the species is compromised by the lack of alternative feeding and roosting sites for wintering populations in southern Japan and Korea.

Other crane taxa are of concern from a conservation standpoint. Since the 1970's, the population of Black Crowned Cranes has declined precipitously in much of its range in sub-Saharan West Africa, mainly as a result of heavy human population and development pressures, compounded by long-term drought in the region. The species has been, or is on the verge of being, extirpated from several countries, including Nigeria, where it is the national bird. The population of Grey Crowned Cranes has also declined during this period. These declines may warrant the listing of both species as threatened.

The Indian race of the Sarus Crane, though still common in the north, is declining in numbers, and has been extirpated from much of its historical range. The south-east Asian race of the Sarus has been reduced to perhaps several thousand birds, mainly in Cambodia and Laos. In the meantime, the Philippine population of the Sarus has probably become extinct, without its taxonomic status ever having been clarified (see Systematics). Although the Sandhill Crane is the most abundant of the world's cranes, two of its six recognized races are severely threatened. The population of the Mississippi race *pulla*, augmented by the release of captive-produced birds, numbers approximately 100 birds, while the Cuban race *nesiotes* may amount to some 300 birds at nine widely scattered locations. Several other species have some small isolated populations with conservation needs that are poorly known. These include, for example, populations of Demoiselle Cranes in Morocco and Turkey, Eurasian Cranes in Turkey and Tibet Wattled Cranes in Ethiopia, Blue Cranes in Namibia and Brolgas in New Guinea.

It is not only the currently threatened cranes that are of interest from a conservation perspective. The most abundant and extensively distributed crane species, the Sandhill, Demoiselle and Eurasian, offer other lessons and challenges. All three of these species have experienced declines, sometimes severe, in portions of their historical ranges, while some of their populations have also recovered dramatically. For example, the numbers of Greater Sandhill Cranes in the Great Lakes region of North America and of Eurasian Cranes in parts of Europe have increased steadily in recent decades. At the same time, these species are being forced to adapt to dynamic forces affecting their habitats, distribution and population structure. All three species have been affected to one degree or another by fragmentation of formerly contiguous populations. This has probably occurred, for example, in the south-eastern USA, where resident Sandhill Cranes were more abundant in the past. Similarly, the Demoiselle and Eurasian Crane populations across Eurasia are becoming increasingly concentrated in discrete populations.

In addition to these internal changes in populations, external changes in their habitats make the future of these abundant species unpredictable. Changes in land use in Western Europe will play a key role in determining the future of the Eurasian Crane in that sector of its range. Similarly, the rapid conversion of the Eurasian steppes to cropland is forcing the Demoiselle Crane to adapt to artificial conditions during its breeding period. Changes in hydrology and vegetation along the Platte River in the central USA have affected habitat conditions in an area used by roughly 80% of the total population of Sandhill Cranes during spring migration. Furthermore, these abundant species occasionally cause crop damage, presenting conservationists with different challenges for harmonizing the interests of cranes and people. Large-scale and long-term factors such as these are of vital importance to these species, if they are to avoid the declines that have affected the more threatened members of their family.

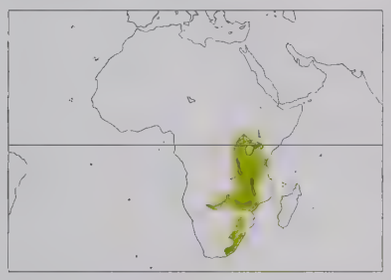
Subfamily BALEARICINAE



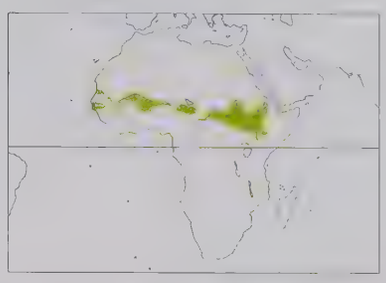
Genus *BALEARICA* Brisson, 1760

1. Grey Crowned Crane

Balearica regulorum

French: Grue royale **Spanish**: Grulla Coronada Cuelligrís
German: Südafrikanischer Kronenkranich
Other common names: Blue-necked/Royal Crane; East African Crowned Crane (*gibbericeps*); South African Crowned Crane (*regulorum*)

Taxonomy. *Anthropoïdes Regulorum* Bennett, 1834, South Africa.
Formerly considered conspecific with *B. pavonina*, with species labelled as *B. pavonina* or sometimes, incorrectly, as *B. regulorum*; but differences revealed by electrophoresis, together with those in vocalizations, bare parts and plumage, advocate recognition of two species constituting a superspecies. Two subspecies recognized.
Subspecies and Distribution.
B. r. gibbericeps Reichenow, 1892 - Uganda and Kenya S to N Zimbabwe and N Mozambique.
B. r. regulorum (Bennett, 1834) - S Angola and N Namibia E through Botswana to Zimbabwe, then S to SE South Africa.



Descriptive notes. 100-110 cm; 3000-4000 g; wingspan 180-200 cm. Iris pale grey to pale blue. Shares distinctive crown of yellow feathers with *B. pavonina*; differs in pale grey neck and larger red throat wattles; white cheek patch has red only at top. Juvenile generally grey, with brown crown and nape, grey to brown body, and brown iris. Race *gibbericeps* has more red in cheek patch than nominate *regulorum*. VOICE: Calls are mellow honks, generally low-pitched.
Habitat. Mixture of wetlands and open grassland or savanna. In E Africa, now found mostly in human-modified habitats, including pastures, cropland, fallow fields, irrigated areas, and ranches. In S Africa, marshes and *vleis* in grassland and savanna, and also agricultural land. Will roost in water, in trees, or on utility line posts; present species and *B. pavonina* are only cranes able to perch in trees.
Food and Feeding. Generalist. Feeds on seed heads (e.g. of *Cyperus* sedges) and fresh tips of grasses; insects, including grasshoppers, crickets, locusts, cutworms and army worms; and other small animals, e.g. frogs, lizards and *Potamon* crabs. Forages in grassland and agricultural land. Takes food with rapid pecks; plants may be uprooted; sometimes stamps feet to disturb insects; associates with grazing herbivores, perhaps benefiting from increased abundance of prey, and also from prey items disturbed.
Breeding. Season variable in response to rains: all year round in E Africa, with peaks during drier periods; in drier portions of S Africa, breeds mainly during rainy periods, c. Oct-Apr, peaking Dec-Feb. Nests in or along margins of wetlands, very rarely in trees; nest consists of uprooted grasses and sedges piled and flattened into circular platform, concealed by surrounding aquatic vegetation. Eggs 1-4; average clutch size 2·5+, largest of any crane; clutch size can vary with altitude. Incubation 28-31 days; chicks umber to brown with buff head; fledging period variable, perhaps 56-100 days. Sexually mature at three (rarely two) years.
Movements. Non-migratory. Variable local and seasonal movements depending on abundance and distribution of food, nest-sites and rainfall. More sedentary in E Africa. Local and seasonal movements both more extensive in drier portions of range, e.g. Namibia and parts of South Africa; in these drier areas, flocking most marked during dry seasons.
Status and Conservation. Not globally threatened. CITES II. Most abundant African crane, with total population estimated at 85,000-95,000 birds; race *gibbericeps* comprises more than 90% of total. Since mid-1980's, population has declined by estimated 10%, as indicated by surveys in Kenya, Uganda and South Africa, with contractions in range reported from South Africa, Namibia and Zambia. This decline reflects widespread threats to habitats resulting from rapid human population growth, drought-related changes in land use, and other factors; loss and deterioration of wetland breeding areas, mainly due to drainage or overgrazing, has been most significant; other habitat problems include heavy pesticide use, declines in the practice of fallowing, high rates of sedimentation, and altered hydrological patterns due to dam construction and groundwater extraction. Live-trapping, trade, egg-collecting and hunting are also of concern. In many areas, local cultural traditions of reverence have provided protection. Research on species remains relatively limited, although field studies have expanded in 1980's and 1990's. Counts and surveys have been conducted intermittently in several range countries. Community-based wetland conservation projects involving the species have been undertaken in Kenya. Non-governmental organizations have been active in conservation projects in several countries, especially Kenya, Uganda and South Africa. Twelve range countries prepared preliminary crane and wetland action plans at 1993 African Crane and Wetland Training Workshop in Botswana. Species breeds readily in captivity. Release and reintroduction programmes have not been necessary.
Bibliography. Allan (1994a), Archibald (1992a), Benson & Benson (1975), Benson *et al.* (1971), Berry (1995), Blossom (1992), Britton, P. L. (1980), Brown, C. J. (1992), Colahan (1990), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Filmer & Holtshausen (1992), Frame (1982, 1985), Gichuki (1993), Gichuki & Gichuki (1991), Ginn *et al.* (1989), Johnson (1992), Johnson & Barnes (1986), Kanyawimba (1996), Katenekwa (1996), Katondo (1996), Konrad (1987), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Mafabi (1991), Mmari (1996), Morris (1987), Mundy (1994), Pinto (1983), Pomeroy (1980a, 1980b, 1987), Rutgers & Norris (1970), Siegfried (1985), Steyn & Ellman-Brown (1974), Steyn & Tredgold (1977), Tarboton (1992a, 1992b), Tarboton, Kemp & Kemp (1987), Tarsnane (1981), Taylor (1992), Urban (1985, 1996), Urban *et al.* (1986), Vernon *et al.* (1992), Walkinshaw (1964).

2. Black Crowned Crane

Balearica pavonina

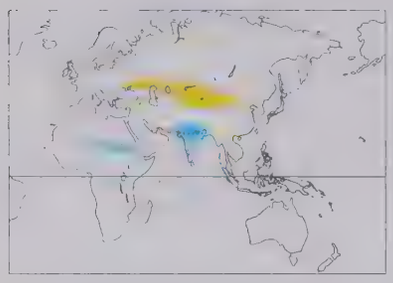
French: Grue couronnée **German**: Kronenkranich **Spanish**: Grulla Coronada Cuellinegra
Other common names: Dark Crowned Crane; West African Crowned Crane (*pavonina*); Sudan Crowned Crane (*ceciliae*)

Taxonomy. *Ardea pavonina* Linnaeus, 1758, Cape Verde, Senegal.
Formerly considered conspecific with *B. regulorum*, with species labelled as *B. pavonina* or sometimes, incorrectly, as *B. regulorum*; but differences revealed by electrophoresis, together with those in vocalizations, bare parts and plumage, advocate recognition of two species constituting a superspecies. Two subspecies recognized.
Subspecies and Distribution.
B. p. pavonina (Linnaeus, 1758) - scattered populations in sub-Saharan W Africa from Senegambia to L Chad.
B. p. ceciliae Mitchell, 1904 - sub-Saharan Africa from Chad to Sudan, Ethiopia and Kenya, especially in basin of upper R Nile.

Descriptive notes. 100-105 cm; 3000-4000 g; wingspan 180-200 cm. Iris pale grey to pale blue. Distinguished from *B. regulorum* by darker neck, small wattles, and red in lower part of cheek patch. Juvenile generally grey, with brown crown and nape, grey to brown body, and brown iris. Race *ceciliae* has red extending somewhat more than half way up cheek patch (only up to about half way in nominate *pavonina*). VOICE: Calls are mellow honks, generally low-pitched, with some differences from those of *B. regulorum*..
Habitat. Mixture of shallow wetlands and grassland. In W Africa, affects flooded lowlands, riverbanks, rice fields and wet cropland, and upland fields. In E Africa, found in extensive marshes, wet meadows, and in margins of ponds, lakes and rivers. Will nest and forage in uplands, but always close to wetlands.
Food and Feeding. Generalist. Feeds on insects, including grasshoppers and flies; other invertebrates, including molluscs, millipedes and crustaceans; fish, amphibians and reptiles; and seed heads and tips of grasses, and also crops, e.g. millet, corn, rice. Normally pecks food off surface, rarely digs; sometimes stamps feet, probably trying to disturb invertebrate prey; in dry season, frequently forages near herds of domestic livestock, where invertebrates occur in greater abundance.
Breeding. Jul-Oct, but variable in response to rains. Nest is circular platform of grasses and sedges built within or along edge of densely vegetated wetlands. Eggs 2-3; average clutch size c. 2·5, similar to that of *B. regulorum*. Incubation 28-31 days; plumage of chicks undescribed; soon after hatching, chicks forage with parents in nearby uplands; fledging period perhaps 60-100 days. Age of sexual maturity undetermined.
Movements. Non-migratory. Daily and seasonal movements, up to perhaps several dozen kilometres, between feeding and roosting areas. Often flocks in large numbers during dry season, dispersing from large permanent wetlands to breed in smaller temporary wetlands during rainy season.
Status and Conservation. Not globally threatened. CITES II. In past, species was probably more numerous and more evenly distributed. Population of race *ceciliae* estimated at 55,000-60,000 birds and considered relatively stable. Population of race *pavonina*, estimated at 11,500-17,500 birds, has fallen dramatically since 1970's due to drought, human population pressures, and habitat loss; contraction of range of this race has led to near or total extirpation in several countries, including Nigeria (where it is the national bird); not recorded in Sierra Leone since 1930's, when was not uncommon in small groups; has become much less common in Ghana, and is now rare. Habitat loss and degradation continue to be the most serious threats; drought-related declines in wetlands have been compounded by intensive agricultural development and expansion and by large-scale dam, drainage and irrigation projects; although most pressing in W Africa, these factors also affect the species in E of range. Hunting and trade are of concern in some areas. Species protected by law in most range countries. Several surveys undertaken at local level. In 1992, *International Conference on the Black Crowned Crane and Its Wetlands Habitat in West and Central Africa* was held in Nigeria, and a Black Crowned Crane Co-ordinating Centre was established. Several range countries prepared crane and wetland action plans at 1993 African Crane and Wetland Training Workshop. Reintroductions of subspecies *pavonina* currently under consideration; several releases have taken place on an experimental basis.
Bibliography. Akinyemi & Iyoha (1983), Archibald & Pasquier (1987b), Daddy & Ayeni (1996), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Fry (1981, 1987), Garba (1996), Goodman *et al.* (1989), Gore (1990), Grimes (1987), Mackworth-Praed & Grant (1957, 1970), Meduna *et al.* (1988), Mustafa & Durbunde (1992), Newby (1979), Newton (1996a), Parker (1971), Rutgers & Norris (1970), Tréca & Ndiaye (1996), Urban (1981, 1987, 1996), Urban & Gichuki (1991), Urban *et al.* (1986), Walkinshaw (1964, 1966, 1981b).

Subfamily GRUINAE

Genus *ANTHROPOIDES* Vieillot, 1816



3. Demoiselle Crane

Anthropoides virgo

French: Grue demoiselle **German**: Jungfernkranich **Spanish**: Grulla Damisela

Taxonomy. *Ardea Virgo* Linnaeus, 1758, India.
Genus sometimes merged with *Grus*, but usually considered sufficiently distinct. Monotypic.
Distribution. C Eurasia, from Black Sea E to Mongolia and NE China. Winters in Indian Subcontinent and in sub-Saharan Africa from L Chad to Ethiopia. Small, disjunct breeding populations in Turkey and in Atlas Mts, NW Africa.
Descriptive notes. c. 90 cm; 2000-3000 g; wingspan c. 150-170 cm. Smallest crane; male slightly larger than female. Present species and *A. paradisea* are the only cranes with entirely feathered head, and lacking red skin on head. Uniform grey, except for black head and neck, black-tipped secondaries, and distinctive white ear tufts extending from behind eye to upper nape; elongated black plumage of foreneck hangs down below breast. Iris reddish orange. Juvenile generally duller grey with paler head and neck; ear tufts less distinct. VOICE: Calls are low-pitched and raspy.
Habitat. Primarily savanna, steppe and other grassland types, often in close proximity to streams, shallow lakes and other wetlands. Inhabits semi-desert and true deserts where water is available. Occurs up to 3000 m in C Asia. Is adapting to agricultural fields in Kazakhstan and Ukraine. Also uses agricultural

On following pages: 4. Blue Crane (*Anthropoides paradisea*); 5. Wattled Crane (*Bugeranus carunculatus*); 6. Siberian Crane (*Grus leucogeranus*); 7. Sandhill Crane (*Grus canadensis*).

fields in wintering areas in India, roosting in nearby shallow waters and wetlands; affects *Acacia* savanna, grassland and riparian wetlands in African wintering grounds.

Food and Feeding. Mainly seeds (especially of grasses) and other plant materials; also insects, especially beetles (Coleoptera) in summer; worms, lizards and other small vertebrates. Walks slowly while foraging. Large flocks at migration staging areas and in Indian wintering grounds forage in cultivated fields, sometimes causing damage to cereal and legume crops.

Breeding. Spring breeder, mainly Apr-May, but as late as Jun in north. Nest is minimally prepared in open patches of grass, in cultivated areas, or on gravel; pebbles and some plant material may be gathered, but eggs are often laid directly on ground. Usually 2 eggs; incubation 27-29 days; chicks pale brown above, greyish white below; fledging 55-65 days, the shortest period in any crane. May reach sexual maturity by second year.

Movements. Migratory, with possible exception of small population in Turkey; in past, species wintered in Mugan Steppe, SE Azerbaijan. Birds from W Eurasia winter in E sub-Saharan Africa. Birds from C Asia, Mongolia and China winter in Indian Subcontinent. Small population of Atlas Plateau may move to L Chad in winter.

Status and Conservation. Not globally threatened. CITES II. Current population estimated at 200,000-240,000 birds. Generally abundant throughout most of historical range, but during last 100 years species has been extirpated from Iberian Peninsula, Balkan Peninsula, and parts of N Africa and W Eurasia. Steppes of E Eurasia are stronghold of species, although even the large eastern populations have become vulnerable to habitat loss. Declines have been noted in C Asia and Kazakhstan in recent decades due mainly to agricultural development of the steppes. Little known about populations of Turkey and Atlas Plateau; latter may now number only 10-12 individuals. Habitat loss and degradation are principal threats across range, especially in steppe regions, but also along migration routes and in wintering areas. Other threats include human disturbance, especially in India and Sudan; and intensive use of pesticides, e.g. in India, Sudan and Morocco. About 5000 cranes (*G. grus* and *G. leucogeranus* are also affected) are taken by sport hunters annually along migration route in Afghanistan and Pakistan. Shooting and intentional poisoning are problems in some areas where crop damage occurs. Extensive research and conservation efforts undertaken in many portions of range over last 20 years. Information exchanged at several international crane conferences, and at a species-specific meeting in Kazakhstan in 1988. Monitoring and survey programmes established in India, Ukraine and Saudi Arabia. Habitat-related research most advanced in Ukraine and Kazakhstan. Efforts to regulate hunting and provide education in Pakistan started in mid-1980's. Breeds well in captivity; no active reintroduction programmes at present, but releases being considered for areas where species is extinct or exists in critically low numbers.

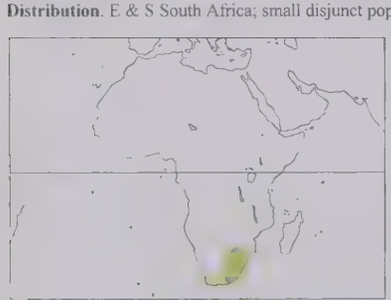
4. **Blue Crane**



Anthropoides paradisea

French: Grue de paradis **German**: Paradieskranich **Spanish**: Grulla del Paraíso
Other common names: Stanley/Paradise Crane

Taxonomy. *Ardea paradisea* Lichtenstein, 1793, inner South Africa.

Genus sometimes merged with *Grus*, but usually considered sufficiently distinct. "Emendation" of species name to *paradiseus* is not justified. Monotypic.

Distribution. E & S South Africa; small disjunct population in Etosha Pan region of Namibia.

Descriptive notes. 110-120 cm; 4900-5300 g; wingspan 180-200 cm; male larger than female. Present species and *A. virgo* are the only cranes with entirely feathered head, and lacking red skin on head. Uniform bluish grey on head, neck and body. Loose feathers of cheek and upper nape give head distinctive "cobra" shape. Elongated secondaries, black-tipped and almost reaching ground. Iris dark brown. Juvenile paler grey; lacks extended secondaries. VOICE: Calls are low-pitched, raspy and broken, similar to those of *A. virgo*.

Habitat. Primarily dry upland natural grassland dominated by grasses and sedges. Also roosts and nests in wetlands. Recent colonizer of agricultural areas, using pastures, cropland and fallow fields.

Food and Feeding. Diet includes seeds of sedges and grasses, roots and tubers; also insects, especially locusts and grasshoppers, and worms, crabs, fish, frogs, reptiles and small mammals; in agricultural areas, feeds on waste cereal grain, e.g. maize and wheat. Some use of artificial foods recorded in livestock feedlots. Forages by searching on ground surface and vegetation; sometimes digs for food.

Breeding. Mainly Oct-Dec, but on occasion as late as Mar. Nests primarily in grasslands near water, but also in pastures, crop fields, and marshes; nest platform of small stones and wetland vegetation, but often only minimally prepared; eggs laid in grass or on bare ground. Usually 2 eggs; incubation 30-33 days; chicks generally grey with yellowish head and neck, and white breast and lower throat; fledging period variable, with earliest at c. 85 days. Sexually mature at 3-5 years.

Movements. Non-migratory. Local seasonal movements within South Africa. Vagrant in other parts of S Africa, e.g. Botswana, Lesotho, Swaziland, Zimbabwe.

Status and Conservation. VULNERABLE. CITES II. Population recently estimated at 21,000 birds, but reliable range-wide data lacking. Population in SW Cape Province expanding into agricultural areas, while Namibian population appears steady at c. 80 individuals. Overall population, however, has fallen since 1980, with dramatic declines in many areas; population declines of as much as 90% confirmed in Transvaal, Natal and E Cape Province during 1980's, with similar losses likely in Orange Free State. Main factors in decline have been intentional and unintentional poisoning in farming regions and commercial afforestation of South Africa's grasslands. Other threats include intensive livestock grazing, disturbance, urban and agricultural expansion, and collisions with utility lines and fences. Some young birds illegally taken into captivity. Expanded conservation efforts since mid-1980's, including adoption of stricter legal protection, local and national surveys in South Africa, increasing research on species' biology and ecology, habitat protection and management programmes (especially on private land), establishment of local conservation organizations, and development of educational facilities, programmes and publications.

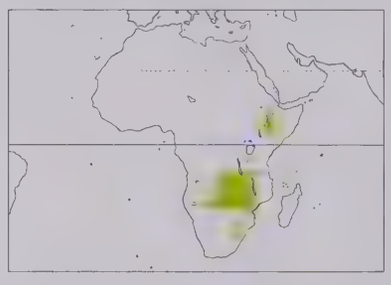
Genus *BUGERANUS* Gloger, 1842

5. **Wattled Crane**



Bugeranus carunculatus

French: Grue caronculée **German**: Klunkerkranich **Spanish**: Grulla Carunculada
Other common names: Great African Wattled Crane

Taxonomy. *Ardea carunculata* Gmelin, 1789, Cape of Good Hope.

Previously placed in *Grus* by some researchers, although recent ethological and DNA analysis suggests a closer relationship with *Anthropoides* species; both genera sometimes merged with *Grus*, but usually considered sufficiently distinct. Species has been considered congeneric with *Grus leucogeranus* alone, on basis of some morphological and behavioural similarities. Three main populations, but not considered subspecifically distinct. Monotypic.

Distribution. Ethiopia; Zaire, Zambia and Tanzania to Botswana and Mozambique, with outlying populations in Angola, Namibia and South Africa.

Descriptive notes. c. 175 cm; male 8300-8500 g, female 7100-7900 g; wingspan 230-260 cm. Only African crane with white neck; prominent wattles, mostly white with some red skin. As in *A. paradisea*, elongated inner secondaries extend beyond tail almost to ground. Iris orange to red. Juvenile similar to adult, but with shorter tertials and white crown; lacks red patch of facial skin, and wattles not fully developed.. VOICE: High-pitched piercing calls.

Habitat. Most dependent on wetlands of all African cranes. Large wetlands in riparian floodplains, primarily in Zambezi and Okavango Basins. Smaller permanent and seasonal wetlands in highlands of Ethiopia and South Africa. Specialized breeder in shallow sedge-dominated wetlands. Tends to breed above 2000 m, but normally occurs below 1000 m outside breeding season.

Food and Feeding. Primarily tubers and rhizomes of aquatic vegetation, e.g. *Cyperus*, *Eleocharis dulcis* and water-lilies (*Nymphaea*); also insects (Orthoptera, Coleoptera), snails, frogs and other small vertebrates. Typically uses large bill for digging in wetland and soft upland soils. Will forage in agricultural fields when convenient.

Breeding. Season highly variable, depending on water levels: mainly Jul-Aug in Ethiopia; mainly Apr-Oct in S population. Nests typically in wet grasslands and sedge marshes when water levels provide new vegetation growth and open water around nests; nest usually consists of wetland vegetation piled into a mound and surrounded by "moat" of open water 4 m wide; nest is 120-180 cm in diameter, and situated in water up to c. 60 cm deep. Usually 1 egg, sometimes 2; average clutch size 1·4, smallest of any crane. Incubation 33-36 days, longest of any crane; chicks pale to dark brown, with slightly developed wattles; fledging period 90-130 days. Sexually mature at 3-4 years.

Movements. Non-migratory, but irregularly nomadic in response to water availability. Movements poorly studied. Birds in permanent wetlands generally less mobile than those inhabiting seasonal riparian and upland wetlands.

Status and Conservation. VULNERABLE. CITES II. Total estimated population of 13,000-15,000 birds remained constant between mid-1980's and mid-1990's, but this was mainly due to more thorough surveying: during this period, core population in Zambia fell from estimated 11,000 to 7000-8000 birds; discovery of 2500 birds in Mozambique in early 1990's partially compensated for this loss. N population of Ethiopia, estimated in 100's, apparently remained constant during that same period. The most important threats to species are loss and degradation of wetlands due to intensified agriculture, indiscriminate use of wetland resources, and dam construction and subsequent changes in flooding regimes. Other threats include human disturbance, poisoning, and collisions with utility lines. Conservation measures have been undertaken most extensively in South Africa, but are expanding in other range countries. Species strictly protected in most countries. Protected areas have been established in several of the key wetlands, especially in Zambia, Namibia and Botswana. Field surveys and studies of the species have increased greatly since early 1980's. In South Africa, efforts have been made to encourage private landowners to protect and manage habitat, to mark and relocate utility lines, and to develop education and awareness programmes. Species is somewhat more difficult to breed in captivity than other cranes. Habitat conservation needs have taken priority over release or reintroduction programmes.

Allan (1994a), Banda (1996), Beall (1996), Beilfuss (1995), Benson & Benson (1975), Bousfield (1986), Brooke (1984a), Brooke & Vernon (1988), Colahan (1990), Collar & Andrew (1988), Collar & Stuart (1985), Collar *et al.* (1994), Conway & Hamer (1977), Cooper (1969), Dodman (1996), Douthwaite (1974), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Dyer (1992), Field (1978), Filmer & Holtshausen (1992), Ginn *et al.* (1989), Goodman (1992), Herholdt & Bernitz (1995), Hines (1996), Johnson & Barnes (1985, 1986, 1991), Johnson & Sinclair (1983), Kamweneshe (1996), Konrad (1981), Macartney (1968), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Malambo & Chabwela (1992), Mangubuli (1996), Masterson (1986), Nhlane (1993), Pinto (1983), Rutgers & Norris (1970), Tarboton (1984, 1995), Tarboton & Johnson (1992), Tarboton, Barnes & Johnson (1987), Tarboton, Kemp & Kemp (1987), Urban (1996), Urban & Walkinshaw (1967), Urban *et al.* (1986), Vernon & Boshoff (1986), Walkinshaw (1965), Wennrich (1985), West (1963, 1976, 1982), Williams, J. (1987), Woolcock (1983a, 1983b, 1984a, 1984b).

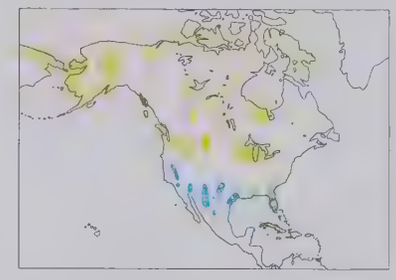
Genus *GRUS* Pallas, 1766

6. Siberian Crane

Grus leucogeranus

French: Grue de Sibérie **German**: Schneekranich **Spanish**: Grulla Siberiana
Other common names: Great/Siberian/Asiatic White Crane

Taxonomy. *Grus Leucogeranus* Pallas, 1773, central Siberia along Ischim, Irtysh and Ob' Rivers.
Formerly considered congeneric with *Bugeranus carunculatus*, based on morphological and behavioural similarities. Alternatively proposed to merit separate monospecific genus, *Sarcogeranus*. Three wintering subpopulations, but no evidence as yet of geographical variation. Monotypic.
Distribution. Arctic W & EC Siberia; possibly also extreme NW Russia. Three wintering areas: middle R Yangtze in China; Keoladeo (Bharatpur) and other wetlands in India; and S Caspian Sea in Iran.



Descriptive notes. 140 cm; 4900-8620 g; wingspan 210-230 cm; male slightly larger than female. Distinguished from other white cranes, *G. americana* and *G. japonensis*, by entirely white cap with dark red mask extending from bill to behind eye. Iris yellow. Juvenile has mask feathered; neck and body plumage buff or cinnamon. VOICE: Calls flute-like and musical, quite different from those of other cranes.
Habitat. Most aquatic member of family, using exclusively wetlands for nesting, feeding and roosting. Breeding habitat in lowland tundra and taiga-tundra transition zone includes tidal flats, bogs, marshes and other wetland depressions with unrestricted visibility. Migration resting areas and stopovers in large, isolated wetlands. In China, winters in shallows and mudflats of seasonal lakes of Yangtze Basin; winter habitats in India and Iran consist of artificial water impoundments and flooded rice fields.
Food and Feeding. Omnivorous. Summer diet is broader, consisting primarily of roots, rhizomes, seeds, sprouts of sedges, and other plant materials, but also insects, fish, rodents and other small animals. On migration and in wintering areas, eats mainly roots, bulbs, tubers (especially of sedges), rhizomes, sprouts, and stems of aquatic plants; aquatic animals consumed if readily available. Generally forages by wading and digging in shallow water, up to 30 cm deep.
Breeding. Spring breeder, with start of laying varying with weather conditions: eggs generally laid from late May to mid-Jun, peaking in first week of Jun. Nest is flat mound of grass and sedge 50-80 cm in diameter, elevated 12-15 cm above water level; surrounding water may be 25-60 cm deep. Usually 2 eggs; incubation 29 days; chicks yellowish to chestnut brown; fledging 70-75 days. High rate of post-hatching mortality, due in part to aggressiveness between chicks, usually resulting in only one fledging successfully. Age of sexual maturity uncertain, but probably 3 years.
Movements. Three wintering populations. Birds from main, "eastern" population migrate between breeding grounds in Yakutia and wintering grounds along middle R Yangtze in SC China; traditional stopovers in E Russia and E China, including wetlands now protected in Xianghai, Momoge and Zhalong Nature Reserves in China. A second "central" population of 4 known birds (Feb 1996) migrates between breeding grounds in W Siberia, probably in lower basin of R Kunovat, and wintering grounds in Rajasthan, NW India; presumed migration route passes through Kazakhstan, Uzbekistan, Turkmenistan, Afghanistan and Pakistan, with traditional stopovers at L Akusat and Nar Zum wetlands in Russia, and Ab-i-Estada in Afghanistan. A third "western" population of c. 10 birds migrates between undetermined breeding grounds in W Siberia, or NW European Russia, and wintering grounds at a single marsh at Fereindoonkenar on S coast of Caspian Sea in N Iran; current information suggests a migration route that follows W coast of Caspian Sea with a traditional stopover point at the Astrakhan Nature Reserve at mouth of R Volga; in past, unrecorded numbers wintered in Mugan Steppe, SE Azerbaijan, but declined for unknown reasons, and was already only very rare migrant by 1940's.
Status and Conservation. ENDANGERED. CITES I. Although probably never common in historical times, species has suffered dramatic contraction of range and decline in numbers since 1800's. Total population was estimated in 100's until 1980's, when Chinese ornithologists discovered wintering flock at L Poyang, near R Yangtze. Most reliable surveys suggest total current population of 2900-3000 birds, most of which belong to E population. Because of peculiar distribution and specialized habitat requirements, species has been and remains more vulnerable to habitat loss and exploitation than most other cranes. In general, the three populations are secure on their remote breeding grounds, but face wide array of threats outside breeding range, including: heavy human demands upon migratory and wintering habitats, even those within protected areas, in China and India; potential hydrological changes in primary wintering area in China as result of planned dam on R Yangtze, at Three Gorges; human disturbance at many stopover points and in wintering areas; ineffective management of existing protected areas; sport hunting of cranes along C population's migration route in Afghanistan and Pakistan; and, for C and W populations, genetic and demographic problems related to their critically small population sizes. Intensive conservation efforts began in early 1970's. Protected areas have been established at several key migration stopover points and wintering areas. Winter censuses are conducted annually in all known wintering areas. Field research on species has expanded significantly, and information exchanged at regular international meetings. *Memorandum of Understanding Concerning Conservation Measures for the Siberian Crane* recently prepared and signed by most range countries. In 1992, a population and habitat viability assessment was prepared for species. A captive propagation and reintroduction programme initiated in mid-1970's, and captive-raised birds now being released in effort to bolster C and W populations.

7. Sandhill Crane

Grus canadensis

French: Grue du Canada **German**: Kanadakranich **Spanish**: Grulla Canadiense
Other common names: Little Brown/Canadian Crane; Lesser Sandhill Crane (*canadensis*); Canadian Sandhill Crane (*rowani*); Greater Sandhill Crane (*tabida*); Mississippi Sandhill Crane (*pulla*); Florida Sandhill Crane (*pratensis*); Cuban Sandhill Crane (*nesiotes*)

Taxonomy. *Ardea canadensis* Linnaeus, 1758, Hudson Bay, Canada.
Races *canadensis*, *rowani* and *tabida* probably form cline, with gradual changes in morphology, and random pairing among them; these three intergrade along limits of their ranges. Race *tabida* subdivided into five populations; morphological differences among these populations have been noted, but not analysed in terms of taxonomic importance. Subspecies status of *pulla* has not been definitively established; first described in 1972, based mainly on colour differences with *pratensis*; remnant population in Mississippi was probably more widespread in past, and likely to have intergraded with *pratensis*. Six subspecies normally recognized.
Subspecies and Distribution.
G. c. canadensis (Linnaeus, 1758) - Arctic and subarctic North America and E Siberia; winters in SW USA and NC Mexico.
G. c. rowani Walkinshaw, 1965 - subarctic Canada, from British Columbia to N Ontario; winters on Texas coast of Gulf of Mexico, and in SW USA and NC Mexico.
G. c. tabida (J. L. Peters, 1925) - five breeding populations in mid-continental North America from Vancouver I to Great Lakes region; winters in NC Mexico and S USA, from California to Georgia and Florida.
G. c. pulla Aldrich, 1972 - Mississippi, USA.
G. c. pratensis (F. A. A. Meyer, 1794) - Georgia and Florida, USA.
G. c. nesiotes Bangs & Zappey, 1905 - Cuba and I of Pines.

Descriptive notes. Up to 120 cm; average weight ranges from male 3750 g and female 3350 g in *canadensis*, to male 5390 g and female 4300 g in *tabida*; wingspan 160-210 cm. Grey body; only member of *Grus* with fully-feathered grey neck and head, apart from bare red forecrown; iris orange. Juvenile similar to adult, but wing-coverts, nape and back reddish brown toward edges. Races generally very similar, differing more in size than in coloration; plumage of migratory races often stained brown with mud in summer. VOICE: Calls are loud, low-pitched and rattling.
Habitat. Mainly in open wetlands, shallow marshes and wet meadows. During breeding season, the three migratory races occur in wide variety of northern wetland communities, including muskeg, sphagnum bogs, fens, sedge meadows, cat-tail marshes, stream banks and lake shores. Habitats along migration routes tend to be large, open marshes near agricultural areas. Especially important are submerged sandbars and shallows of wide rivers, especially Platte R (C USA). Wintering habitats include coastal and riparian wetlands, wet meadows, playa lakes, oak savannas, and agricultural fields and pastures. Florida and Mississippi races occur in matrix of shallow wetlands, wet prairie, pastures, and savanna. Cuban race uses relatively dry grassland in uplands, also patches of woodland adjacent to marshes (hammocks), and pine and palmetto savannas.
Food and Feeding. Omnivorous. Diet highly varied depending on season and location; common items include tubers, corms, berries, acorns, waste corn and other grains, insects, earthworms, snails and rodents; waste grain in agricultural fields is significant when available. Feeds by probing and gleaning on land and in shallow wetlands.
Breeding. Generally in spring, but more variable in S races: Apr-Jun in N populations; Mar-Apr in Mississippi; mainly Jan-Mar in Florida and Cuba. Nest is usually slight mound of dried and green wetland plants, varying in size depending on available materials; in tundra zone and in Florida and Cuba, nests on drier sites. Usually 2 eggs; incubation 29-32 days; chicks brown above, pale tawny below, with white throat; fledging period varies with race, 50-90 days. Sexually mature at 2-3 years.
Movements. S races essentially sedentary. N races migrate along several major migration routes: W populations follow routes along Pacific coast, E of Cascade Range, through Intermountain West, and through C Rocky Mts to wintering areas in California, Arizona, New Mexico and N Mexico; C populations follow routes across Great Plains to wintering areas in New Mexico and Texas; E populations follow routes from Great Lakes region to C Florida.
Status and Conservation. Not globally threatened. CITES II. Total population estimated at 500,000 birds; the most abundant of all cranes. Races *pulla* and *nesiotes* endangered, numbering 120 and 300 respectively. Hunting, agricultural expansion, drainage of wetlands and other habitat changes in 18th and 19th centuries resulted in extirpation from many parts of breeding range, as well as declines in non-migratory populations. Since 1930's, populations in Great Lakes and Rocky Mts regions have recovered dramatically. Loss and degradation of wetland habitats pose most significant threat to species as a whole. Critical spring staging areas along Platte R in C USA have diminished as result of changes in river's flow, and further threatened by water withdrawals and dam construction projects. W populations subject to regulated hunting. Key habitats are protected in reserves in many areas, including Cuba, Florida, Georgia, Mississippi and New Mexico. Restoration of wetlands has been important factor in recovery of Great Lakes population. Surveys are conducted regularly in most portions of range, and field studies of species have been most extensive for any crane. Recovery plan for race *pulla* has been in effect since 1976; under this plan, since 1981 captive-raised birds have been released to supplement wild population; in 1992, a population and habitat viability assessment (PHVA) was prepared for race *pulla*. In 1994, first comprehensive survey of habitats in Cuba to determine status and needs of population.

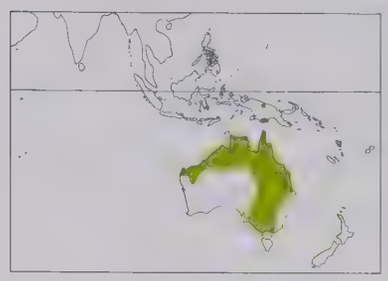
8. Sarus Crane

Grus antigone

French: Grue antigone **German**: Saruskranich **Spanish**: Grulla Sarus
Other common names: Sharpe's Crane (*sharpii*)

Taxonomy. *Ardea Antigone* Linnaeus, 1758, India.
Recently described race *gilliae* sometimes still included within *sharpii*. Possible race *luzonica*, endemic to Philippines, now presumed extinct; possibly synonymous with *gilliae* or *sharpii*, or both. Three extant subspecies normally recognized.
Subspecies and Distribution.
G. a. antigone (Linnaeus, 1758) - N India, Nepal and (formerly?) Bangladesh.
G. a. sharpii Blanford, 1895 - Cambodia and S Laos; winters in Vietnam; status in E India and Myanmar uncertain.
G. a. gilliae Schodde, 1988 - N Australia, mainly in Queensland only scattered populations elsewhere.



Descriptive notes. Up to 176 cm; 6800-12,240 g (*antigone*), 5400-8400 g (*sharpii*), 5200-8400 g (*gilliae*); wingspan 220-280 cm; male larger than female. Tallest of all flying birds; red skin covers head, throat and upper neck, with sparse black feathers on neck; body generally grey; iris orange. Juvenile tinged brown, head and neck feathered. Races differ notably in size, less markedly in plumage: *sharpii* smaller than nominate, *gilliae* smaller still; both lack white collar and tertials of nominate race. VOICE: High-pitched penetrating calls, loudest of any crane.
Habitat. Adapted to human presence in India, using canals, irrigation ditches, village ponds, shallow marshes, *jheels* and cultivated and fallow fields. Breeding habitat in interior wetlands of SE Asia poorly known; in dry season, shallow wetlands, dry sedge meadows, rice fields and wet grasslands of Mekong Delta. In Australia, sympatric with *G. rubicunda*, but shows greater use of upland agricultural fields and grassland during dry season.
Food and Feeding. Generalist: diet widely varied, including sedge tubers, other wetland plants, upland grasses and groundnuts, waste rice and other grains; also snails, crustaceans, grasshoppers and other insects, fish, frogs, snakes and other small vertebrates. Walks along slowly with head down, searching for food; does not dig. Forages in both wetlands and uplands.
Breeding. Nesting associated with wet season throughout range: in India, breeds throughout year (except May and Jun) with Jul-Sept peak; in SE Asia, during monsoon season, Jun-Oct; in N Australia, during wet season, generally Jan-Mar. Nest consists of wetland vegetation and other available materials; in India, breeds in large wetlands and also scattered sites amid human settlements, e.g. irrigation ditches, village ponds, *jheels*; in SE Asia, isolated wetlands; in N Australia, uses similar nest-sites to those of *G. rubicunda*, but often more shaded. Usually 2 eggs, occasionally 3; incubation 31-34 days; chicks yellowish brown, with two darker brown lines down back, and white on breast, belly and base of wings; fledging 85-100 days. Sexually mature at 2-3 years.
Movements. Non-migratory in India and Australia, but some seasonal movement, especially during periods of drought. SE Asian populations undertake limited migration from isolated breeding areas of upper basin of Mekong to delta in Vietnam.
Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Estimated total population 13,500-15,500 birds. Nominate *antigone* common, perhaps numbering 10,000 birds, but declining; extirpated from much of former range within and beyond India; extinct in Pakistan, probably due to human persecution, as still numerous just across border in parts of India; may still survive in Bangladesh, but only one recent record. Race *sharpii* has been devastated throughout SE Asia, and since 1960 has disappeared from S China, Thailand and other portions of its historical range; estimated population 500-1500 birds. Race *gilliae* has population of perhaps 5000 birds; considered secure. Probably extirpated from Philippines (possible race *luzonica*), where early in present century moulting birds were reported to be hunted and lassoed from horseback; no recent records, despite surveys in 1970's and 1980's. Most significant threats are loss and degradation of wetlands due to agricultural expansion, drainage, industrial development, pollution, warfare and heavy pesticide use. In India and Vietnam, human population pressures compound these threats and increase the level of human disturbance of cranes; eggs are occasionally stolen and chicks captured and raised for food; some trading reported in India, Cambodia and Thailand. Species protected by local traditions and religious beliefs in many parts of range, especially N India, W *terai* of Nepal, and Vietnam. Conservation efforts have been most intensive in SE Asia, where international agreements and collaborative conservation projects have expanded significantly since mid-1980's. In 1990, *International Sarus Crane and Wetland Conservation Workshop* was conducted in Vietnam. Comprehensive field studies of the species have been conducted in India and Nepal. There have been several surveys of wintering grounds in Vietnam, and of potential breeding grounds in Cambodia. Tram Chim National Reserve in Vietnam provides partial protection for winter habitat of race *sharpii*; ecological restoration and management of Tram Chim wetlands have been undertaken. A national wetland management plan is being developed in Cambodia, in part to protect breeding habitat. The species has also been centrepiece of environmental education programmes in Vietnam, Nepal and India. No captive-raised birds being released at present, but reintroduction plans have been advanced in Thailand and other portions of historical range.

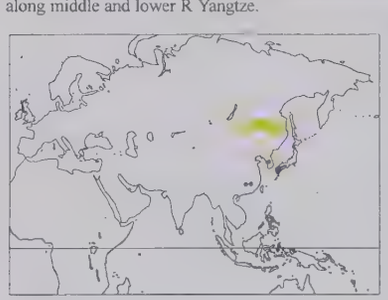
9. Brolga

Grus rubicunda

French: Grue brolga **German**: Brolgakranich **Spanish**: Grulla Brolga
Other common names: Australian Crane

Taxonomy. *Ardea rubicunda* Perry, 1810, Botany Bay, New South Wales.
N and S populations formerly placed in separate races, with *argentea* for N birds; subspecific division no longer widely accepted, although the two populations are probably independent. Monotypic.
Distribution. N & E Australia; small populations in New Guinea, in basin of R Sepik and in Trans-Fly.
Descriptive notes. c. 160 cm; male 4761-8729 g, female 3628-7255 g; wingspan 200-230 cm; male slightly larger than female. Iris orange. Distinguished from similar *G. antigone* by slightly smaller size, small dewlap, uniform grey body and darker legs; bare skin patch in *G. rubicunda* limited to head. Juvenile has head entirely feathered, iris dark brown. VOICE: Calls lower, more guttural than in other *Grus* species, except *G. canadensis*.



Habitat. Varies by season, and between N and S Australia. S birds prefer shallow freshwater marshes, with water less than 50 cm deep; also use deeper marshes, wet meadows and brackish wetlands; move to traditional flocking areas, including permanent wetlands, upland pastures and other drier foraging areas in summer, Dec-May. N birds more tolerant of saline conditions; use coastal freshwater sedge marshes; partial dispersal to suitable nesting areas in ephemeral inland marshes with onset of wet season in Dec. Habitat in New Guinea unstudied.
Food and Feeding. Widely varied diet. Major food item is sedge tubers, which are excavated from mud of drying marshes. Bulkuru sedge (*Eleocharis dulcis*) is especially important in N. Also takes insects, crustaceans, molluscs, frogs, small mammals and birds; cereal grains and nut crops in cultivated areas. Feeds by digging with large bill, especially in drier areas; also forages in shallow waters and wetlands, including freshwater and saltwater marshes.
Breeding. In Australia, breeding coincides with wet season in N, peaking in Feb-Mar; season less distinct in S, Jul-Nov. Nest is large mound, up to 1·5 m in diameter, of grass and sedge stems, built in densely vegetated wetlands as water levels rise. Usually 2 eggs; incubation 28-31 days; chicks grey with buff head and neck; fledging c. 100 days. Sexually mature at 3-5 years.
Movements. Non-migratory. Local movements in response to seasonal conditions. In Queensland and Northern Territory, substantial dispersal during wet season to upstream sections of coastal floodplains and to inland nesting sites; birds return gradually to coasts and form flocks as dry season advances. Inland dispersal has probably increased with proliferation of stock ponds and other small water developments. In S Australia, disperses to isolated wetlands during breeding season, returning to traditional flocking sites as dry season advances. Movements of New Guinea population unknown.
Status and Conservation. Not globally threatened. CITES II. No range-wide surveys, but current population estimated at 20,000-100,000 birds, generally stable with local declines. Still occupies most of historical range; is apparently expanding into W Australia, with retraction of range in Victoria and other portions of SE. No information available on status of New Guinea populations, but species is locally common in Trans-Fly, occurring in flocks of up to 600 birds; no recent records from Sepik region. In Australia, most significant threats are loss and degradation of wetlands due to soil erosion and sedimentation, vegetation change, and, especially in S, land reclamation for agriculture. S Australian birds also affected by land subdivision, utility lines and predation by introduced red fox (*Vulpes vulpes*). Degree of legal protection varies in Australian states. Limited field studies, concentrated in SE & E Australia. Since mid-1980's, private wetland management and restoration efforts have expanded, especially in Victoria. Surveys and education programmes conducted by "Friends of the Brolga", established in 1991.
Bibliography. Archibald (1974), Archibald & Swengel (1987), Arnol *et al.* (1984), Beehler *et al.* (1986), Blackman (1971, 1977), Blakers *et al.* (1984), Bransbury (1991), Brownsmith (1978),Christidis & Boles (1994), Coates (1985), Goldstraw & DuGuesclin (1991), Hesch (1987), Jaensch & Vervest (1990), LaRue (1979), Lavery (1965), Lavery & Blackman (1969), Marchant & Higgins (1993), Morton *et al.* (1993), Rand & Gilliard (1967), Rutgers & Norris (1970), Serventy & Whittell (1976), Storr (1977, 1980), White (1987).

10. White-naped Crane

Grus vipio

French: Grue à cou blanc **German**: Weißnackenkranich **Spanish**: Grulla Cuelliblanca
Other common names: Japanese White-necked Crane

Taxonomy. *Grus vipio* Pallas, 1811, Transbaikalia. Monotypic.
Distribution. NE Mongolia, NE China and extreme SE Russia. Winters in Korea, S Japan and CE China, along middle and lower R Yangtze.

Descriptive notes. 125+ cm; 4750-6500 g; wingspan 200-210 cm. Slate grey body with white throat and distinctive vertical white stripe from crown down back of neck; iris orange. Juvenile has head entirely brown, with pale throat. VOICE: High-pitched penetrating calls.
Habitat. Breeds in shallow open wetlands and wet meadows in broad river valleys and along lake edges. Also frequents grassland and cropland adjacent to breeding areas. During migration and on wintering grounds, will use both fallow fields and wetlands, e.g. riparian and brackish marshes, rice paddies and estuarine mudflats. On Chinese wintering grounds, niche intermediate between sympatric congeners: less so than *G. leucogeranus*, but more aquatic than *G. grus* and *G. monacha*.
Food and Feeding. Feeds on roots and tubers of sedges and other wetland plants; also insects, small vertebrates, seeds and rice gleanings. During non-breeding season, consumes relatively more waste grain, seeds and tubers; rice and other cereal grains provided at winter feeding stations in Japan. Digs for roots and tubers, but forages at large for animal prey and grain; more territorial when digging.
Breeding. Spring breeder, with eggs laid from Apr to late May. Nest is mound of dried sedges and grasses in open wetlands. Usually 2 eggs; incubation 28-32 days; chicks brownish yellow with darker spots; fledging 70-75 days. Sexually mature at 2-3 years.
Movements. Birds from E portion of breeding range migrate through Korean Peninsula: several hundred birds overwinter in the Demilitarized Zone between North and South Korea; as many as 2100 birds continue S to Kyushu, S Japan, where they join the main wintering population of *G. monacha*. About 3000 birds from W portion of breeding range migrate across C & E China to wintering grounds in Hunan, Jiangxi, Anhui and Jiangsu Provinces.
Status and Conservation. VULNERABLE. CITES I. Formerly more abundant and more extensively distributed than at present, but declined steadily through first half of 1900's due to habitat loss, hunting and effects of warfare. Population began to recover in 1950's and is currently estimated at 5000 birds. Most significant threat is extensive loss and alteration of habitat in the Amur Basin, the Sanjiang Plain in NE China, and other portions of breeding range, primarily as result of agricultural conversion. Migration and wintering habitats in China and Korea, especially Korean Demilitarized Zone, are also under heavy development pressure. In S Japan, concentration of c. 40% of total population winters at Izumi, SW Kyushu, where artificial feeding began in 1952; susceptible to outbreak of disease and other catastrophic events. Species is legally protected in all range countries; has benefited from a series of bilateral migratory bird

On following pages: 11. Eurasian Crane (*Grus grus*); 12. Hooded Crane (*Grus monacha*); 13. Whooping Crane (*Grus americana*); 14. Black-necked Crane (*Grus nigricollis*); 15. Red-crowned Crane (*Grus japonensis*).

agreements in E Asia, and international agreements to protect key habitats at L Khanka on China-Russia border, and in China-Russia-Mongolia border region; these efforts were advanced at *International Workshop on Cranes and Storks of the Amur Basin* in 1992 and *International Symposium on the Future of Cranes and Wetlands* in Japan in 1993. Winter counts have been carried out regularly in Japan since early 1950's, in Korea since 1970's and in China since early 1980's. Field studies of species have expanded greatly in all portions of range since mid-1970's. Several non-governmental organizations, including Wild Bird Society of Japan, Socio-Ecological Union of Russia, National Audubon Society, and International Crane Foundation, have been active in conservation efforts for the species. Breeds readily in captivity and release of semi-wild birds has taken place on a limited basis at Zhalong Nature Reserve in China and Khinganski Nature Reserve in Russia.

11. Eurasian Crane

Grus grus

French: Grue cendrée **German**: Kranich **Spanish**: Grulla Común
Other common names: Common Crane

Taxonomy. *Ardea Grus* Linnaeus, 1758, Sweden.
Sometimes divided into W and E races, with *lilfordi* for E birds; division based on plumage colour variations, due in part to differences in feather-painting behaviour, and no longer widely accepted. Monotypic.
Distribution. Scandinavia and NE Europe to NC China and Russian Far East; also Turkey and Caucasus, in Armenia and possibly Azerbaijan. Winters in France, Iberian Peninsula, NW & NE Africa, Middle East, Pakistan, India and S & E China.

Descriptive notes. c. 115 cm; male 5100-6100 g, female 4500-5900 g; wingspan 180-200 cm. Slate grey body, with black primaries; dark head has white stripe starting behind eye and extending down nape; red skin patch on crown; iris yellow to orange. Similar to *G. nigricollis*, but has extensive white on head. Juvenile has crown feathered; body plumage tipped with yellowish brown. VOICE: Calls high-pitched and penetrating.
Habitat. Breeds in wide variety of shallow wetlands, including forested swamps (especially of birch and alder), sedge meadows and bogs. In Europe, has adapted to use of smaller natural, artificial and restored wetlands. Throughout winter range, forages in agricultural fields and pastures, and roosts in nearby wetlands or other shallow waters.
Food and Feeding. Omnivorous. Plant items generally more important, especially outside breeding season: roots, rhizomes, tubers, stems, shoots, leaves, berries, seeds of emergent wetland plants, grasses, forbs and crop plants; also takes acorns, nuts, legumes and waste grain. Animal items more frequent in summer diet: mainly invertebrates, including worms, snails, insects and other arthropods; also frogs, snakes, lizards, fish and rodents. Forages on land and in water by probing and picking.
Breeding. Spring breeder; most eggs laid in May. Nest is mound, c. 80 cm wide, of wetland vegetation; situated in shallow marsh or bog, often near trees. Usually 2 eggs; incubation 28-31 days; chicks dark brown above, pale brown below; fledging c. 65-70 days. Sexually mature at 4-6 years.
Movements. Major migration routes: from Scandinavia and N continental Europe through W Europe to wintering areas in France, Spain, Portugal and Morocco; from NE Europe through C Europe and Italy to wintering areas in Tunisia, Libya and Algeria; from E Europe and W Russia, through Balkans and across and around Black Sea to wintering areas in E Africa, Middle East and Asia Minor; from C Russia around Caspian Sea to SE Iraq and SW Iran; from W Siberia through Afghanistan and Pakistan to wintering areas in W & C India; from N China and C Siberia across China to wintering areas along middle R Yangtze; and from Xinjiang and Qinghai Provinces on Tibetan Plateau to wintering areas in S China. Small breeding population in Turkey; may breed in Azerbaijan, where until fairly recently species regularly overwintered at several sites.
Status and Conservation. Not globally threatened. CITES II. Total estimated population 220,000-250,000 birds, but only European and European Russian populations reliably surveyed on regular basis. Extirpated as breeding species in much of historical range in S, W & E Europe: last breeding known in England c. 1600, Italy c. 1880, Austria c. 1885, Hungary 1952, Greece 1965. Species as a whole stable, but W populations recovering, while some E populations may be declining. Threats include loss and degradation of wetlands throughout breeding range, human pressures on wetlands in wintering grounds, changes in beneficial agricultural land uses, and persecution due to crop damage. Hunting is of concern in some areas, particularly in Afghanistan and Pakistan. Conservation efforts mainly focused on W portion of range, co-ordinated through regular international meetings of European Crane Working Group. Key migration and wintering habitats protected in reserves and in agreements with landowners, especially in Germany, France and Spain. Populations monitored closely in Europe, and species often included in waterbird surveys in other portions of range. Ringing and telemetry studies of migration routes in Europe, W Siberia and E Asia. Extensive field studies in Europe, Russia, Ukraine, Pakistan, India, Nepal and China. Focus of education projects in W Europe, Pakistan, Russia and elsewhere.

12. Hooded Crane

Grus monacha

French: Grue moine **German**: Mönchskranich **Spanish**: Grulla Monje

Taxonomy. *Grus monacha* Temminck, 1835, Hokkaido and Korea.
Monotypic.
Distribution. SE Russia and N China. Winters mainly in S Japan; also South Korea and C & E China.

Descriptive notes. c. 100 cm; male 3280-4870 g, female 3400-3740 g; wingspan 160-180 cm. Grey body; head white except for "hood" of bare red skin above eye on forecrown; iris orange to red. Similar to *G. vipio*, but smaller, with fully white neck. Juvenile plumage tinged brown; crown black and white. VOICE: Loud, high-pitched calls.
Habitat. In breeding range, occupies isolated bogs and higher altitude forested wetlands, e.g. of larch (*Larix*). Non-breeders use open wetlands, grassland and agricultural fields. Winter habitat more diverse: shores of rivers and shallow lakes, grassy marshes, rice paddies and agricultural fields. Found at feeding stations and in agricultural fields in Korea and Japan.
Food and Feeding. In breeding areas, feeds on aquatic plants, berries, insects, frogs and salamanders. In winter, rhizomes, seeds and grains; artificial foods, rice and other waste cereal grains in Korea and Japan. In both breeding and natural wintering grounds, forages by digging and by picking food off surface.
Breeding. Spring breeder; eggs laid in late Apr or early May. Nest constructed of damp moss, peat, sedge stalks and leaves, and branches of larch and birch; situated in sphagnum bog with widely scattered larch trees. Usually 2 eggs; incubation 27-30 days; chicks dark brown above, paler below; fledging c. 75 days. Sexually mature at 3-4 years.
Movements. Migrates through NE China. Most of population (c. 8000 birds) crosses Korean Peninsula between breeding range and wintering grounds on Kyushu, S Japan. Smaller populations winter along R Naktong near Taegu, South Korea, and in S Honshu, S Japan. Several hundred birds migrate down coastal China to wintering grounds on R Yangtze in Hubei, Anhui, Hunan and Jiangxi Provinces. Non-breeders occasionally occur W to NE Mongolia.
Status and Conservation. Not globally threatened. CITES I. Conservation Dependent. Total population estimated at 9000-11,000 birds. Numbers known to have risen and fallen dramatically since 1920's. After artificial feeding began in 1952 at Izumi, SW Kyushu, population began to increase steadily. Although species might still be threatened, it is somewhat more secure than the other declining cranes of E Asia, due to absence of intensive human economic activity in its remote breeding grounds. Held in high regard in Japan, species nonetheless remains vulnerable to pressures associated with high human population density, including conflicts with farmers. Faces other critical threats, including drainage of wetlands and intensified logging pressure in taiga forests, alteration of wetlands in wintering areas of China, rapid development of key wintering areas in Korean Peninsula, and high risk of disease outbreak in the concentrated flocks at winter feeding stations in Japan. Legally protected throughout range, and has benefited from international agreements, conferences and co-operative measures to protect cranes and wetlands in E Asia. Population surveyed annually in wintering areas. Field studies were extremely limited until late 1970's; research has since expanded, especially studies of breeding habitats, winter ecology and migration routes. Key winter habitats have been secured in several protected areas. Species is well represented in captive propagation programmes, but does not breed consistently; reintroduction programmes have not been necessary to date.

Bibliography. Abe (1989), Ali & Ripley (1980), Andreev (1974), Bohmke (1992), Brazil (1991), Chen Bin & Wang Zuoyi (1991), Cheng Tsohsin (1981), Cho & Won (1990), Chong *et al.* (1992), Collar & Andrew (1988), Collar *et al.* (1994), Dementiev & Gladkov (1951a), Eguchi *et al.* (1991), Fan Zhongmin *et al.* (1994), Flint (1978), Formozov & Smirin (1987), Halvorson & Kaliher (1995), Harris (1992b), Higuchi (1991a, 1991b, 1993), Higuchi, Ozaki, Golovushkin *et al.* (1994), Higuchi, Ozaki, Soma *et al.* (1992), Jo & Won (1989), Kawamura (1981, 1991), King (1978/79), Knystautas (1993), Li Lin (1993), Liu Bowen & Sun Zhaofeng (1992), Liu Zhiyong *et al.* (1987b), Nagano *et al.* (1992), Neufeldt (1977, 1981, 1982), Ohsako (1987, 1989), Ozaki (1991), Ozaki & Baba (1994), Perennou *et al.* (1994), Potapov & Flint (1987), Pukinski (1977), Pukinski & Ilyinski (1977), Rogacheva (1992), Roslyakov (1995), Sonobe & Izawa (1987), Swengel (1992), Vorbiev (1963), Wang Liantie & Du Wei (1989), Wang Qishan (1988, 1991), Wang Qishan & Hu Xiaolong (1987), Williams, Bakewell *et al.* (1991), Williams, Carey *et al.* (1992), Zhao Haizhong (1991).

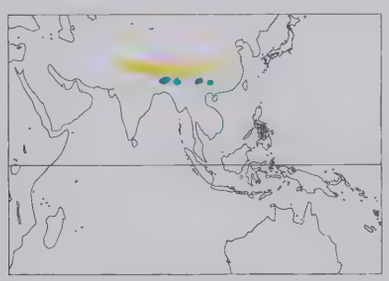
13. Whooping Crane

Grus americana

French: Grue blanche **German**: Schreikranich **Spanish**: Grulla Trompetera
Other common names: Whooper (!), Big White Crane

Taxonomy. *Ardea americana* Linnaeus, 1758, Hudson Bay, Canada. Monotypic.
Distribution. WC Canada (Wood Buffalo National Park). Winters on Texas coast of Gulf of Mexico (Aransas National Wildlife Refuge). Small experimental flock introduced in Rocky Mts, W USA; experimental non-migratory flock currently being established in Florida, SE USA.

Descriptive notes. 130-160 cm; 4500-8500 g; wingspan 200-230 cm; male slightly larger than female. Tallest North American bird; pure white apart from dark red crown, dark red or black elongated malar stripe, and black primaries and alulae; iris yellow. Of the other two primarily white cranes: *G. leucogeranus* has white head, mask of bare red skin, and black primaries; *G. japonensis* has blackish neck and black secondaries. Juvenile has fully-feathered pale brown head; mottled white and cinnamon body. VOICE: Calls loud and trumpet-like.
Habitat. Historical breeding habitat was mainly potholes and other wetlands of northern plains and prairies of North America. Birds of remaining wild population nest in poorly drained area of intermixed ponds, marshes, muskeg and boreal forest; emergent vegetation of nesting grounds consists primarily of bulrush, with cat-tail and sedge common. During migration, uses wide variety of feeding and roosting habitats, including riparian marshes, other wetlands, reservoir margins, submerged sandbars and cropland. Winter habitat comprises mainly brackish bays, saltflats and coastal marshes. Experimental flock in Rocky Mts uses intermountain lacustrine and riparian wetlands; experimental flock in Florida established in savannas, wet meadows and shallow marshes and lake margins of Kissimmee Prairie region.
Food and Feeding. Omnivorous. Summer diet includes insects, small fish, frogs, small birds and rodents, and berries. During migration will also consume tubers and waste grain. Winter diet consists primarily of animal food, especially blue crabs and clams, with occasional foraging in uplands for acorns and invertebrates. Feeds by probing soil with bill and also by taking items from surface.



Breeding. Spring breeder; eggs laid from late April to mid-May. Nesting territory averages 7·2 km², but wide range of 1·3-47 km². Nest built of wetland plants; 60-150 cm in diameter, and up to 45 cm above surrounding water. Usually 2 eggs; incubation 28-31 days; chicks cinnamon brown above, pale grey or brownish white below; fledging 80-90 days. Individuals recorded forming pairs at 2 years old, and nesting at 3 years; but, on average, eggs first produced at slightly over 4 years. Maximum longevity in wild believed to be 22-24 years; captive individuals have lived up to 40 years old.
Movements. Birds of remaining wild flock migratory, as are those of experimental Rocky Mts flock. Main migration route follows a corridor, 100-300 km wide, across 9 provinces and states of Canada and USA, with important resting and staging areas at several large marshes and riparian wetlands along the way, especially along Platte R. Birds of experimental Rocky Mts population migrate between E Idaho and C New Mexico. Birds released into experimental flock in C Florida, though non-migratory, have dispersed up to 120 km from release site.
Status and Conservation. ENDANGERED. CITES I. Intensively protected, studied and monitored since reaching brink of extinction in 1930's and 1940's. Probably never very abundant in historical times; decimated by hunting, collecting and habitat loss during European settlement of North America. Main historical breeding range was in N prairies and plains of North America, from Alberta to L Michigan; wintered in highlands of N Mexico, USA Gulf Coast in Texas and Louisiana, and S Atlantic coast of USA; a non-migratory flock occurred in Louisiana. Species declined rapidly in late 1800's and early 1900's due to hunting and conversion of habitat to agriculture in main breeding range. By late 1930's, only two populations remained: the non-migratory population in Louisiana, which disappeared in late 1940's; and the remaining migratory population, which reached a low of 15 or 16 birds in 1941. This population hovered between 20 and 40 birds until 1960's, when it began slow, but steady, increase to its current level of c. 150 birds. Partial recovery of wild population has been accomplished through strict legal protection, extensive public awareness campaigns, co-operative international research and management, careful monitoring and surveying programmes, development of co-ordinated Whooping Crane Recovery Plans, and protection of the species' breeding, migration and wintering habitat. Threats include continuing loss and degradation of migration and winter habitats; pollution; vulnerability to catastrophic accidents and storms; human disturbance; collision with utility lines; illegal and accidental shooting; and loss of genetic diversity within the species. In 1975, efforts were undertaken to establish a second migratory flock by placing eggs from the wild flock into nests of *G. canadensis*, in W USA; this cross-fostering experiment proved unsuccessful, however, when the resulting birds failed to form pair-bonds with conspecifics, and hence failed to reproduce; the experiment was curtailed in 1989. An active programme of captive propagation has been under way since mid-1960's, using eggs removed from nests of wild birds; first eggs were produced in captivity in 1975. Birds are now maintained at three captive propagation centres: at Patuxent, Maryland, USA; at the International Crane Foundation in Baraboo, Wisconsin, USA; and at Calgary Zoo in Calgary, Alberta, Canada. In 1994, there were c. 120 birds in captivity at these and several other locations. Birds raised in captivity have been used to establish the non-migratory population in Florida; the first birds were released there in 1993. Further efforts to establish a self-sustaining migratory population in the wild are planned for late 1990's.

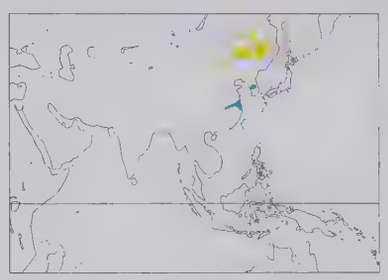
14. **Black-necked Crane**

Grus nigricollis

French: Grue à cou noir **German**: Schwarzhalskranich **Spanish**: Grulla Cuellinegra

Taxonomy. *Grus nigricollis* Przevalski, 1876, Tsinghai Province, China. Monotypic.
Distribution. E Ladakh (NW India) through Tibet to Xinjiang, Qinghai, Gansu and Sichuan (W & C China). Winters from S Tibet-Qinghai Plateau, Bhutan and NW Arunachal Pradesh (NE India) E to Yunnan-Guizhou Plateau (SC China).



Descriptive notes. c. 115 cm; 5000-7000 g; wingspan 180-200 cm. The only grey crane with black primaries and secondaries; black neck and tail distinctive; iris yellow. Juvenile plumage greyish yellow; neck mixed black and white. VOICE: Calls high-pitched and penetrating.
Habitat. Summer habitat at high altitudes of 2950-4900 m: grassy wetlands, boggy meadows, marshes along shores of lakes and small streams, and pastures; often near human settlements. In winter occurs at much lower altitudes, down to 1375 m, typically in open country on agricultural land, e.g. deserted paddyfields.
Food and Feeding. Feeds on plant roots and tubers, snails, fish, shrimps, frogs, lizards and voles. In wintering areas, consumes waste barley, spring wheat and other cultivated crops, as well as tubers, seeds, earthworms, insects and, snails. In breeding zone, forages in wetlands, streams and pastures; in winter, mainly in agricultural fields and pastures.
Breeding. Spring breeder; eggs laid from early May to mid-Jun; in C & W Tibet, most laying in late May. Nest built in shallow peat wetlands on small, grassy islands or in water; constructed of sedges, grass, other aquatic vegetation and mud. Usually 2 eggs; incubation 31-33 days; chicks brown; fledging c. 90 days.
Movements. Limited migration between high altitude breeding areas and lower altitude agricultural valleys in SC & E Tibet, C & NE Bhutan, NW Arunachal Pradesh, NW & NE Yunnan and W Guizhou; formerly also in N Myanmar and N Vietnam, though no recent records; occasionally wanders to Nepal. Birds arrive on wintering grounds from mid-Oct to early Dec, remaining until Mar or mid-Apr.
Status and Conservation. VULNERABLE. CITES I. Total population currently estimated at 5600-6000 birds. Species has evidently declined in many portions of range since 1950's. Although numbers for species as a whole may be stabilizing, declines in wintering sub-populations have been documented since 1970's in Tibet, Bhutan and Yunnan. Loss and degradation of habitat constitute principal threats to the species; drainage and conversion of wetlands, canalization of rivers, hydroelectric projects, overgrazing, peat mining, siltation and industrial pollution have affected habitat throughout winter range and in some breeding areas. Recent studies in Tibet indicate that changing agricultural practices, especially autumn ploughing and adoption of winter wheat varieties, have reduced availability of winter food. Species has long been protected by religious traditions in many areas, and enjoys complete legal protection throughout range. Nevertheless, increasing availability of firearms has made hunting a more significant threat, especially in Arunachal Pradesh and Yunnan. Regular surveys of population have been conducted in India since mid-1970's, in Bhutan since 1978, and in China since 1988; during this period, field studies of species have expanded dramatically throughout range, and protected areas have been established at several important wintering areas in Tibet, Bhutan, Yunnan and Guizhou. Concerted programme of habitat protection and management, community development, and watershed planning has been undertaken at one especially important wintering site, Cao Hai Nature Reserve in Guizhou Province, SC China. A variety of national and international conservation organizations have worked with government authorities to support and co-ordinate surveys, research, habitat management, training and education programmes.

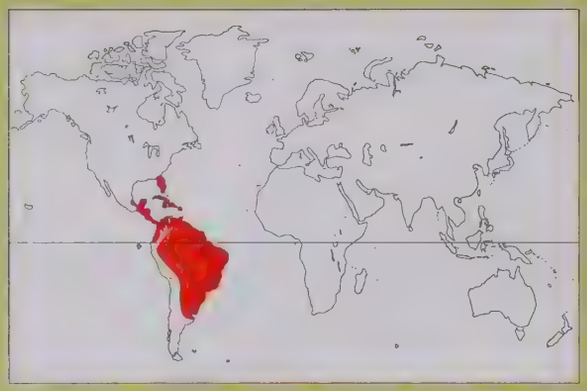
15. **Red-crowned Crane**

Grus japonensis

French: Grue du Japon **German**: Mandschurenkranich **Spanish**: Grulla Manchú
Other common names: Japanese/Manchurian Crane

Taxonomy. *Ardea (Grus) Japonensis* P. L. S. Müller, 1776, Japan.
Subspecies status formerly suggested for mainland and Japanese breeding populations, based on differences in vocalization patterns; some variation between these populations exists in morphology, coloration and egg size, but preliminary DNA analysis has shown no significant genetic distinction. Monotypic.
Distribution. Resident on Hokkaido, N Japan. Also breeds in NE China and adjacent extreme SE Russia. Winters in Korea and in and around Jiangsu, CE China.



Descriptive notes. c. 150 cm; 7000-10,000 g (up to 12,000 g in winter); wingspan 220-250 cm. White primaries unique in cranes; iris dark brown or dark green. Differs from other mainly white cranes, *G. leucogeranus* and *G. americana*, by black secondaries and blackish neck with white nape; *G. nigricollis* has black neck, but is smaller, with grey body. Juvenile also white, but primaries tipped black, neck and secondaries dull brown or grey. VOICE: Calls high-pitched and penetrating.
Habitat. More aquatic than other sympatric cranes. In summer, frequents deeper portions of reed, sedge and cat-tail marshes, and extensive bogs and wet meadows. On Hokkaido, birds found in open low meadows and sparsely wooded boggy areas. Sometimes forages in crop fields, typically along dykes. In winter, occurs at rivers, freshwater wetlands, coastal salt-marshes and mudflats, and paddyfields.
Food and Feeding. Generalist. Feeds on insects, aquatic invertebrates, fish, amphibians and rodents; also reeds, grasses and other plants. Waste rice and other grains taken during winter in Japan and Korea; Hokkaido birds use feeding stations in winter. Uses "walk-and-peck" more than probing or digging.
Breeding. Spring breeder; eggs laid mainly in Apr, but also in May. Breeding territories vary widely in size, from c. 1-7 km² in Japan, to 2-3·2 km² in China, to 4-12 km² in Russia. Nest of reeds and grass built in relatively deep water, up to 50 cm deep; will only nest in areas with dead standing reeds 30-200 cm tall. Usually 2 eggs; incubation 29-34 days; chicks brown with white spot at base of wing; fledging c. 95 days. Age of sexual maturity 3-4 years.
Movements. Mainland populations migrate across NE China, dividing into 3-4 wintering sub-populations: birds from E portion of breeding range move across North Korea to wintering areas in and near Korean Demilitarized Zone; birds from W migrate along N China Sea to coastal wintering areas in and around Jiangsu. Hokkaido population essentially sedentary: some family groups remain in breeding area; others move up to 150 km to wintering areas in Kushiro District of Hokkaido. Vagrant to Mongolia.
Status and Conservation. VULNERABLE. CITES I. Second rarest crane with current population estimated at 1700-2000 birds. Population has fluctuated over last 100 years, reaching lowest point in years following Second World War. Hokkaido population has risen from 33 birds in 1952, when feeding stations were established, to over 600 in 1990's. Loss and degradation of wetlands due to agricultural and industrial development constitute main threat to the species' breeding areas in Hokkaido, the Sanjiang Plain in NE China, and Amur Basin in extreme SE Russia; proposed dams on R Amur may affect breeding populations. Wintering area in Korean Peninsula threatened by potential for conflict or development in Demilitarized Zone. Chinese wintering areas threatened by potential loss of coastal marshes due to upstream dam on R Yangtze. Other anthropogenic threats include overharvesting of wetland resources, human disturbance, intentional setting of fires in breeding areas, and poisoning. Species has benefited from intensive conservation efforts since early 1950's. Hunting prohibited in all range nations. Several international agreements have been developed to benefit this and other E Asian cranes. Wintering populations counted annually. Nature reserves provide protection for key breeding, migration and winter habitats. Marking of utility lines in Hokkaido in 1971 resulted in 70% decline in death rate from collisions. Co-operative international telemetry studies have provided information on migration routes and timing. Several international symposia and meetings have been held to exchange information on this and other E Asian crane species, most recently in 1993, in Japan. Population and habitat viability analysis conducted in 1992. Extensive education projects undertaken in Russia, China and Japan. Species breeds readily in captivity; captive-raised birds have been released into the wild at three natural breeding sites.

Class AVES

Order GRUIFORMES

Suborder GRUES

Family ARAMIDAE (LIMPKIN)

- Large brown, rail-like or ibis-like wading birds, with long bill, neck and legs.
- 56-71 cm.

- Tropical and subtropical parts of the Americas.
- Mainly in and around freshwater wetlands; also mangroves, and occasionally much drier zones.
- 1 genus, 1 species, 4 taxa.
- No species threatened; none extinct since 1600.

Systematics

The Limpkin (*Aramus guarauna*) is traditionally placed in a monospecific family within the Gruiformes, which also includes cranes (Gruidae), rails (Rallidae), bustards (Otididae), and an assemblage of other specialized birds. The cranes, Limpkin, trumpeters (Psophiidae) and rails are generally thought to constitute the core group, with the other eight as satellite families.

The Limpkin has been characterized as having had a somewhat stormy nomenclatural career. It has been variously thought to be related to the shorebirds or waders, the gallinaceous birds, and the herons, but most consistently has been positioned as a connecting link between the cranes and rails. In certain aspects it is more crane-like, notably in general anatomy; osteology and skeletal structure, especially the skull morphology; musculature; and feather patterns. However, the morphology of the bill and feet, certain external characteristics, wing size and shape, digestive system, behaviour, nesting, feather lice and egg-white protein patterns are all more rail-like. Yet another author claimed that its feather lice pointed to a relationship with the ibises and spoonbills (Threskiornithidae). Recent DNA-DNA hybridization evidence surprisingly suggests the Limpkin to be most closely related to the Sungrebe (*Heliornis fulica*), and on this basis it has been speculatively placed in Heliornithidae, alongside the three traditional members of the finfoot family; the Heliornithidae are sometimes considered to be more closely related to the cranes than to the rails.

The extant limpkin species ranges from Florida, USA, south through Central and much of South America to Buenos Aires, Argentina. However, the earliest fossil aramids were recorded from Wyoming, USA, in 54 million year old sediments of the early Eocene, and they are known to have occurred as far south as Patagonia, Argentina, in the Middle Miocene. The genus first appears in the Lower Pliocene in Nebraska, while the modern day species is known from the Pleistocene.

During the period 1856-1934, the Limpkin was regularly considered to constitute two separate species, northern birds being treated as distinct from the nominate South American form, but subsequently it has received almost universal treatment as a single species, with four races. The South American race, *guarauna*, has on occasion been split into two races, the division coming somewhere around southern central Brazil, but this proposal has now generally been rejected. Slight size differences, the darkness of the plumage, and the extent of white markings distinguish the four currently accepted races. Curiously, John James Audubon's painting of the Florida Limpkin in his 1840 *Birds of America* shows white markings only on the head, neck and mantle, suggesting that his model specimen might have been of the South American form.

Morphological Aspects

The Limpkin is a large brown rail-like or ibis-like wading bird, with long bill, neck and legs. It measures about 56-71 cm in overall length, with a 10-12 cm bill, and tarsi 11-13 cm long. In the northern race *pictus*, breeding males weigh 1130-1370 g, while there is a slight overlap in the range of the sexes, with breeding females weighing 1050-1170 g.

The deep brown colour of the plumage, shading from umber to olive brown, has a bronzy iridescence. Feathers on the head, neck, breast, upper back, scapulars and upperwing-coverts have white streaks along their shafts, while each of these, in turn, narrows to a point at the end of its feather. On the neck and head, the feathers are very small and predominantly white, giving a whitish cast. On the back, scapulars and wing-coverts, the larger overlapping feathers create broad bright white triangles, producing a striking speckled appearance; however, this feature is variable between subspecies, and is greatly reduced or even absent in nominate *guarauna*. The sexes are similar, although the white wing markings of males usually appear distinctly larger than in females, at least in the race *pictus*. Juveniles are similar, but are paler brown with thinner white markings, which appear as streaks from a distance. Chick down is lost by the fifth week. In Florida a complete pre-breeding moult occurs from February to April, and a complete post-breeding moult from August to November.

The wings are broad, fairly long, and rounded, with 26 remiges, and, when stretched out, are 100 cm or more across. The outermost primary is short, sickle-shaped, and clubbed at the end, and is used to produce a buzzing winnow during territorial and night flights. The tail is short and broad, with twelve rounded feathers. When the bird has its wings folded, the tail extends roughly to their tips and is covered by them.

The Limpkin's bill is dark greenish yellow and dusky towards the tip of both mandibles, while the eyes are hazel-coloured. The long, slightly decurved bill is notable because of a bend it takes to the right in the last centimetre or so, probably because of frequent blows and insertions into its most common

Closely linked to the fortunes of the apple snail (Pomacea), *which constitutes its favourite food item, the Limpkin frequents freshwater swamps and marshy areas along lakes and sluggish rivers. Wading or walking on mats of dense aquatic vegetation in jacana-like fashion, the Limpkin catches its prey either by sight or by probing. This individual, after a successful hunt, will now repair to a favourite feeding perch where it will disembowel its victim with dexterous use of its formidable bill. Note the lack of white markings on the upperwing, indicative of the nominate, South American race.*

[*Aramus guarauna guarauna*, Pantanal, Brazil. Photo: Günter Ziesler]

food, the right-handed apple snail (*Pomacea*). Also, the very tip of the (lower) mandible is twisted almost horizontally and sharpened against the tip of the maxilla (or upper mandible). This knife-edge is used to wedge under the snail's operculum and cut the attaching muscle, a technique that recalls that used by the two openbills (*Anastomus*), which have even stranger bills (see Volume 1, page 443). The tongue extends almost to the end of the bill and ends in split horny filaments, suggesting some specialized use during snail extraction.

The blackish olive legs are long, with the tibiae partially bare. The toes are long and slender and the claws are long and sharp, allowing the bird both to walk on mats of floating vegetation and move about easily in trees; similar developments can be seen to varying degrees in other birds that regularly move about on floating vegetation, such as the jacanas (Jacanidae) and the Shoebill (*Balaeniceps rex*).

Although appearing somewhat awkward, Limpkins are strong fliers, fast runners and good swimmers. The choice of retreat by flying as opposed to running is apparently dependent only on the situation. In order to take flight, a bird rises with a quick spring, and for short distances dangles its long legs, but on longer flights stretches them out behind. Flight has usually been described as crane-like, with the wing strokes fairly deep and steady, about two per second, and at the top of the high upstroke a noticeable upward flick of the wings. The neck is stretched forward and down at an angle, making the back appear somewhat humped in distant silhouette. Most flights are for relatively short distances within the territory, but in open marshes a bird may fly for a kilometre or more, if cover is not available. Long flights are usually carried out at higher altitudes, perhaps about 15 metres above ground, when birds occasionally sail on set wings. At the end of a flight, the Limpkin pitches abruptly downward with the wings held high, and, if alarmed, scampers quickly into cover.

When at ease, a Limpkin walks slowly with the body axis parallel to the ground and the upper neck almost vertical. Its head and neck often bob with each step, in a manner recalling rails. When foraging in shallow water, it will step high so that its long toes clear the vegetation. When surprised on the ground it typically tends to run from danger; early American artist J. J. Audubon reported that few birds excelled it in speed and it could not be caught even by the best dogs. Limpkins, including even newly-hatched chicks, are capable of swimming well, although they do so relatively infrequently; birds swim high on the water and elevate the wing tips and tail.

Habitat

Limpkins are typically found where habitat is suitable for their favoured prey, *Pomacea* apple snails, as well as for other aquatic snails and mussels. The apple snails themselves need sufficient year round water depths, sufficient submerged aquatic plants on which to forage, sufficient water hardness to manufacture shells, emergent vegetation on which to lay eggs, and fairly stable water levels in their breeding season to prevent egg inundation. Limpkins, furthermore, need water depths that are shallow enough for wading, and thus are most often found on or near the marshy or wooded shorelines of lakes and slow-moving rivers. They can also occur throughout very shallow marshes, notably in the Everglades of Florida, and well out into deeper rivers and lakes, wherever dense floating vegetation can support their weight. These aquatic habitats are used throughout the species' range, even where it occurs at higher elevations, for example up to 1500 m in Costa Rica.

However, in some parts of its range, the Limpkin uses a greater diversity of habitats. For example, in Jamaica and Haiti historically it has ranged into mid-level humid forests, wooded mountain gullies (especially in summer months), and mountain rivers. In Puerto Rico, it also occurred in dense wet forest usually on steep slopes, reportedly eating land snails and lizards; however, it is now very rare or even extirpated in this area, since much forest has been cleared. In Mexico, the species can also occupy arid brush, savanna, pastureland, hillsides and humid forests far from water, and it can be found near mountain streams at altitudes again up to 1500 m. In Panama and Brazil, birds are reported to occur in flooded farmland. Because nesting locations range from a few centimetres above water level in marshes to high tree limbs in wooded swamps, nesting requirements do not normally seem to limit acceptable habitat.

General Habits

The Limpkin is one of the many remarkable birds of the Americas, with its unique appearance, unusual diet and extraordinary calls. The use of an unusual variety of nesting sites, ritualistic courtship feeding, and a mix of monogamy and polyandry are less known characteristics. It is generally a very unaggressive bird, seemingly indifferent to other species and only infrequently fighting with its own kind over disputed territory boundaries. Indeed, in the hand, it is very calm and is not prone to peck its handler. Aggression between juveniles, including downy young, is virtually never seen,

even to the extent that while one juvenile is fed repeatedly by a parent, all other siblings may stand nearby in total calm.

To date, detailed behavioural studies have only been carried out in Florida, but general notes from throughout the species' range suggest similar behaviour. Breeding territories in north and central Florida are defended by males, and most are held all year round. Territorial males will fly at intruders, calling loudly in flight, chasing them closely behind or displacing them by landing virtually onto them. Territories are also ritualistically defended with counter-calling, counter-positioning in tall trees, charging displays and occasional foot-fighting at territory boundaries. Despite strong territoriality in some areas even in the non-breeding season, elsewhere in the species' range birds readily aggregate and flock in large groups to exploit local abundances of food. There have been two reports of a crippled wing display, but the commonest distraction display is limited to the male clucking loudly and walking about prominently while the female leads the brood into hiding.

Limpkins frequently stand on one leg, like other wading birds, and perform unilateral wing-leg stretches and, less commonly, double wing stretches over the back. They do not jump-dance like cranes, although they do occasionally jump. The resting posture, day and night, is usually hunched, on one or both legs, with the neck drawn in and the eyes closed. Adults sometimes droop the wings while resting in the sun. Sitting is brief and rarely observed, although it is common in chicks and juveniles.

Limpkins usually roost in trees or shrubs at night, although when the female incubates overnight on a nest close to the water level, the male usually stands nearby. Occasionally at night adults will tuck the head under the scapulars. Nocturnal foraging is common year round, and nocturnal calling and territorial flights are common during the nesting season.

Voice

Several male Limpkins calling at once has been referred to as "one of the weirdest cacophonies of nature". A quite extraordinary variety of descriptions can be found: "a hoarse rattling cry like the gasp of person being strangled"; "little boys lost in the swamps forever"; "an unearthly shriek"; "a quality of unutterable sadness"; and "some lost spirit on the swamps, or Nickar the soulless himself, shrieking and crying"! The adult male trachea is twisted in loops and convolutions resulting in an amplified voice distinctly audible two miles away; this modified trachea is said to be similar to that of cranes (see page 61).

Males use two loud call types, which are almost always emitted in series of several to many calls. Both calls may be started or ended, or both, with a throaty rattling sound which seems to emphasize agitation. "Kreow" calls are given apparently spontaneously from perches, and are used in counter-calling with adjacent males, and also during territorial flights. Calling can be contagious and up to seven or eight males may end up calling simultaneously. "Kow" calls are loud and persistent, and are given at a quicker rate, about one per second. They are used especially in the mating season, day and night, by unpaired territorial males in order to attract mates. Up to 80 consecutive calls have been counted without pause, and such calling can continue for hours on end.

Females are characteristically silent, but they have a single common call type, "gon". When heard alone, it is usually as a single or double call when other females or juveniles enter the breeding territory, or during an incubation switch. However, female calls are most noticeable when given in a short antiphonal duet with the mate during his "kreow" or "kow" calls. Juveniles make "wheeteee" calls when adults approach with food, songbird-like chirps, and other sounds. Both males and females also give an impressive diversity of rattles and loud clucks, either spontaneously or when predators are nearby, and soft call notes to the mate and the young. Subspecific variation in calls has not been reported.

Food and Feeding

Throughout most of its range, the Limpkin eats almost exclusively apple snails (*Pomacea*), and, to a lesser extent, freshwater mussels (Unionidae) and other smaller snail species. When foraging, a bird will apparently pick up and open any species or size individual that it encounters. In the West Indies, in areas away from water, Limpkins eat terrestrial snails and lizards. Elsewhere in their range during drought or flooding they are observed readily to switch from their normal diet to other prey, including earthworms, woodworms, slugs, insects, crayfish, small crabs, frogs and geckos. In Florida and Jamaica, the eating of small amounts of rotten wood, usually before or after foraging on normal prey, is occasionally noted.

In riparian habitats, Limpkins forage by wading on the bottom or by walking on dense mats of floating vegetation. In terrestrial habitats or during drought, they grab at moving prey, or chase it, or probe into cracks in the mud for aestivating snails. Foraging in water is performed by means of visual searching or by touch alone. The latter method involves either jabbing through the surface vegetation and catching a snail before it drops off and sinks, or probing the bottom sediments with the head alternatively above or under the water. After capturing a snail or mussel, the bird moves to a solid base to extract the meat, where it sometimes creates characteristic shell piles. In rare cases, a bird will extract a snail from its shell under water. Where snails are abundant, Limpkins can capture and eat a mollusc every two to three minutes.

In order to open a snail, a Limpkin places it on a relatively solid surface with its aperture up and its spire towards the bird's feet. If the operculum is shut tight, it drives a blow or two at its inner edge; inserts the lower bill between the operculum and the columella, while bracing the upper bill against the outside of the shell; inserts the curved tip of the lower bill around the bend inside the aperture; uses the bill as forceps to cut the muscle; removes the snail's body; and detaches the operculum with scissor-like motions of the bill. The orange-coloured yolk gland of *Pomacea* females is routinely shaken loose and rejected. The entire procedure of opening a snail can take as little as 10-20 seconds, but, despite such speed, the thin shell is rarely broken.

To open a bivalve, a Limpkin places it hinge downward and directs several hard blows to the ventral posterior end where the valves meet, as this is the thinnest area of the shell; when the hole is sufficient, the lower bill is inserted and the adductor muscles are cut.

Breeding

Territories are chiefly defended by males, although females contribute, especially by displacing other females. Where water levels are steady and food is abundant, territories are held all year round, whereas poorer quality territories are defended only seasonally. On one Florida river, a colour-ringed and frequently censused male was never seen outside his territory in his 12 years of life. Territories are relatively large, averaging 2-4 ha on Florida rivers and marshes, but they can also vary considerably in size, depending on prey abundance and foraging space. Territories are usually aggregated, occurring edge to edge in suitable river and lake habitat, and also are clumped in vast and apparently uniform marshes.

In Florida, nesting typically occurs from February through to June, a few weeks later in the north than in the south; however, markedly early and late nests are fairly common. In Jamaica nesting occurs from April to November; in Cuba nests were reportedly found in every month; while in Costa Rica nesting occurs from the middle of the wet season to early in the dry season, from July to December. In South America, the nesting season varies but can generally be situated between August and January.

During the courtship period, mated pairs forage and rest side by side. Courtship feeding occurs during final nest building, and involves the male capturing and extracting snails for the waiting female. She approaches and crouches below the male or stands beside him, and will take the snail from his bill as does a juvenile being fed by an adult.

In Florida, nest-sites include an impressively wide variety of situations, including nests on piles of slowly sinking aquatic veg-

Various facets of the Limpkin's lifestyle are remarkable, none more so than the wide diversity of sites used for nesting. Nests may be built in marshland grass, shrubs or trees, or on water. Aided by its partner, this bird has piled up aquatic vegetation to form a floating raft where the eggs have been laid in a slight, unlined depression. Incubation of the largish, variably coloured eggs lasts an average of 27 days and is undertaken by both parents.

[*Aramus guarauna pictus*, Florida. Photo: Stan Osolinski/ Oxford Scientific Films]

etation, among tall marsh grasses, in tangles of vine-covered shrubs, between bald cypress (*Taxodium distichum*) knees, on live oak (*Quercus virginiana*) tree limbs, in parasitic vegetation on trees, in cabbage palm (*Sabal palmetto*) tree tops, on cypress branches up to 14 m up, and even in more unusual sites, such as an abandoned Osprey (*Pandion haliaetus*) nest, or a large tree cavity. Nests seem to be situated to give the occupant a clear view of the immediate surroundings; reuse of the approximate or exact same nest-site is fairly common. Similar nesting habitat is described elsewhere in the Limpkin's range, and, additionally, ground-nesting is reported from Colombia and Jamaica.

The nests themselves are also quite varied. When on the water, they are constructed of floating aquatic vegetation that is merely piled up, or of dead pieces of reeds and grasses which are piled or crudely woven among growing reeds. When elevated, they are constructed of vines, sticks, palm fronds or any other materials that are within reach, and can be pulled to the nest-site; the carrying of materials to the nest site is very unusual. Nests of sticks and vines are usually lined with finer materials, while those of aquatic plants are usually unlined. Nests are roughly circular, about 40-60 cm in diameter and 20 cm deep, with a shallow egg cup depression. Nest building is generally started by the male, and he may build a few partial nests before pair-bonding takes place. The female contributes relatively equally to final nest building, and to all other aspects of nesting and the care of the young.

Eggs are laid daily. Most Florida clutches are of 4-7 eggs, averaging 5·5 eggs, and second-year and older females usually lay 6-7 eggs, while first-year females usually lay 4-5 eggs. The eggs are large for the size of the bird; in Florida, on average they measured 60·08 x 43·98 mm and weighed 57·4 g; dimensions of Argentine eggs are similar. The colour of eggs within and between sets is quite variable, but they are generally a buff or greyish white ground colour, blotched with light, purplish or chocolate brown, especially at the larger end.

Incubation is sometimes delayed until the last egg is laid, but not always. It averages 27 days and is shared, although only the female incubates at night. All eggs hatch during a period of 18-24 hours, and the adults immediately lead the downy young as a group to a newly constructed brooding platform, situated at ground or water level, near a productive foraging area. The brooding platform is about the size of a nest, but consists merely of piled or trampled aquatic vegetation. It is used only for about a week before the family relocates, either for better foraging opportunities or because of some form of disturbance. One initial platform was noted to be as much as 85 m away from the nest, but this presents no problem, as the downy chicks swim, walk and run very ably soon after hatching.

Newly-hatched chicks are described as black by some workers and brown by others; in any case, they almost immediately lighten to cinnamon brown. Young juveniles appear to have disproportionately large legs, and the wings are late to develop. By the end of the sixth week, juveniles are almost as large as an adult but with a slightly shorter bill. Six week old juveniles can fly short distances and can find and open snails, albeit slowly.

Both parents feed the young, but by the end of the seventh week they begin to withhold food. After parental feeding stops at 8-9 weeks, the previously close sibling group dissolves. As early as 11 weeks after hatching, juvenile males begin establishing sub-territories within the parents' territory. Juveniles can start dispersing as early as at 12-14 weeks, but more usually they do so at 15-17 weeks. Second clutches are common and are usually laid when care for the first brood ends. In cases where adults have disappeared, both male and female juveniles have been observed to inherit their parents' territories. When parents remain, they eventually chase the juveniles from the territory, presumably to search for suitable unoccupied habitat elsewhere.

Adult females stay entirely within the territories of their mates during courtship, incubation and the five week downy young stage. At 1-5 weeks after the downy stage, however, females often leave the family and begin to forage and rest in distant parts of the territory, and such abandonment is especially common when high mortality of juveniles has occurred. The wandering female will forage in the neighbouring territory, when no female is present. Most of these females return to their previous mates for a second clutch, but some will pair and mate with an unpaired territorial neighbour that is still advertising with the repetitive "kow" call, thereby engaging in serial polyandry. On one occasion, a subsequent return of the female to the original mate was recorded.

Juvenile survivorship information is sparse, but one observer recorded that in 51 hatchings where the final outcome was known, 25 (49%) produced flying birds. However, the present author once followed 26 hatchings, of which none survived. The maximum known longevity is twelve years, recorded in a colour-ringed male.

Movements

In many parts of its range the Limpkin readily deserts its typical habitats as flooding or drought affect food availability. It subsequently aggregates in unusual numbers or in unusual places, where

All the eggs hatch within 24 hours. Almost immediately the nidifugous chicks are led away in a troop by their parents to a special brooding platform, usually formed of aquatic plant material placed at ground or water level and strategically near a good foraging area. The young are fed by both parents for six to seven weeks, after which time they are almost adult size and are beginning to master the difficult art of dealing with apple snails.

[*Aramus guarauna pictus*, Alexander Srings, Florida. Photo: Dana C. Bryan]

food can still be found. Post-breeding dispersal has also been documented by a wing-tagging study, which recovered a bird from central Florida some 325 km away. Such dispersal probably accounts for the rare vagrant records in eight other south-eastern states of the USA, all occurring between April and November. One intriguing report documents a January 1901 observation of a group of nine Limpkins flying by a Bahama lighthouse well out at sea; some authors speculate on a migration between Cuba and Florida, noting about 20 records from the Florida Keys and the isolated Dry Tortugas, but others suggest this is simple vagrancy.

The Limpkin is usually described as being non-migratory and a year round resident. In parts of Brazil, however, Limpkins emigrate from their breeding marshes in the dry season, after breeding, and return with start of the rains. In addition, a partial migration has been documented on Florida rivers even though water levels remain stable. At two different sites, most post-breeding females, some of them colour-ringed, and a few males, disappeared after spring breeding, and remained absent until mid-winter, when they gradually reappeared at their previous season's breeding territories. Some females paired and successfully mated with the previous year's mates, which had been in continuous residence.

In autumn and winter, in south Florida, many Limpkins gather in the wet prairies and savannas, some in remarkably large groups. A distinct flock of 101 individuals was counted by the author, and the combination of their silence and their small white wing markings support his speculation that the group might be female migrants. It seems reasonable to suppose that migrations may occur elsewhere in the Limpkin's range, but that they have simply gone unnoticed, because some individuals remain in residence year round, as observed in Florida.

Relationship with Man

The Limpkin's common name is said to have come from a characteristic limping gait, but this feature is by no means apparent to all observers, although nervous birds do make some characteristic movements, including wing-flicking, tail-bobbing and neck-jerking. Many vernacular names mimic its calls: "Guareáo" in Cuba; "Carão" and "Guarauna" in Brazil; "Correa" in Costa Rica; "Carrao" in Venezuela and Puerto Rico; "Carau" in Argentina; and "Carrara" in the Dominican Republic. Some descriptive common names are colourful: "Mad, Crazy or Mourning Widow"; "Lamenting Bird"; "Crying Bird"; "Screamer"; "Clucking Hen"; and "Crippled Bird". Only one example of the bird's participation in folklore is reported: in Amazonia, when the Limpkin begins to call, local inhabitants believe that water levels of rivers will not rise any further.

The tame and unsuspicious nature of the species is remarkable. In the early days of European settlement in Florida, Limpkins were reportedly shot standing still, having no fear of man or gun, and they could frequently be caught by hand on their nests. In an open marsh in the 1950's, many Limpkins were observed to remain on their nests even while a deafening airboat approached to within 3-4 m. This tameness is still apparent today in areas where no hunting occurs; Limpkins often let canoes approach closely, even pecking at a paddle while they incubate on the nest. Beyond this simple tolerance, Limpkins also readily utilize man-made habitats when molluscs are not available, foraging for insects on residential lawns and in gardens, and in one case even feeding on mash put out for domestic ducks.

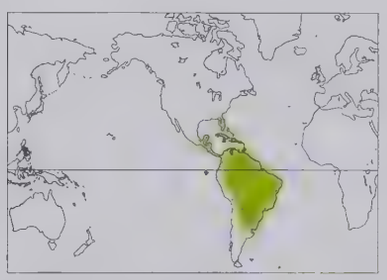
Status and Conservation

Throughout the Limpkin's range, the species is typically described as being locally common in appropriate freshwater marshes and swamp forest habitats. However, this was not always the case. Its tame nature, large size and excellent flavour all caused it to be heavily hunted in Florida around the turn of the century, and most populations within easy access were eliminated. Likewise, in Cuba in 1923, Limpkins were said to be rare due to hunting in their upland habitat. In Puerto Rico, hunting, forest clearing and the introduced mongoose *Herpestes auropunctatus* were blamed for the decline of a formerly abundant population, and, although rumored still to be present, Limpkins have not been recorded there since 1959. The populations of Haiti and Jamaica were also decimated, as the Limpkin was considered the best-tasting of the game birds. In all those areas where hunting pressure was great, populations were described as having been reduced to those individuals living in relatively inaccessible swamps and marshes.

Further problems occurred in Florida, as wetlands were drained for agriculture, permanently reducing the historical distribution of the species, especially in the upper Everglades, the upper St Johns River Valley, and the Kissimmee River Valley. For example, the St Johns Marsh, on the east coast of central Florida, was documented to have lost thousands of breeding Limpkins due to agricultural drainage in the 1950's. Fortunately, in recent years greater environmental regulation and major hydrological restoration projects have begun to restore more natural hydro-periods, for example, in the Everglades and the Kissimmee River Valley. Despite this, a recent analysis of Limpkin population trends in Florida, using Breeding Bird Survey data, indicates a further decline from 1966 through to 1993, although the more recent years of that period are almost stable. The Limpkin is listed as a "species of special concern" by the Florida Game and Fresh Water Fish Commission.

Except for apparently long-term declines within upland habitats of the West Indies, and a possible extirpation on the Pacific Slope in El Salvador, Limpkins apparently remain locally common throughout their range in their typical marsh habitats. However, where drainage and land conversion, hunting and severe disturbance continue to occur, local populations will be affected. Yet, because the Limpkin lives in some very inaccessible wetland habitats, populations will probably remain locally robust wherever apple snails and mussels are abundant. Fortunately, the wide distribution throughout Central and South America may allow eventual recolonization, if local populations do become extirpated.

The current proliferation of invasive exotic aquatic plants in many freshwater habitats is a modern potential threat. The native plants eaten by the apple snail are easily shaded or crowded out by floating and rooted exotics, which themselves may not fulfil the molluscs' ecological needs. As if to exacerbate the situation, repeated herbicide treatments of the exotics to keep boat channels open also threaten the health of the aquatic ecosystem. While such herbicide treatments are not suspected to be directly dangerous to Limpkins, they may harm the molluscs and certainly introduce abnormally large amounts of dead plant material, as muck, onto the river or lake bottom. If apple snail populations are adversely affected, Limpkins are bound to suffer related effects.



Genus *ARAMUS* Vieillot, 1816

Limpkin

Aramus guarauna

French: Courlan brun **German**: Rallenkranich **Spanish**: Carrao

Taxonomy. *Scopolax* [sic] *Guarauna* Linnaeus, 1766, Cayenne.
Shows morphological affinities with Gruidae and Rallidae; recent work with DNA suggests possible grouping with finfoots in family Heliornithidae. In past, N birds were considered to constitute a separate species, *A. pictus*. Present species formerly known as *A. scolopaceus*, but species name pre-dated by *guarauna*; in past, on occasion, South American birds were split into two races, *scolopaceus* (Colombia to C Brazil) and *carau* (S Brazil to Paraguay, Uruguay and N Argentina). Monotypic.
Subspecies and Distribution.
A. g. pictus (F. A. A. Meyer, 1794) - Florida, Cuba and Jamaica.
A. g. elucus J. L. Peters, 1925 - Hispaniola and Puerto Rico.
A. g. dolosus J. L. Peters, 1925 - SE Mexico to Panama.
A. g. guarauna (Linnaeus, 1766) - South America, except arid W coast, Andes and extreme S.
Descriptive notes. 56-71 cm; in race *pictus*, male 1130-1370 g, female 1050-1170 g; wingspan 100+ cm. All darkish oily brown, with white marks on feathers, giving speckled appearance; distinctively shaped long bill. Resembles some immature ibises (Threskiornithidae), but has much straighter, somewhat thicker bill. Female very similar to male, but usually slightly smaller. Juvenile similar to adults, but appears streaked, not speckled, with white. Races differ in extent of white markings, size and deepness of brown coloration; nominate can have virtually no white markings on body plumage.
Habitat. Freshwater river and lake margins, open freshwater marshes, margins of mangroves, and in some areas arid brush, savanna and humid forests; recorded up to 1500 m in some areas, e.g. in Costa Rica.
Food and Feeding. Feeds primarily on apple snails (*Pomacea*), but also takes other aquatic snails, and mussels; in terrestrial habitats, diet includes land snails, lizards and variety of other small prey. Wades in shallow water locating molluscs by sight and by touch; modified bill facilitates extraction of snails and bivalves from shells (see page 91). Nocturnal foraging not uncommon.
Breeding. Nesting season varies with region: Feb-Jun in Florida, all months in Cuba, Apr-Nov in Jamaica, Jul-Dec in Costa Rica, generally Aug-Jan in South America. Some pairs monogamous but some females switch mates for second clutch. Inviolate territories defended by males year round, or at least seasonally, by distinctive loud calls, chasing and ritualistic charging displays at territory boundaries; unpaired males call monotonously day and night to attract mates; courtship feeding accompanies nest building. Nest-sites diverse, from piles of aquatic vegetation to stick nests on high tree branches, and even ground-nests. Clutch usually 5-7 eggs, averaging 5·5; incubation 26-28 days; chicks have black or dark brown down, quickly lightening to cinnamon brown; nidifugous, moving to a brooding platform of aquatic vegetation; almost fully grown at c. 7 weeks; disperse at c 15-17 weeks. All parental duties shared. Young reach sexual maturity during following breeding season; record longevity 12 years.

Movements. Sedentary in many areas, although in Florida partial migration occurs in some breeding habitats, mostly involving females; migration also noted in Brazil, but details not well known; most numerous in *llanos* of Venezuela during period Jun-Oct; distinct local movements also noted in Costa Rica, in relation to varying water levels. Elsewhere pronounced movements occur during periods of flooding or drought.
Status and Conservation. Not globally threatened. Locally common with extensive distribution. In Florida and West Indies, many populations decimated by hunting in late 19th century and early 20th century, as species highly favoured as game bird. Wetland drainage and conversion to agriculture have also had impact on species in Florida, but loss has been slowed through regulation. Populations of Puerto Rico and Pacific slope of El Salvador have been greatly reduced or extirpated, with hunting, habitat destruction and introduced predators amongst the causes; otherwise apparently stable throughout range. Rare to uncommon and local in Panama, apparently due to scarcity of suitable habitat; very local in French Guiana; locally abundant in parts of lowland E Bolivia. Spread of invasive exotic plants in freshwater habitats is additional threat to native ecosystems, although widespread adverse effects on mollusc populations not yet noted. Drainage for development and hunting likely to continue as problems, at least locally. Nevertheless, relative inaccessibility of many wetland habitats may allow species to remain locally common wherever apple snails and mussels are naturally abundant.

Class AVES

Order GRUIFORMES

Suborder GRUES

Family PSOPHIIDAE (TRUMPETERS)

- Medium-sized terrestrial birds, with fairly long neck and legs, short, stout bill and hump-backed appearance.
- 45-52 cm.

- N South America.
- Dense tropical forest.
- 1 genus, 3 species, 7 taxa.
- No species threatened; none extinct since 1600.

Systematics

Although systematists agree that the trumpeters (Psophiidae) belong in a family of their own in the order Gruiformes, there is rather less of a consensus regarding which of the other gruiform families is most closely related to them. This problem essentially arises from the combination of a lack of psophiid fossils and differences in opinion as to which characteristics of living psophiids best indicate their evolutionary relationships with other families.

In the late nineteenth century, several of the earliest taxonomists to examine psophiids in detail decided that they were most closely related to the seriemas (Cariamidae) and the Kagu (Rhynochetidae). This view was held by most systematists until 1930, when A. Wetmore proposed that cranes (Gruidae) and limpkins (Aramidae) were trumpeters' closest relatives. This second construct has been supported for the most part by subsequent systematists, including J. J. Morony, W. J. Bock and J. Farrand, who in their 1975 publication grouped trumpeters, cranes, the Limpkin (*Aramus guarana*) and rails together in the suborder Grues.

However, more recent work by J. Cracraft, comparing derived characters of the skeletal anatomy of fossil and living gruiform families, suggests that trumpeters may be most closely related to the seriemas and an extinct family of birds, the Phororhacidae, and second most closely related to the Kagu (*Rhynochetos jubatus*) and the Sunbittern (*Eurypyga helias*, Eurypygidae). In light of these findings, Cracraft proposed expanding the suborder Grues to include these four families, in addition to the trumpeters, cranes and Limpkin, and placing the rails by themselves in their own suborder. Alternatively, C. G. Sibley and J. E. Ahlquist's comparisons of the DNA of living species suggests that trumpeters are most closely related to cranes, the Limpkin and finfoots (Heliornithidae), and second most closely related to the seriemas and the Kagu. They place these six families, along with the Sunbittern and the bustards (Otididae) in the same suborder.

Both the paleontological evidence and DNA comparisons suggest that the psophiids probably originated some time in the late Cretaceous or early Tertiary approximately 70-60 million years ago. The trumpeter family currently consists of a single genus and three species which occupy non-overlapping ranges in the northern half of South America. The three species are almost entirely separated by major rivers: the Grey-winged Trumpeter (*Psophia crepitans*) occurs north of the Amazon; the Pale-winged Trumpeter (*Psophia leucoptera*) is found mostly south of the Amazon and west of the Madeira; and the Dark-winged Trumpeter (*Psophia viridis*) occurs south of the Amazon and east of the Madeira. The three species are very similar in appearance, and differ primarily in the coloration of their wings and lower throat (see Morphological Aspects). J. T. Zimmer proposed combining the Grey-winged and the Pale-winged into a single species, but H. W. and M. Koepcke report that local hunters around Iquitos, Peru, claim that these two species co-exist there and do not interbreed, which if verified, would mean that they merit treatment as two legitimate species.

The three trumpeter species are further divided into subspecies based on subtler differences in their coloration and differences in their distribution, which again appears to have been determined in part by the course of the River Amazon and some of its larger tributaries. Within the Grey-winged Trumpeter, nominate *crepitans* occurs mainly to the east of the Rio Negro, a northern tributary of the Amazon, while the race *napensis* occurs mainly to the west of this river. In the Pale-winged Trumpeter, nominate *leucoptera* occurs south of the Amazon, while *ochroptera* is found north of it. Based on aspects of its appearance, such as its ochraceous wing patch (see Morphological Aspects), *ochroptera* has traditionally been considered to be a subspecies of the Pale-winged Trumpeter; some systematists, however, feel that the geographical location of *ochroptera*, on the opposite side of a wide stretch of the Amazon from nominate *leucoptera*, and its distribution, nestled between the ranges of the two accepted races of the Grey-winged, make it more likely to be a race of that species. Nevertheless, the western portion of the *ochroptera* population is thought to be in contact with race *napensis* of the Grey-winged, and there is no strong evidence that these two forms have interbred, which supports the idea that *ochroptera* is a race of the Pale-winged rather than of the Grey-winged.

Three subspecies of Dark-winged Trumpeter are found south of the Amazon, and appear to have been separated into distinct populations by some of its large southern tributaries. Nominate *viridis* is separated from *P. l. leucoptera* to its west by the Madeira, and from *P. v. dextralis* to its east by the Tapajós. The *dextralis* population extends to the east, where it is separated from *P. v. obscura* by the Tocantins River. A fourth subspecies, *P. v. interjecta*, was described by L. Griscom and J. C. Greenway based on a single specimen. They suggested that this race formed

a population on the western bank of the Tocantins, but subsequent descriptions of this form suggest that it is probably only an intermediate population which represents an intergradation between the *dextralis* and *obscura* populations.

It has been proposed that the three trumpeter species arose during the Pleistocene period, at which time the rain forests of South America underwent a series of contractions and expansions, which paralleled the growth and decline of the major glaciers in the temperate zone. During glacial episodes, the broad expanse of Amazonian rain forest is thought to have shrunk into a number of smaller isolated patches, or refugia, which were separated from each other by more arid savanna zones. It is thought that what was once a single pan-Amazonian species of trumpeter prior to the Pleistocene, began to differentiate into separate species when different parts of the population became restricted to several isolated Pleistocene rain forest refugia. As the rain forest re-expanded following these periods of contraction, the Amazon River and its major tributaries helped to act as barriers to keep these ecologically similar species separated. It is also thought that these rivers separated populations of the same species as they re-expanded into their prior range, leading to the creation of the various trumpeter subspecies that are recognized.

Morphological Aspects

Trumpeters are about the size of a domestic chicken, measuring in the region of 49 cm and weighing up to 1·5 kg. They have a somewhat hump-backed appearance, and superficially resemble some of the larger gallinaceous birds more than they resemble other Gruiformes. Trumpeters appear to have stout bodies, but this is largely a result of the wings being held in a slightly arched and fanned-out manner, so that they completely cover the sides and back of the body and the very short tail. When the wings are lifted, the true slightness of the body is revealed.

The head and neck are covered with short, dense, velvety-looking feathers, which contribute to making the head appear somewhat small in relation to the rest of the body and to making the neck look thin. The eyes are large and dark, and the neck is long and is typically held in an S-shaped posture, which gives the bird a rhea-like profile and accentuates the hump-backed appearance. The bill bears some resemblance to those of gallinaceous birds, being short, relatively stout, slightly curved, and with a sharp tip. It is used for feeding on a range of different-sized objects, from tiny insect larvae to fruits up to 25 mm in diameter which are swallowed whole, and it is also used for removing fruit pulp surrounding the seeds of larger fruits, and occasionally for killing small vertebrates such as snakes (see Food and Feeding).

As is true for many avian species with terrestrial habits, a trumpeter's legs are strong and quite long. The front toes are sturdy, and the hind toe is elevated, as it is in a number of the other Gruiformes, including the cranes and the rails. Trumpeters spend most of their day walking around their territory, foraging for fruit and invertebrates on the forest floor. Pale-winged Trumpeters normally travel at a pace about equivalent to that of a person on a leisurely walk, but they are also able to run very fast. Among undisturbed trumpeters, running is most commonly observed among individuals that are playing or are chasing intruders off their territory (see General Habits). Trumpeters also run or fly off to safety when they encounter terrestrial predators, such as jaguars, ocelots or humans.

The wings are short and rounded, and, although the birds have relatively large pectoral muscles, their powers of flight are weak, allowing them to fly for short distances only. Trumpeters are more inclined to walk around a small obstacle, such as standing water, than to fly over it. Flight is usually limited to getting to and from trees where they roost and nest, escaping from terrestrial predators, and the occasional crossing of narrow streams or channels. Although trumpeters have been reported by some authors to be able to swim, they appear only to do so when they exhaust their powers of

The trumpeters, three allopatric species of somewhat chicken-like birds, are found only in the humid equatorial forests of the Amazon Basin. In overall appearance the three are very similar, but they are differentiated most notably by the coloration of the wings and, to a lesser extent, of the lower foreneck. The Pale-winged Trumpeter, for example, has a striking white to ochre hind-wing patch with iridescent wing-coverts. The seeming corpulence of the body is deceptive: the wings are held somewhat arched and distended, thus concealing the rather slight body structure, and contributing to give the bird a hunch-backed look; this is accentuated by the small head and slender neck, the latter habitually held in an S-bend position.

[*Psophia leucoptera leucoptera*, Tambopata Reserve, Peru. Photo: Günter Ziesler]

The trumpeter's short, dense neck and head feathers contrast strongly with the much laxer soft plumage of the wings and mantle. This Dark-winged Trumpeter is easily identified by the dull greenish colouring on the upperparts; it also shows off the iridescent purple on the lower part of the foreneck. Note the large, dark eye and the stout, downcurved bill with its sharp tip, handy for removing pulp from large fruits and similarly for dealing a deathblow to a small snake.

[*Psophia viridis viridis*, Amazonas, Brazil. Photo: Luiz Claudio Marigo]

flight, as they attempt to fly across water, for instance to escape from gunfire. Under normal conditions, they do not swim and do not attempt to cross rivers or other wide bodies of water.

Male and female trumpeters are identical in appearance, although adult male Pale-winged Trumpeters weigh on average about 10% more than adult females; data on adult weights are scant for the other two species. Trumpeters have a predominantly black plumage with the exception of their secondaries and inner wing-coverts, which are grey in the Grey-winged, ochre to white in the Pale-winged, and dark green in the Dark-winged. When the wings are held in their resting position, the contrastingly coloured secondaries and wing-coverts form a large distinctive oval patch that covers much of the back, the sides and the rump. This "hind-wing patch" is given a soft and uniform appearance by the similarly coloured, overlying, long hair-like filaments present on the lower portions of the inner wing-coverts.

The contrastingly coloured hind-wing patch appears to facilitate maintenance of visual contact among individuals in groups that are travelling or foraging. It also appears to play a role in accentuating some of the inter-individual social displays that are performed with the wings (see General Habits). Additionally, the patch appears to convey some information about the age of the individual bird. In Pale-winged Trumpeters, the parts of the secondaries that form the hind-wing patch are darker brown in young individuals than in birds that are a year old or more, with the result that young birds have a hind-wing patch that is darker than older birds; it is not known whether this phenomenon also occurs in the other species.

Once a young Pale-winged Trumpeter's first full set of feathers has grown in, it initiates a pattern of gradual year round moult, replacing one to several primaries or secondaries at a time. The moult patterns of the other two species are not known, but are presumed to be similar.

Habitat

Trumpeters live in dense tropical forests in the Amazon and Orinoco Basins of South America, where they are year round residents. They are found in the cloud forest that covers the eastern foothills of the Andes at elevations as high as 750 m, and their range extends far into the eastern lowland rain forests of Amazonia. Trumpeters tend to be heavily hunted near human settlements (see Status and Conservation), and for this reason are most abundant in the interior of large areas of forest in which there has been no long-term detrimental impact by humans.

Although little is known about Dark-winged Trumpeters, Pale-winged Trumpeters defend, and Grey-winged Trumpeters appear to defend, permanent year round territories, on which they feed, roost and breed. In a five-year study of wild Pale-winged Trumpeters, the present author found that territories were very large, ranging from 58 ha to 88 ha, with an average of 72 ha, and that all forested habitat was occupied by territorial groups. A series of experimental manipulations of the density of fallen ripe fruit on Pale-winged Trumpeters' territories at different times of year produced results which suggest that the territories need to be large to provide the resident group with sufficient quantities of fruit during periods of low food abundance, such as occur during the dry season.

Trumpeters' territories can contain a variety of different forest types, including mature forest, late and early successional forest, and small areas of seasonally flooded swamps. Pale-winged Trumpeters feed throughout the area encompassed by their territories, but most heavily utilize areas of forest that are in late successional or mature stages, where there is a high diversity of plant species, a high density of trees, and a relatively open understorey, allowing for ease of travel and facilitating detection of predators. Trumpeters also forage in early successional forest that is growing back, in regions where rivers have shifted course and laid down new muddy beaches, or where

vegetation is growing back over sediment-filled lakebeds. As forests begin to recolonize such regions, they pass through a series of successional stages, some of which contain relatively high densities of fruiting trees, such as *Cecropia tesmanii* or *Ficus*, which produce fruit that is eaten by trumpeters. The areas of early successional forest that are used by Pale-winged Trumpeters have an understorey that ranges from moderately dense to fairly open, and a moderate density of trees that provide a covering canopy. All three species appear to be wary of entering regions of the forest that have a low density of trees or other covering vegetation.

Trumpeters obtain their drinking water throughout the year from streams or channels in the forest, or from pools that form on the forest floor as a result of rainfall. Much of the lowland rain forest that they inhabit becomes partially flooded during the rainier portion of the year, at which time the birds walk around or fly across the areas of standing water that form on their territories. J. Price noted that on average about 15% of a Pale-winged Trumpeter group's territory might be covered with water at the peak of the rainy season, but the present author found that the substantial increase in the abundance of fallen fruit at this time of year more than offsets the loss of feeding area due to flooding.

As a general rule, trumpeters roost in the branches of trees in different parts of their territory from one night to the next, and lay their clutches in elevated, hollowed out, hole-like cavities in tree trunks. Pale-winged Trumpeters show a special preference for cavities that have been excavated in the elevated bulge that is characteristic of *Iriartia* palm trees. These palms grow in mature forest, and are harvested in settled areas both for their bark, which is used to make strong, termite-proof wood planks, and for the delectable "heart of palm" that grows in the centre of the tree crown.

General Habits

Trumpeters live all year round in groups of 3-13 individuals. Although very few data are available on wild Grey- or Dark-winged Trumpeters, Pale-winged Trumpeter groups contain an average of seven birds, which usually include three unrelated adult males, two unrelated adult females, and sexually immature offspring.

Trumpeter groups are quite cohesive and social, and members travel, forage, defend their territory, preen, play, bathe and roost together. On a typical day, a Pale-winged Trumpeter group flies down from the night-time roost to the forest floor at first light. There usually follows a short period of social interaction, during which young birds and subordinate adults approach more dominant birds and "Wing-spread", crouching before the dominant bird, spreading the primaries and secondaries horizontally, and giving a high-pitched twittering call that mimics the twittering call of young chicks (see Voice). This display of subordinance is given by individuals of all ages, from newly hatched chicks to adults, and is always directed towards individuals that are higher in dominance rank than the displaying bird.

Within Pale-winged Trumpeter groups, adult individuals have a within-sex dominance hierarchy, and usually limit social display to other individuals of the same sex. Chicks that are three months of age or younger perform the Wing-spread display frequently to all birds in their group, and older birds perform the display regularly during social interactions that occur throughout the day. The Wing-spread display puts the displaying individual in a vulnerable position, and also prominently exhibits the secondaries, which are darker in juvenile birds than in adults (see Morphological Aspects). By displaying their juvenile plumage, or mimicking juvenile birds, subordinate individuals appear to be acknowledging their subordinate status to more dominant individuals. Dominant individuals frequently respond to subordinates that perform the Wing-spread display with a "Wing-flick" display, during which the dominant bird rapidly flicks its folded wings forward to a vertical position and then drops them back down to cover the back, several times in succession. The Wing-flick display appears to be a means by which a dominant trumpeter may non-aggressively affirm its dominance over a subordinate individual.

After several minutes of social interaction, the group sets off walking, and usually travels directly to a large fruiting tree, where the birds feed on ripe fruits that have fallen to the ground. The group typically spends the day traversing its territory, feeding at different fruiting trees and hunting for arthropods in the

Trumpeters live in well organized social groups, and bathing is one of the many activities that are performed in small parties, as is also the case, for example, of foraging, preening and roosting. Bathing is important for cleaning the plumage and helping to remove any unwanted parasites. This Grey-winged Trumpeter enjoys a dip in a shallow forest pool, immersing itself partly and moving the wings vigorously about. It has been reported that trumpeters are capable of swimming, although when they encounter major water barriers, they normally prefer to walk round or fly over.

[*Psophia crepitans*, Brazil. Photo: R. Seitre/Bios]

leaf litter. During the course of its daily travels, a group may detect another group intruding on its territory. Trumpeters have excellent hearing and can detect the presence of groups that are several hundred metres distant, and inaudible to the human ear. When they detect an intruding group, Pale-winged Trumpeters respond immediately, running silently at full speed towards them. If the intruders hear the residents coming and retreat rapidly, they may be able to escape, leaving the territory before the resident group catches up with them, but usually the residents catch the intruders while they are still trespassing and a fight ensues.

During territorial fights between two groups, the residents chase the intruders towards the residents' territorial boundary. Resident birds chase after individuals of the same sex in the opposing group with their heads lowered, and their wings "back-arched", or held slightly arched above their backs, with their flight-feathers fanned down so that they almost touch the ground. If a resident catches up with an intruder, it may peck it and then jump into the air, flapping its wings and kicking forward like a fighting cock. If it succeeds in knocking the other bird over, it may continue to alternate between pecking and kicking forward until the fallen bird is able to get up and either flee or fight back.

During territorial fights, in addition to chasing and attacking intruders, the resident birds give the loud territorial call for which the trumpeters have received their vernacular name (see Voice). It is usually the females and juveniles that stand and call, while the males continue to chase after individuals in the other group. After a resident Pale-winged Trumpeter group has fought an intruding group and chased it to a territorial boundary, males in the two groups sometimes interact in a less aggressive manner, approaching each other to perform subordinate Wing-spread and dominant Wing-flick displays, and occasionally offering food to each other, in a manner described in more detail below.

Subordinate adult male Pale-winged Trumpeters sometimes transfer between groups during territorial fights. The lower the rank of the male, the more likely he is to transfer. These transfers appear to allow males to assess whether reproductive opportunities may be better in other groups (see Breeding), as a male always returns to his original group within a few weeks, unless he attains a position of higher dominance status in the new group.

The amount of time that Pale-winged Trumpeter groups spend in loafing activities is related to the amount of ripe fallen fruit that is available on their territories. When little fallen fruit is available, groups spend most of the day actively searching for food. When there is an abundance of fallen fruit, they tend to follow a more relaxed schedule, travelling slowly and occasionally flipping over leaves to look for arthropods (see Food and Feeding), and taking longer breaks to preen or, on hot days, to bathe and to sun.

Preening is frequently a social activity among Pale-winged Trumpeters. Adults of the same sex will approach each other and solicit preening by bowing down their heads before one another, and juveniles will approach other juveniles or adults and do the same. A trumpeter will preen mites and small bits of dried skin from another bird's head and upper neck, rapidly opening and closing its bill in these regions. The sensation caused by such preening appears to be pleasurable to the recipient, which usually closes its eyes, further lowers its head, and, at times, relaxes to the point where it may briefly lose its balance. The individual that has been preened usually reciprocates by preening the preener. Dominant individuals preen subordinates and vice versa, and observations show that either of the birds is equally likely to be the first to solicit and receive preening from the other.

When food is relatively abundant, feeding is also sometimes a social activity. A Pale-winged Trumpeter will pick up a fruit or an arthropod in its bill, hold its head high with its wings slightly arched over its back, and parade around giving a repeated, medium-pitched single note call. Birds of the same sex or juveniles will then run over and beg for the food, crouching down, giving a food-begging call (see Voice) and twittering submissively. The individual carrying the food usually keeps it for several seconds, or sometimes several minutes, before offering to feed it to one of the begging birds. The food is usually eaten immediately by the begging bird, but sometimes it can be passed back and forth several times between the donor and the recipient before one of them finally swallows it. Dominant individuals will beg for food from subordinate birds, but the dominant bird may stop behaving submissively and grab the food away, if the subordinate does not relinquish it after several seconds.

Play is a loafing activity that can involve a single bird, several birds or the whole group. During play, Pale-winged Trumpeters engage in many forms of behaviour that are similar to those observed during territorial fights. Individuals flap their wings, jump into the air and run in short bursts, with the head lowered and the wings back-arched. Birds also attack objects such as leaves or fallen twigs, alternating between pecking and kicking forward at them. When more than one bird plays, the individuals involved usually alternate between attacking objects by themselves and chasing after one another. In the middle of a chase, two birds will sometimes face off, raise their necks, and peck at each other without making contact for a short period of time, and then split up and chase after other individuals. Bouts of play by one or more individuals usually do not last more than a few minutes.

The trumpeters' day comes to an end after the sun has set and the forest has begun to darken, when they fly 8-15 m up to roost in the branches of trees. Individuals within a group usually spread out onto different branches in the same tree or in several different trees. Groups do not have specific roosting sites that they use on a regular basis.

Voice

In general, trumpeters are quite vocal birds, and produce a variety of different calls which serve a wide range of functions. The call for which trumpeters are named does not sound very trumpet-like, but is quite loud and consists of a quick descending series of 3-5 staccato notes followed by a long, low-pitched, descending resonant vibrato "Oh-oh-oh-oh-ooooooooh". All birds except chicks can produce this call, and it is most frequently used by resident groups to proclaim their territorial occupancy. During territorial fights the resident group calls and chases the intruding group, while the intruders usually remain silent until they have retreated back onto their own territory, at which point they return the territorial call. At night, all groups produce this territorial call from their roosts more or less simultaneously. Starting about two hours after sunset, members of one group will call and then other groups will respond, each group calling for a total of about one to two minutes. These calling bouts appear to be used to announce territorial occupancy, and continue throughout the night at intervals of about two and a half hours. When two territorial groups roost in close proximity to each other near a shared territorial boundary, the following morning, after flying down from their night-time roost, they will usually run towards the shared boundary, where each group will then stand on its respective side and exchange territorial calls.

Various other types of call are produced by Pale-winged Trumpeters during social interactions. An aggressive threat call is quite similar to the staccato notes that make up the first part of the trumpeters' territorial call, except that it has a harsher, more cackling sound and often consists of ascending notes. The high-pitched twittering that is one of the first calls produced by newly hatched chicks is retained into adulthood, and is given frequently by subordinate individuals during social interactions with more dominant birds. The chicks' food-begging call, consisting of two short pure tones, the second higher in pitch than the first, is also used by adults when they beg for food from another individual (see General Habits). An individual carrying food which it intends to feed to another bird gives a somewhat nasal "enhh-enhh-enhh-enhh..." call that consists of a soft, medium-pitched short note that is repeated at medium speed.

Trumpeters are highly frugivorous. It is estimated that 90% of their diet consists of fruit pulp, the remaining 10% being made up of arthropods and small vertebrates. The Pale-winged Trumpeter forages on the forest floor, for the most part relying on the large primates to knock down ripe fruits from the branches above. There is no need to follow the monkeys as they search for fruiting trees, as the competitors for fallen fruit are few.

[*Psophia leucoptera leucoptera*, Manu National Park, Peru. Photo: Peter T. Sherman]

This same call may be given by adult males or females during the short period of solicitation that may precede copulations (see Breeding).

Pale-winged Trumpeters also produce distinct calls to alert other group members to potential predators. Individuals react to terrestrial predators, such as felids or humans, or to other types of terrestrial disturbance, by producing loud, sharp squawks. Individuals react to potential aerial predators, such as raptors perched in trees or flying overhead, by producing a low-pitched, low-volume call that is a mixture of a hum and a growl. Pale-winged Trumpeters also produce a distinctive "hm-hm-hm-hm-hm..." call on encountering a snake. This call consists of a short, rapidly repeated medium-pitched note that is given by the individual that discovers the snake, and by other individuals which join it, while they investigate the snake from a distance of some 50-100 cm away. Small non-poisonous snakes under 25 cm long are usually investigated briefly, and then killed and eaten, while larger snakes are investigated for several minutes or longer, throughout which time all of the birds investigating the snake produce this unmistakable call.

Food and Feeding

Trumpeters are primarily frugivorous. C. Érard, M. Théry and D. Sabatier found that fruit pulp accounted for 90% of the dry weight stomach contents of Grey-winged Trumpeters that were collected at different times of year in French Guiana. Similarly, the pulp of ripe fruit accounted for 90% of the dry weight, and 88% of the total calories, ingested by adult Pale-winged Trumpeters throughout the year. Trumpeters are unable to remove husks from most fruit, and thus feed mainly on soft fruits that lack thick protective coverings. Small fruits of under 20 mm are usually swallowed whole, while pulp may be pecked away from larger fruits. All seeds that are swallowed are defecated intact and unscarred.

Although trumpeters remove fruit from some small plant species that grow close to the forest floor, the majority of the fruit that they ingest comes from tree species of medium to large height and crown diameter, that produce substantial quantities of fruit. When ripening fruit is present, these tree species attract a variety of arboreal frugivores, which, in the process of feeding, knock some of this ripe fruit to the ground. Fruit-eating birds such as guans (Cracidae), toucans and aracaris (Ramphastidae) knock down small amounts of ripe fruit, but trumpeters are primarily dependent on primates, such as spider monkeys (*Ateles*), capuchins (*Cebus*) and squirrel monkeys (*Saimiri*), which knock much greater quantities of ripe fruit to the ground when they feed. Although Pale-winged Trumpeters commonly forage below trees in which primates are feeding, they rarely follow primate troops from one fruiting tree to another to eat ripe fruit as it is being knocked down. Most species of ripe fruit on which trumpeters feed persist for several days to a week on the ground before they begin to rot or mould, and there are very few animals which compete with trumpeters to feed on fallen fruit.

Invertebrates and small vertebrates make up the remaining 10% of the trumpeters' diet. Wild Pale-winged Trumpeters consume a wide variety of arthropods, including beetles and beetle larvae, caterpillars, cicadas, grasshoppers, katydids, spiders, millipedes, centipedes, scorpions, and ants and termites and their larvae. Stinging or biting arthropods are usually disabled by repeated pecking before being swallowed. The larger species of millipedes eaten by trumpeters exude hydrogen cyanide droplets when disturbed, and Pale-winged Trumpeters wipe these species against the contour feathers below their wings before eating them, the preliminary rubbing often lasting several minutes. It is quite common for a pair of Pale-winged Trumpeters to take turns, one bird wiping a millipede against its own contour feathers for a short while before dropping it, after which the other picks it up and takes over for another brief turn. After several minutes of this behaviour, the two birds usually share

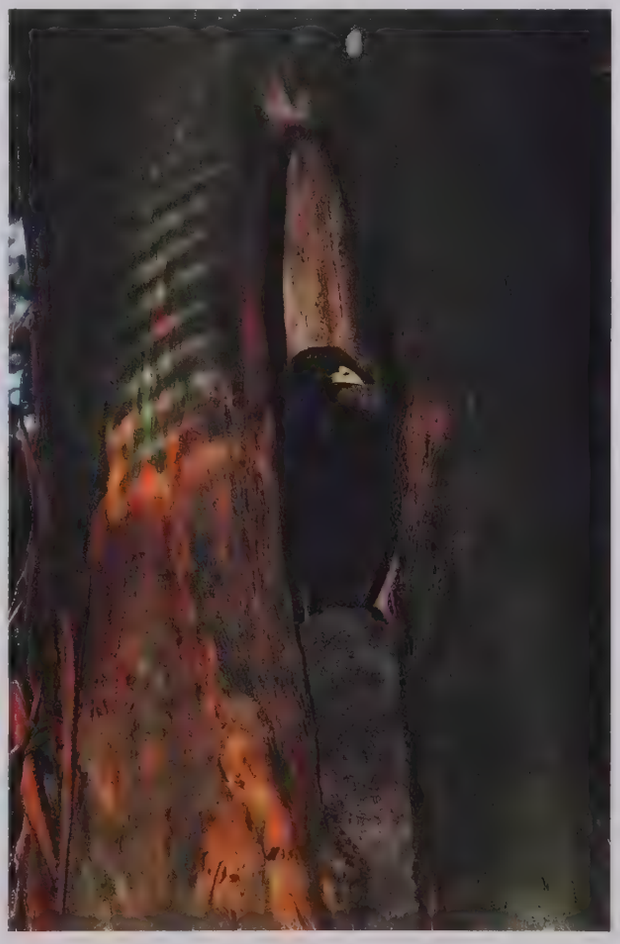
in eating the millipede. In addition to removing some of the noxious exudate from the millipede before it is eaten, rubbing millipedes against the feathers and skin probably also serves to repel some of the trumpeter's ectoparasites in the same way that "anting" behaviour is thought to serve a similar function in other birds. Grey-winged Trumpeters have also been observed to rub their feathers with millipedes, as have two other avian species, the Jungle Myna (*Acridotheres fuscus*) and the European Robin (*Erithacus rubecula*).

Trumpeters locate arthropods in several ways. One common method is to use the bill to flip over dead leaves and other vegetation during periods of slow travel or rest. All three species also feed commonly on arthropods that are flushed from the leaf litter on the forest floor by swarms of foraging army ants. When a trumpeter group locates a foraging army ant swarm, the birds stand close to the areas in which the ants are hunting prey, and dash in to grab arthropods that are attempting to escape from the ants. Trumpeters also occasionally feed on arthropods that drop or fly to the ground when large groups of primates, such as squirrel monkeys, engage in bouts of arboreal insect-foraging. At such times, trumpeters follow along beneath the primate troop, catching mainly grasshoppers and katydids. They also feed on alate termites which periodically emerge and fly away from their colonies in large numbers, and termite and ant larvae, if these are being transported across the surface of the forest floor.

Small vertebrates are only occasionally eaten. Pale-winged Trumpeters periodically kill and eat small snakes, usually under 25 cm long, and on very rare occasions they scavenge, eating dead frogs or lizards, and on one occasion a dead mouse.

Although adults are highly frugivorous, newly hatched chicks are fed large numbers of arthropods. For the first several weeks after they hatch, Pale-winged Trumpeter chicks consume about twice as many arthropods as fruits, but the proportion of fruit in their diet then increases gradually.

Breeding



Both wild Pale-winged Trumpeters and captive Grey-winged Trumpeters form co-operatively breeding groups: although only a few individuals in the group breed, all group members help raise the chicks. In Pale-winged Trumpeter groups, only the dominant female contributes eggs to the clutch; adult males in the group are usually unrelated; and the three highest ranking males copulate with the dominant female. This mating system in which several males copulate with a single breeding female and then help to raise a single brood is a special type of co-operative breeding known as co-operative polyandry. The strategy of co-operative polyandry is extremely rare, and has been reported for only eight other avian species, including the Tasmanian Native-hen (*Gallinula mortierii*), the Galapagos Hawk (*Buteo galapagoensis*), the Dunnock (*Prunella modularis*) and the Stripe-backed Wren (*Campylorhynchus nuchalis*).

Trumpeters' breeding appears to be timed so that chicks hatch around the beginning of the rainy season, at which time the abundance of fruit and arthropods begins to increase steadily in South American rain forests. Pale-winged Trumpeters start showing the first signs of breeding activity when the dominant male and the dominant female in each group begin to investigate nesting cavities, about two and a half months before the breeding female begins to lay the clutch. The majority of the cavities investigated are holes in tree trunks that have been excavated by other animals, such as parrots, and are protected from the rain. Occasionally, Pale-winged Trumpeters lay clutches in roofless, naturally occurring cavity-like spaces, formed where a tree trunk splits into two halves. During the investigation of nesting cavities, one member of the dominant pair, or occasionally both, flies up and enters the cavity, remaining inside for anything from ten seconds to several minutes. The individual sometimes kicks or tosses out leaves and other debris from the cavity floor, and may occasionally sit down as if to incubate.

Investigation of nesting cavities increases in frequency up to the time when the breeding female begins laying her clutch. Pale-winged Trumpeters investigate 10-12 different nesting cavities on their territories, but begin to focus their attention on a single cavity about a week before laying. Preparation of the chosen cavity is undertaken either by the dominant male or by the dominant female, and consists simply of clearing out any loose debris, leaving a thin layer of well packed decayed wood on the cavity floor, on top of which the eggs are laid. Nesting cavities used by Pale-winged Trumpeters are located an average of 11 m above the ground, and have a shallow lip between the cavity floor and entrance, presumably to make it easier for chicks to climb out of the cavity the day after they hatch.

About a month after the dominant pair begin investigating cavities, and a month and a half before the breeding female begins to lay the clutch, adult male Pale-winged Trumpeters begin to feed the breeding female fruit and arthropods. Although males offer and feed food to each other throughout the year (see General Habits), they only provide food to the breeding female during the breeding season. The dominant male feeds the breeding female most of the food that she receives from other birds; he locates most of this food himself, but receives some, and grabs some away, from other adult males in the group.

Trumpeters rarely copulate outside the breeding season. In Pale-winged Trumpeter groups, males begin to copulate with the breeding female about six weeks before she begins to lay. P. Eason and P. Sherman estimated that during the first four weeks of this period, it is still too early for the breeding female's eggs to be fertilized, and at this time males in a group disrupt each other's copulations about half of the time. Eggs can potentially be fertilized during the final two weeks before laying begins up until 24 hours before the final egg is laid, and during this time the three most highly ranked males in a group all try to guard the breeding female closely, and attempt to interrupt all of each other's copulation attempts. The dominant male wins the battle, obtaining about two thirds of the copulations with the breeding female during her fertile period. He is unable to prevent subordinate males from sneakily obtaining the remainder of the suc-

All three species live in highly organized hierarchical groups and practise co-operative polyandry, a rare breeding system in which several males copulate with one breeding female and, together with the rest of their group, help to raise a single brood. The nest-hole is normally sited well up a tree trunk. The hole, often previously excavated by another species, is cleared of loose debris after which the clutch, normally of three eggs, is laid. Pale-winged Trumpeters have been extensively observed in the wild and it is known that incubation is carried out by the dominant female, with the aid of the first three dominant males. When an incubating bird is due to be relieved at the nest, the whole group assembles below the nest-site, waiting for the change-over to take place, a real co-operative effort.

[*Psophia leucoptera leucoptera*,
Manu National Park, Peru.

The three chicks of a normal clutch hatch synchronously after some four weeks' incubation. Highly precocial at one day old, the chicks quite literally launch themselves into society as they "freefall" from the rim of the nest cavity, accompanied by the encouraging calls of the attendant group 10-11 metres below. Covered with stripy russet down, they blend in well with the leaf-covered forest floor, but are mainly reliant on older group members for protection against predators. This month-old Pale-winged Trumpeter chick is still being fed by an adult; by three months old it will have become almost fully independent, although it may continue to beg some food.

[*Psophia leucoptera leucoptera*, Manu National Park, Peru. Photo: Peter T. Sherman]

cessful matings, of which the second highest ranked adult male (the Beta male) obtains about three quarters, and the third highest ranked adult male (the Gamma male) obtains about a quarter.

Mating in Pale-winged Trumpeters is often preceded by a short period of solicitation, during which the female crouches and presents her rump to the male, and the male stands close behind, stretches his neck and walks in partial circles, while the female pivots to keep her rump facing the male as he circles. These solicitations usually last about 5-10 seconds, after which the male mounts the female and they copulate. Although several general accounts report that trumpeters engage in noisy and acrobatic courtship dances, the authors of these accounts give perfect descriptions of the actions and behaviour exhibited during play within groups and in territorial fights between groups (see General Habits), and thus appear to have mistaken these activities for courtship display.

Trumpeters lay white eggs that have a somewhat rough shell and measure about 60 x 48 mm. Wild Pale-winged and captive Grey-winged Trumpeters lay clutches ranging from two to four eggs, and averaging about three. Eggs are laid at two day intervals, and incubation does not begin until the final egg is laid, after which the clutch is incubated continuously.

In a captive Grey-winged Trumpeter group of three individuals, C. Horning, M. Hutchins and W. English found that the male and two females all shared incubation. In wild Pale-winged Trumpeter groups, the dominant female incubates from dusk through to late morning, and one of the adult males incubates during the rest of the day. In this species, the dominant male takes about 75% of the late morning to dusk incubation shifts, while the remaining 25% of these shifts are split about equally by the group's Beta and Gamma males. When it is time for a male to replace the dominant female, or vice versa, the entire group travels to the nesting cavity and waits while the change occurs. Subsequently, the group and the replaced individual leave the vicinity of the nesting cavity, to travel and forage elsewhere on the group's territory.

For all three species, incubation lasts about four weeks. The chicks hatch simultaneously, and leave the nesting cavity the following day. While the group members call from the ground, each Pale-winged Trumpeter chick climbs onto the entrance lip of the nesting cavity and then jumps. After hitting the ground following the free-fall descent of up to 11 m, the chicks initially appear stunned, but within seconds they are on their feet and begging for food.

When chicks hatch, they are covered with down that is primarily russet-coloured. A stripe runs across the top of the head and several run down the back, creating a pattern that is highly effective in helping them to blend in with the dead and decaying vegetation on the forest floor. By ten days of age, the black contour feathers and flight-feathers have grown out enough to become just visible. By six weeks of age, the chicks are beginning to look like small versions of adults, and are able to fly for short distances.

Trumpeter chicks are precocial and are able to walk, run and climb the day after they hatch. Although newly hatched chicks peck at the ground, they do not pick up anything edible and are completely dependent upon older birds to provide them with food for about three weeks. By four weeks of age, wild Pale-winged Trumpeter chicks provide themselves with about 25% of their daily food intake, and by three months old, they are feeding almost completely independently, although they continue to beg food from older individuals in their group.

Newly hatched chicks are also dependent upon older individuals in their group to help protect them from predators. In a captive Grey-winged Trumpeter trio and wild Pale-winged Trumpeter groups, all individuals helped with the chick-care, albeit to varying degrees. During four years of observation on wild Pale-winged Trumpeter groups, the dominant male and female and the group's previous offspring all fed young chicks roughly equal amounts of food. The subordinate adult female, however, always fed the chicks significantly less than the dominant female, and the Beta male always fed the chicks significantly more than the dominant male. The Gamma male fed chicks more food than the dominant male during two years, and roughly equivalent amounts during the other two years.

Potential predators of both chicks and adults include raptors, felids and snakes. In Pale-winged Trumpeter groups, the dominant male was most frequently involved in protecting chicks from predators, and the subordinate adult female was least frequently involved, while the remainder of the group contributed about equally at an intermediate level. Beta and Gamma males'

participation in incubation, feeding and protecting chicks may be due in part to their having some probability of fathering one or more of the chicks through their copulations with the breeding female during her fertile period. Similarly, the subordinate adult female's lack of participation in these same activities may be due partially to her lack of relatedness to the chicks or other group members.

In Pale-winged Trumpeter groups, if one or more of the chicks from the first clutch survive, no subsequent clutch is laid until the next breeding season. If a clutch is lost before or after the chicks hatch, the breeding female will lay a subsequent clutch, as long as the breeding season has not yet ended. About half of the clutches incubated by Pale-winged Trumpeters failed to produce young, and appeared to have been lost to arboreal egg predators such as primates or snakes. Additionally, about half of the Pale-winged Trumpeter chicks that hatched disappeared during their first month of life. This seems to be due in part to roosting chicks' vulnerability to predators such as ocelots and other felids, or snakes. Until they are able to fly, Pale-winged Trumpeter chicks roost alone, climbing up lianas or sloping trunks of small trees. For their first three weeks chicks roost about 1-2 m above the ground, but for the next three weeks roost height increases to 3-5 m. Adult Pale-winged Trumpeters roost at heights of 8-15 m in the trees above the chicks, and, lacking the ability to see in the dark, are unable to protect the chicks from predators. All Pale-winged Trumpeter chicks that survived their first month of life lived to adulthood, at which time they left their natal groups.

The offspring of wild Pale-winged Trumpeters usually help to raise one clutch of siblings before dispersing from their natal group. Males, and presumably females, reach sexual maturity at two years of age, and it is around this time that individuals of both sexes independently disperse from their natal groups and join other groups. In wild Pale-winged Trumpeter groups, offspring rarely obtain a breeding position in their natal group due to a combination of the longevity of established breeding individuals and incest avoidance. Additionally, all forested habitat is occupied by other territorial trumpeter groups (see Habitat), making it extremely difficult for offspring to establish a new territory of their own. Sexually mature Pale-winged Trumpeter offspring are thus left with the option of staying "at home" and not breeding, or dispersing and attempting to obtain a breeding position in another group.

Dispersing is an easier task for males than for females: whereas adult males are readily accepted by the dominant individuals in new groups, adult females that attempt to transfer into new groups are treated aggressively and are frequently chased off. The acceptance of unrelated adult male Pale-winged Trumpeters into a territorial group may be related to the group's need to contain several adult males in order to defend successfully a territory that is large enough to provide sufficient quantities of food throughout the year (see Habitat).

This need may have helped to set the stage for the evolution of co-operative polyandry in Pale-winged Trumpeters. When adult males in a group are unrelated to the breeding female, there is the possibility for these males to copulate with her. Although a group's dominant male attempts to maintain exclusive paternity of the clutch by aggressively guarding the breeding female during her fertile period, the female co-operates with subordinate adult males in her group during all of their copulation attempts. As explained above, subordinate adult males provide a significant amount of help with raising the group's chicks. It has been shown for several other co-operatively breeding avian species, such as the Dunnock and the Acorn Woodpecker (*Melanerpes formicivorus*), that the amount of help that males contribute to rearing chicks appears to be related to their probability of paternity. Thus a breeding female Pale-winged Trumpeter may be able to increase her fitness, as measured by the likelihood of her offspring surviving and successfully reproducing, by copulating with all males in her group as equally as possible. Whether subordinate male Pale-winged Trumpeters would contribute equivalent amounts of help to raising chicks if they did not obtain any copulations with the breeding female is not known.

Movements

Trumpeters are non-migratory. Although little is known about the Dark-winged, the Pale-winged defends, and the Grey-winged appears to defend large, year round territories with stable boundaries (see Habitat). Although Pale-winged groups occasionally trespass in the areas that lie just outside their territorial boundaries, they spend the majority of their time on their own territories.

Typically, a Pale-winged Trumpeter group spends the morning visiting a succession of different fruiting trees on the territory, and feeding at them. The afternoon is more likely to be spent walking around different parts of the territory and foraging for arthropods, with occasional visits to fruiting trees. If there is a lot of fallen fruit available below one tree and little fruit available elsewhere on the territory, the group may remain near that tree for much of the morning, alternating between feeding at the tree and preening or foraging for leaf litter arthropods a short distance away. Usually there is a limited amount of edible fruit available below any given tree, and after feeding for 2-6 minutes, the group travels, often in a straight and direct path, to another fruiting tree. In the course of a day, Pale-winged Trumpeter groups traverse much of their territory, travelling an average of 3·7 km on a typical day.

Relationship with Man

There are several legends concerning trumpeters. Some Brazilian tribes consider them to be amongst their ancestors. At the turn of the century, natives of Guyana told naturalists that trumpeters learned how to make their loud trumpeting call from the rooster, and that tame trumpeters were used in Brazil to herd cattle, and were especially skilled at making strays rejoin the herd.

Trumpeters' local names vary from region to region. In Surinam, the common name for the trumpeter is "Kamee-kamee", or "camel-back", derived from the Dutch word *kameel* for camel. In Brazil and elsewhere, the trumpeter is commonly known as the "Jacamim", which in the language of the Tupi Indians means "bird with a small head". In the Pará region of Brazil, and in French Guiana, the common name for the trumpeter is "Agami", a name which the French have adopted as their standard vernacular name for these birds. The English name "Trumpeter" and the German "Trompetervogel" derive from *oiseau trompette*, the eighteenth century French scientist-explorer C. M. de La Condamine's translation of *trompetero*, the name given to the birds by Spanish colonists of Maynas on the upper Amazon, to describe the trumpeters' loud territorial call, which was considered to have a trumpet-like quality.

Linnaeus named the genus *Psophia* based on the Greek word *psophos*, meaning an "inarticulate sound", and referring to the belief that trumpeters produced their loud call with their anus, while breaking wind. Although this notion was contested by Pallas in 1766 and Vosmaer in 1768, the belief persisted into the twentieth century. In 1908, F. and A. Penard reported: "Long before science discovered it, natives knew the booming call (of trumpeters) was made by the anus and not the beak". These authors further report that the Guyanan Indians believe that trumpeters stole this trick from the rooster, who cries over its loss every morning.

Trumpeters are commonly kept as pets by the local people living in or near South American rain forests. Pet trumpeters are generally acquired by capturing young birds from the wild or by removing eggs from nesting cavities and then adding them to clutches being incubated by hens. Trumpeter chicks that are raised in captivity become tame and very affectionate towards their human masters. Chicks raised from a young age often imprint on people and come to recognize the individuals associated with their household as members of their "group". A tame trumpeter, when approached by a familiar person after some period of absence, will frequently behave subordinately, running over to him to Wing-spread at his feet. Tame trumpeters will

Trumpeters do not appear to be in any imminent danger of extinction, but it is known that their populations are dwindling. The main threat comes from deforestation, for trumpeters need extensive undisturbed areas in which to live and breed. While they make delightful, very tame pets, unfortunately they are not easily bred in captivity. To date, very few chicks have been reared successfully in zoos, almost all of them Grey-winged Trumpeters.

[*Psophia crepitans*, San Diego Zoo, California. Photo: Kenneth W. Fink]

also solicit preening and beg for food from familiar people in the same manner that wild trumpeters carry out these social activities with each other (see General Habits).

Pet trumpeters are also valued by their owners for their utility as "watch dogs". Tame trumpeters respond to unfamiliar people, potential predators and disturbances with the loud, squawking alarm call used in the wild to draw other group members' attention to terrestrial predators (see Voice). Although trumpeters have a reputation for being excellent snake hunters, in normal circumstances they will only attack and kill small snakes (see Food and Feeding). They do have a keen eye for spotting snakes, and will draw attention to larger snakes by standing close to them and producing a distinct call for several minutes or sometimes longer (see Voice). Pet trumpeters are often kept with poultry and they are commonly considered to help protect them from potential harm.

Status and Conservation

Although trumpeters are not currently considered to be in immediate danger of extinction, their populations are in a state of decline and their future remains uncertain. The main threat is deforestation. As trumpeters occur only in dense tropical forest, partial or total clearing of rain forests, as is occurring in South America at an ever-increasing pace, makes areas uninhabitable for trumpeters. The fact that they need to defend very large areas to provide themselves with a year round supply of food (see Habitat) further contributes to the problem. Animals like trumpeters that require large areas of undisturbed habitat for survival are more severely affected by deforestation than those that are able to survive within smaller or more disturbed habitat patches. As large tracts of relatively undisturbed rain forest become increasingly scarce, habitat suitable for sustaining trumpeter populations is declining correspondingly. At present, stable populations of trumpeters are found only in large protected reserves and in remote areas which have remained largely unexploited by humans due to their inaccessibility.

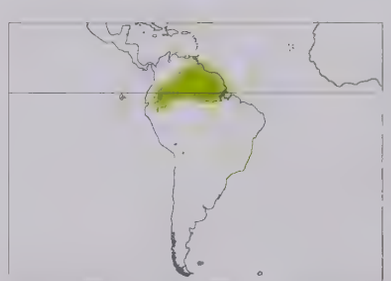
The hunting of all three species throughout their range has also significantly contributed to the decline of populations. They are attractive game species: their meat is considered to taste good, and their social habits usually allow for the simultaneous harvest of several individuals. Hunters can locate groups by imitating the territorial call, which frequently elicits an approach or a response in kind from the group. This allows hunters to attract groups during the day or locate them on their roost at night. During the day, capture of several birds is facilitated by trumpeters' tendency to remain near wounded group members allowing several birds to be shot. At night, hunters spotlight groups from below and the birds' disorientation, combined with their poor night vision, also allows the harvest of several birds. The ease with which trumpeters can be hunted leads to their rapid extirpation in the vicinity of settled areas.

A secondary effect on trumpeters of both deforestation and hunting is their negative impact on the primate populations, upon which trumpeters depend to knock down the ripe fleshy fruits that make up the majority of their diet. Primates are sloppy feeders, and most of the ripe fruit with soft unprotected pulp that falls to the ground in Neotropical rain forests falls as a result of being dropped or knocked free by primates. As the population density of forest-living non-human primates declines, the amount of edible fruit available to trumpeters decreases, leading to a further reduction in the size of the trumpeter population that can be sustained within a given area of rain forest.

Attempts to breed trumpeters in captivity have for the most part been unsuccessful. Although they have been kept by zoos and private aviculturists since the late 1800's, only a small number of females have been reported to lay eggs, and an even smaller number of chicks have hatched. People who live in or near South American rain forests and keep trumpeters as pets also claim that they never breed in captivity. To date, one Dark-winged and eight Grey-winged Trumpeters are reported to have been hatched and reared successfully in captivity. There is no record of captive Pale-winged Trumpeters ever having bred successfully.

General Bibliography

(1982), Haffer (1974), Haverschmidt (1985), Hellmayr & Conover (1942), Hendrickson (1969), Meyer de Schauensee (1982), Peters (1934), Rutgers & Norris (1970), Sibley & Ahlquist (1990), Sibley & Monroe (1990), Sick (1968, 1993), Willis (1983).



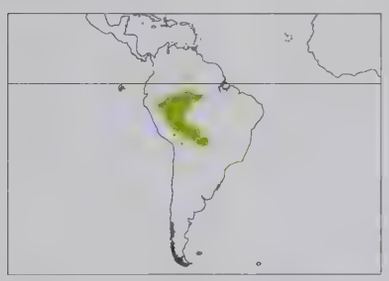
Genus *PSOPHIA* Linnaeus, 1758

1. Grey-winged Trumpeter
Psophia crepitans

French: Agami trompette **German**: Grauflügel-Trompetervogel **Spanish**: Trompetero Aligrís
Other common names: Common Trumpeter

Taxonomy. *Psophia crepitans* Linnaeus, 1758, Cayenne.
Forms superspecies with *P. leucoptera* and *P. viridis*. Present species sometimes treated as conspecific with *P. leucoptera*; alternatively, considered to include race *P. l. ochroptera*, because distribution of *ochroptera* appears more compatible with that of present species, and plumage pattern intermediate; however, apparent lack of interbreeding in areas of overlap between *P. l. ochroptera* and *P. c. napensis* indicates that these two races probably belong to separate species (see page 96). Two subspecies normally recognized.
Subspecies and Distribution.
P. c. napensis P. L. Sclater & Salvin, 1873 - SE Colombia through E Ecuador to NE Peru, and extreme NW Brazil (N of R Amazon/Solimões and mostly W of R Negro.
P. c. crepitans Linnaeus, 1758 - SE Colombia through E & S Venezuela to the Guianas and S to N Brazil (N of R Amazon and E of R Negro).

Descriptive notes. 45-52 cm; 1000-1500 g. Uniform black, with reddish brown band above ash grey hind-wing patch; lower throat has purple and green iridescence; legs pale greenish grey. Juvenile similar to adult. Races differ only in coloration, race *napensis* having iridescence almost entirely purple, and paler grey hind-wing patch.
Habitat. Mature dense tropical moist forest, from lowlands up to 750 m, in areas distant from human settlement.
Food and Feeding. Mainly pulp of ripe fruit, constituting 90% dry weight of food ingested; fruit eaten includes Moraceae, Lauraceae, Euphorbiaceae, Arecaceae, Myrtaceae, Cucurbitaceae. Also takes arthropods and other invertebrates, occasionally small vertebrates. Fruit primarily picked up from forest floor, occasionally removed from small plants. All seeds ingested with fruit are defecated intact.
Breeding. Season Dec-Jun in Guianas; in Venezuela, collected birds had enlarged reproductive organs in Feb, others observed breeding in Mar; presumably during main rainy season in other locations. Appears to live in co-operatively breeding groups. Nest-site is in elevated cavity; no nest constructed. Clutch 3 eggs (2-4); eggs white, 56-61 x 46-50 mm; incubation 28 days. Chick has russet face and wings, dark grey crown and back, cream-coloured underparts and black bib covering throat and upper breast; russet stripe bisects crown, extending from rear of upper mandible to base of neck; similar stripes run lengthwise down back.



Movements. Appears to be sedentary and territorial.
Status and Conservation. Not globally threatened. Apparently widespread in undisturbed rain forest, in large protected reserves and remote areas which remain essentially unexploited by humans. Uncommon in suitable habitat in Colombia, usually far from presence of humans. In French Guiana, still locally common in remote undisturbed forest, but overall population has declined greatly, and species has virtually been exterminated from coastal plain; main problem is hunting, especially near areas of human habitation; opening up of new roads facilitates access deeper into forest for hunters. Rare or absent in many parts of former range where previously common; population decline principally due to deforestation and hunting, but data on rate and severity of decline not available.

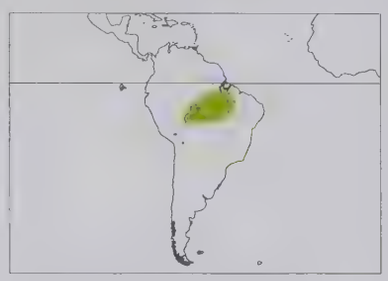
2. Pale-winged Trumpeter

Psophia leucoptera

French: Agami à ailes blanches **Spanish**: Trompetero Aliblanco
German: Weißflügel-Trompetervogel
Other common names: White-winged Trumpeter

Taxonomy. *Psophia leucoptera* Spix, 1825, Rio Negro; error = left bank of Rio Madeira, Brazil.
Forms superspecies with *P. crepitans* and *P. viridis*. Present species sometimes treated as conspecific with *P. crepitans*; alternatively, race *ochroptera* transferred to that species, because distribution appears more compatible with that of *P. crepitans*, and plumage pattern intermediate; however, apparent lack of interbreeding in areas of overlap between *P. l. ochroptera* and *P. c. napensis* indicates that these two races probably belong to separate species (see page 96). Two subspecies normally recognized.
Subspecies and Distribution.
P. l. ochroptera Pelzeln, 1857 - NW Brazil (N of R Amazon/Solimões and W of R Negro).
P. l. leucoptera Spix, 1825 - E Peru, CW Brazil (generally S of R Amazon/Solimões and W of R Madeira) and NE Bolivia.



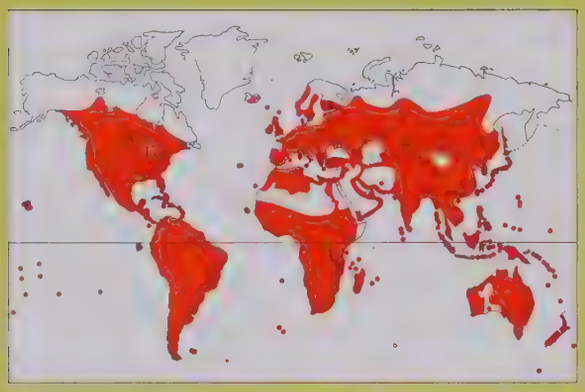
Descriptive notes. 45-52 cm; male 1280-1440 g, female 1180-1320. Uniform black, with similar appearance to *P. crepitans*, but hind-wing patch white to ochre, lower throat lacks green iridescence, and outer wing-coverts tipped in iridescent purple, green and bronze. Juvenile similar to adult, except for dark brown edging at tips of contour feathers of body. Races differ mainly in coloration, race *ochroptera* having an ochraceous hind-wing patch, as opposed to white of nominate race.
Habitat. Mature dense tropical moist forest, from lowlands up to 750 m, in areas distant from human settlement.
Food and Feeding. Mainly pulp of ripe fruit constituting 90% dry weight, 88% calories of food ingested; fruit eaten includes Moraceae, Lauraceae, Euphorbiaceae, Icacinaceae, Annonaceae, Verbenaceae. Also feeds on arthropods, occasionally annelids, and small vertebrates. Fruit primarily picked up from forest floor, occasionally removed from small plants. All seeds ingested with fruit are defecated intact. In wild, individuals ingest average of 260 kJ of food per day during periods of low fruit abundance, and 470 kJ food/day during periods of high fruit abundance.
Breeding. Season Sept-Apr. Forms co-operatively polyandrous groups. Nest-site is in elevated hollowed-out hole in tree trunk, at average of 11 m above ground; no nest constructed. Clutch 3 eggs (2-4); eggs white, 60-69 x 47-50 mm; incubation 23-29 days. Chick predominantly russet with cream-coloured underparts and black bib covering throat and upper breast; one black bordered white stripe runs from rear of upper mandible to base of neck; four similar stripes run lengthwise down back. Chicks jump from nesting cavity on morning after hatching; completely dependent on adults for food for first 3 weeks, and partially dependent on adults for food until 3 months old. Sexual maturity at 2 years. Longevity in wild probably 10-15 years.
Movements. Groups defend year round territories with stable boundaries.
Status and Conservation. Not globally threatened. Apparently widespread in undisturbed rain forest, in large protected reserves and remote areas which remain essentially unexploited by humans. Population density under ideal conditions in remote undisturbed rain forest in Manu National Park, Peru, is c. 8 birds/km². Species rare or absent in many parts of former range where previously common; population decline principally due to habitat destruction and hunting pressure; latter has grown over past century with the increased availability of firearms; data on rate and severity of population decline not available.
Bibliography. Blake (1977), Eason & Sherman (1995), Forrester (1993), Koepcke & Koepcke (1971), Parker *et al.* (1982), Pinto (1964), Price (1985), Remsen & Traylor (1989), Ruschi (1979), Sherman (1991, 1995a, 1995b), Sick (1985c, 1993).

3. Dark-winged Trumpeter

Psophia viridis

French: Agami vert **German**: Grünflügel-Trompetervogel **Spanish**: Trompetero Aliverde
Other common names: Green-winged Trumpeter

Taxonomy. *Psophia viridis* Spix, 1825, Parintins, Lower Amazon.
Forms superspecies with *P. crepitans* and *P. leucoptera*. Proposed race *interjecta* differs only slightly from races *dextralis* and *obscura* and adjoins their ranges; generally thought to represent an intergradation between populations of these two races. Three subspecies usually recognized.
Subspecies and Distribution.
P. v. viridis Spix, 1825 - C Brazil (S of R Amazon, between R Madeira and R Tapajós).
P. v. dextralis Conover, 1934 - EC Brazil (S of R Amazon, between R Tapajós and R Tocantins).
P. v. obscura Pelzeln, 1857 - NE Brazil (S of R Amazon, in NE Pará E of R Tocantins).



Descriptive notes. 45-52 cm. Uniform black, with similar appearance to *P. crepitans*, but hind-wing patch dark green to olive brown and typically more extensive; lower throat has purple iridescence, and outer wing-coverts tipped in iridescent purple; bill and feet green to olive. Juvenile similar to adult. Races differ only in coloration, with hind-wing patch dark green in nominate race, but olive brown in race *dextralis*, darker olive brown in race *obscura*; latter two races have dusky brown bill and feet.
Habitat. Mature dense lowland tropical moist forest in areas distant from human settlement
Food and Feeding. Little information available. Known to feed on fruit, arthropods, small vertebrates and carrion.
Breeding. Few data available. Female shot near Pará in Jan had large eggs in ovary. In captivity, 5 eggs incubated in one clutch, of which 1 egg hatched after 27 days. Published black and white photo of chick is similar in appearance to chick of *P. leucoptera*.
Movements. Probably sedentary and territorial.
Status and Conservation. Not globally threatened. Appears to be widespread in undisturbed rain forest, in large protected reserves and remote areas which remain unexploited by humans. Rare or absent in many parts of former range where previously common; population decline principally due to deforestation and hunting pressure; no data available on rate and severity of decline. Very poorly known.
Bibliography. Anon. (1981a), Ayres *et al.* (1991), Blake (1977), Dathe (1974), Forrester (1993), Pinto (1964), Ruschi (1979), Sclater (1898), Sick (1985c, 1993), Willis (1983).

Class AVES

Order GRUIFORMES

Suborder GRUES

Family RALLIDAE (RAILS, GALLINULES AND COOTS)

- Small to medium-sized terrestrial, marsh and aquatic birds, with short and deep to long and slender bill, moderately long neck, broad wings, short, soft tail and strong legs.
- 12-63 cm.

- Worldwide, except for polar regions and waterless deserts; widely distributed on oceanic islands.
- Many types of wetland; also grassland, forest and dense scrub.
- 33 genera, 133 species, 309 taxa.
- 33 species threatened; probably 2 of these, as well as 14 other species and 4 subspecies, extinct since 1600.

Systematics

The Rallidae form by far the largest family in the Gruiformes, comprising 147 species, 133 extant and 14 recently extinct. The family is cosmopolitan, having one of the widest distributions of any family of terrestrial vertebrates.

The order consists essentially of ground-living birds and its only other widespread family is Gruidae (cranes). The relationships of the Gruiformes to other orders are unclear but they are probably closest to the Charadriiformes and the Galliformes. In a few classifications the rails have been assigned to an order Ralliformes, while some classifications have allied the Rallidae to the Charadriiformes, and it has also been suggested that the charadriiform family Jacanidae may be derived from *Gallinula*-like stock, and could be placed within the Rallidae.

The fossil record tells very little about the origins and relationships of the Rallidae. The earliest fossils which can be assigned to the family are from the Lower Eocene, about 50 million years ago, and they reveal little about how these birds may have resembled modern rails. It is possible that the family existed earlier than the Eocene, but there is no solid evidence for this, although recent DNA-DNA hybridization studies have indicated that the rails may have diverged from the other gruiform groups as much as 86 million years ago, in the Upper Middle Cretaceous. Only in the Upper Oligocene and Lower Miocene, 20-30 million years ago, are three genera of fossil rails to be found which are based on adequate and diagnostic material, and by this period these birds had achieved a morphology not greatly different from that of modern rallids. Fossil rails occur fairly regularly in various younger Tertiary deposits from Europe, Asia and North America, and most continental fossil rails from Pliocene and Pleistocene deposits have been assigned to modern genera. As well as the Tertiary evidence in continental deposits, the more recent late Quaternary deposits of oceanic islands have produced numerous well preserved specimens of extinct rails, most of which can be assigned to modern genera; indeed, the discovery of many more fossil species on oceanic islands may be predicted. Only five extinct genera of island rails are known, and of these *Hovacrex* may be synonymous with *Gallinula*, while *Capellirallus* and *Diaphorapteryx* of New Zealand, *Aphanapteryx* of the Mascarenes, and the enigmatic *Nesotrochis* from the Greater Antilles, are valid, being morphologically quite distinct from modern genera.

The relationships of the Rallidae to the other gruiform families have not been clearly resolved. The family is commonly placed in its own superfamily (Ralloidea) within the suborder Grues, together with Aramidae (Limpkin), Psophiidae (trumpeters) and Gruidae. Skeletal morphology suggests a close alliance of Rallidae, Psophiidae and Heliornithidae (finfoots). The Aramidae, Eurypygidae (Sunbittern) and Cariamidae (seriemas) of South America, The Rhynochetidae (Kagu) of New Caledonia and the extinct Aptornithidae of New Zealand are also closely related, and it has been proposed that some of these families could be included as subfamilies within the Rallidae. However, DNA-DNA hybridization evidence suggests that the Rallidae form a distinct cluster, which is separate from cranes and their allies, and has had a distinct lineage for a long time; in line with this, it has been proposed that the rallids should be elevated to their own suborder, Ralli, alongside Grues.

Arrangements within the Rallidae have varied, and several classifications have been proposed. The first really modern one, published by R. B. Sharpe in 1894, listed 50 genera and 165 species of recent rails, while in 1934 J. L. Peters listed 52 genera and 138 species. The family was traditionally divided into three subfamilies, Rallinae, Gallinulinae and Fulicinae, although there had been little justification for this treatment, and in 1957 R. Verheyen proposed a subdivision into five subfamilies, but with no solid supporting arguments. In 1973, S. L. Olson produced a new classification for the family, reducing the number of genera to 35 and the number of subfamilies to two, Himantornithinae and Rallinae, the former being intermediate between the Rallinae and Psophiidae and containing only the Nkulengu Rail (*Himantornis haematopus*), of West and west-central Africa. Olson provided no sequence of species but discussed about 135. The more recent 1975 classification of J. J. Morony, W. J. Bock and J. Farrand listed 152 species of rails.

Olson considered *Himantornis* to be the most primitive and distinctive rallid. Its downy young are uniquely patterned in the Rallidae, and its skull is unlike that of any other rail but is very similar to that of the Psophiidae, while several elements of its postcranial skeleton are also distinct from those of other rails and closer to *Psophia*. He found that all other rails were so alike morphologically that further subfamilial separation was unwarranted. As he pointed out, one of the difficulties of rallid taxonomy arises from the relative homogeneity of the family, rails

for the most part being rather generalized birds, with few groups clearly defined by morphological modifications. As a result, some particularly well marked genera had previously been elevated to subfamilial rank on the basis of characters which, in more diverse families, would not be considered significant.

Although S. D. Ripley subsequently reduced the number of rallid genera to 18, Olson's classification has found general acceptance. The most significant subsequent reappraisal of relationships within the Rallidae has been made by C. G. Sibley and J. E. Ahlquist on the basis of DNA-DNA hybridization. These workers found that the flufftails (*Sarothrura*) of Africa and Madagascar diverged from the rest of the group about 60 million years ago, in the Paleocene, and they therefore proposed that the flufftails be placed in a separate family, the Sarothruridae, within its own superfamily, Sarothruroidea; they subsequently suggested that confirmation of this arrangement should wait until further genetic material becomes available. The flufftails are a distinctive genus within the rallids: they are strongly sexually dimorphic in plumage and they lay white, unmarked eggs, both of which characters are rare in the family; they also have distinctive hooting or moaning voices. Olson had proposed that *Sarothrura* was closely allied to the *Rallicula* (herein included in *Rallina*) forest-rails of New Guinea, mainly on the basis of plumage characters and the fact that *Rallina* species also lay white eggs. He had also suggested a possible link with the genera *Coturnicops* and *Micropygia*, small species which have a similar build and ecological preferences to those of flufftails; furthermore, the three *Coturnicops* species have white secondaries, a character which they share with the White-winged Flufftail (*Sarothrura ayresi*), and which is found in no other rallid. Lack of genetic material from *Rallina*, *Coturnicops* and *Micropygia* prevented Sibley and Ahlquist from commenting on these possible relationships, and the problem of the affinities of the flufftails remains unresolved.

This work follows the taxonomic treatment of Olson, modified in some cases by more recent morphological studies. It follows Sibley and Monroe in emphasizing the distinctiveness of the genus *Sarothrura* by placing it at the beginning of the family but not assigning it to a separate subfamily. However, this has the disadvantage that the primitive and distinctive genus *Himantornis* can not be given the subfamilial rank which it probably deserves.

Most works on the family recognize, for convenience, two broad "natural groups" within it: the crakes, rails and wood-rails, most of which are terrestrial; and the gallinules (including moorhens) and coots, which tend to be more aquatic. The term "rail" is applied generally to the whole family and also to longer-billed species in many genera, while "crake" is applied mostly to the smaller, short-billed species, particularly in the genera *Laterallus* and *Porzana*. Neither term has a precise taxonomic meaning, and different species in different genera are sometimes called by either name, while crake-like birds seem to have evolved independently several times. The term "gallinule" can cover all the birds in the second group except the coots, though it is sometimes restricted to certains species of *Gallinula* and *Porphyrio*.

The greatest number of rallid species and of peculiar genera, and the most primitive species, are found in the Old World tropics. The New World has relatively fewer groups, most of which are apparently derived from Old World stem groups, and a few genera appear to have specialized and radiated in the New World, some of them subsequently re-invading the Old World. Olson suggested that the most primitive rallids are found in forest, and that an adaptation to aquatic habitats and grassland (see Habitat) may be a more recent development, but he admitted that such adaptation could have evolved several times in different groups.

In attempting to determine relationships within the Rallidae, *Himantornis* provides some clues as to which species may be the most primitive, useful indications being *Psophia*-like skeletal characters, long, slender tarsi, patterned natal down and forest habitat. Flightlessness has evolved many times in rallids (see Morphological Aspects), and therefore has no major phylogenetic significance; the incidence of flightlessness and its associated morphology can be used as a taxonomic character in the family only at the specific or subspecific levels.

The primitive nature of the forest-dwelling genus *Canirallus*, of Africa and Madagascar, is indicated by its sharing two primitive skeletal characters with *Himantornis* and by the possession of patterned natal down in the Madagascar Wood-rail (*Canirallus kioloides*). There are significant similarities in the plumage, structure and natal down of *Canirallus* and the four forest-rails (sometimes called "chestnut rails") endemic to New Guinea which were formerly placed in the genus *Rallicula*, and Olson suggested maintaining *Rallicula* as a subgenus of *Canirallus*. However, on

The nominate race of the White-throated Rail is endemic to Madagascar, where it frequently occurs along forest and woodland streams and feeds readily in shallow water, immersing the head and digging and raking vigorously with the strong bill. The bill is also a useful weapon; indeed, the Aldabra race, aldabrensis, *successfully defends itself against introduced rats by pecking forcefully at them. The white areas of plumage are prominent in signalling: in greeting and threat displays, and when singing, the bird stretches its neck vertically to display the white throat patch, while the undertail-coverts are spread during song, in the threat display, and by the female when soliciting copulation.*

[*Dryolimnas cuvieri cuvieri*, Madagascar. Photo: Patryck Vaucoulon/ Bios]

The Spot-flanked Gallinule is a rather atypical small Gallinula *species which was originally placed in a monospecific genus,* Porphyriops. *In shape it resembles a large* Porzana *crake rather than a* Gallinula, *but its behaviour is typical of gallinules: it feeds while swimming, seldom walking on vegetation or on the ground; it is not shy and is easily observed; it occurs in family parties and occasionally in flocks; and it tends to be quarrelsome, birds often chasing each other and pattering across the water. Its frontal shield is small and it is the only member of its genus to have profusely spotted flanks and lobed toes, the lobes being small and difficult to see.*

[*Gallinula melanops*. Photo: Hector Rivarola/ Bruce Coleman]

the basis of plumage similarities, Ripley included them in the genus *Rallina*, along with four species of forest and marshland from Asia and Australia, even though the latter species differ in not being sexually dichromatic. Olson regarded *Rallina* as a separate group, apparently in transition from the woodland habitat of the more primitive rails to the wetland habitat more typical of the family. Opinions still differ as to whether the forest-rails should be placed in *Rallicula* or *Rallina*.

The sequence of the first six genera in the currently adopted classification is unsatisfactory in several ways. Interposing the genera *Coturnicops* and *Micropygia* between the genera of the *Canirallus-Rallina* group is somewhat arbitrary, and reflects the assumed affinity of these small grassland and marsh crakes with the flufftails, as described above, while also acknowledging the aforementioned possible affinities between the flufftails and the *Rallina* group and attempting to reflect the primitive status of *Himantornis* and *Canirallus*.

Two New World genera of small crakes, *Anurolimnas* and *Laterallus*, appear to be derived from Old World *Rallina* stock, some *Laterallus* species showing striking plumage similarities to *Rallina*; indeed, the forest- and thicket-dwelling Chestnut-headed Crake (*Anurolimnas castaneiceps*) was formerly placed in *Rallina*. The other two *Anurolimnas* species were formerly included in *Laterallus* but are more properly included with the Chestnut-headed Crake in a distinct genus. The nine species remaining in *Laterallus* form a group of small crakes, predominantly of marsh and wet grassland, the South American representatives of which are relatively poorly known. A recently discovered and very distinctive form (*tuerosi*) of the Black Rail (*Laterallus jamaicensis*) is confined to marshes fringing Lake Junín, central Peru, and is reckoned to be endangered. It is sometimes treated as a separate species, and this may be justified because it differs from the other forms of the Black Rail as much as does the Galapagos Rail (*Laterallus spilonotus*); awarding it specific status emphasizes the conservation priorities which should be accorded to it.

The relationships of the group of barred-winged rails currently placed in the genus *Gallirallus* have been greatly obscured by the combination of some species with the more specialized species of *Rallus*, and by the creation of several unnecessary genera for flightless forms of the group. The Weka (*Gallirallus australis*), a large, flightless species endemic to New Zealand, at first sight appears to be a strange and distinctive rail, and it was originally the only species placed in the genus. Early classifiers were deceived by the neotenic characters associated with flightlessness and considered it a peculiar, primitive form without close relatives. However, it shows marked similarities, in both plumage and skeletal characters, to the volant Buff-banded Rail (*Gallirallus philippensis*), and the differences in the wings, the pectoral girdle, and some plumage features of the adults, are simply recently derived neotenic characters. It occurs alongside the Buff-banded Rail, this situation reflecting the multiple invasion of New Zealand by *G. philippensis*-like stock. The presence of two fossil relatives, one on North Island and one on an offshore island, indicates that the Weka has a long history of isolation on the New Zealand islands.

Other possible insular derivatives of *G. philippensis* stock are the recently extinct Tahiti Rail (*Gallirallus pacificus*) and the Lord Howe Rail (*Gallirallus sylvestris*), both flightless species. The flightless New Caledonian Rail (*Gallirallus lafresnayanus*) is now also regarded as a possible *G. philippensis* derivative, although Olson could see no indication of a relationship between it and the Lord Howe Rail, and regarded it as having diverged so far that any external resemblance to a possible common ancestor has been obscured. He accordingly placed it in *Tricholimnas*, moving the only other species in that genus, the Lord Howe Rail, to *Gallirallus*. Other flightless or weak-flying *Gallirallus* species endemic to oceanic islands and possibly derived from *G. philippensis* stock are the Guam Rail (*Gallirallus owstoni*) and the recently described Roviana Rail (*Gallirallus rovianae*), as well as the recently extinct Chatham Rail (*Gallirallus modestus*), Wake Rail (*Gallirallus wakensis*) and

Dieffenbach's Rail (*Gallirallus dieffenbachii*), the last of these sometimes being considered conspecific with *G. philippensis*.

An interesting, though confusing, situation has arisen concerning an extinct form of rail, apparently from the Kiribati (Gilbert) Islands in the Pacific, and known only from a specimen preserved in alcohol in the Harvard Museum of Comparative Zoology. This form, designated the Gilbert Rail (*Tricholimnas conditicius*), was subsequently dismissed by J. C. Greenway as an immature specimen of the Lord Howe Rail, the locality from which the bird was collected being in doubt. Subsequently, however, on reviewing the historical and morphological evidence, M. Walters concluded that the original designation was probably correct, but since then Olson, also reviewing morphological and historical evidence, has concluded that the bird is indeed an immature Lord Howe Rail and that the confusion is probably traceable to a misassociated specimen label.

Another subgroup within *Gallirallus* is formed by the Barred Rail (*Gallirallus torquatus*) of South-east Asia and the New Britain Rail (*Gallirallus insignis*), to which can be added the recently described flightless Okinawa Rail (*Gallirallus okinawae*). The recently extinct volant Sharpe's Rail (*Gallirallus sharpei*), known from a long-overlooked single specimen of unknown origin, is most similar to the Buff-banded Rail but differs from it strikingly in coloration and plumage pattern. The remaining species in the genus, the Slaty-breasted Rail (*Gallirallus striatus*), is the only member of the group found in continental Asia and is considered by Olson to be an advanced form of the genus that has paralleled the evolution of the *Rallus* group towards a slender marsh-dwelling build.

The species of *Rallus* are much more specialized than those of *Gallirallus* and are highly adapted to a semi-aquatic existence in reedy marshes. The genus appears to have radiated in the New World, with only three allopatric species found in the Old World. The Water Rail (*Rallus aquaticus*) of Eurasia is one of the few Palearctic rallids which does not migrate to sub-Saharan Africa, where it is replaced by the African Rail (*Rallus caerulescens*). The third species, the Madagascar Rail (*Rallus madagascariensis*) is endemic to Madagascar. All three probably had their origins in a single invasion of *Rallus* from the New World.

The recognition of the King Rail (*Rallus elegans*) as a distinct species, rather than a form of the Clapper Rail (*Rallus longirostris*), has long provoked argument, and even recent mitochondrial DNA studies have yielded inconclusive results. Although the separation is currently accepted by many authorities, the problem is likely to fuel discussion for some time to come.

The genus *Lewinia* comprises three species which are often treated as one. Olson regarded the Brown-banded Rail (*Lewinia mirificus*) of Luzon in the Philippines as a well marked form of Lewin's Rail (*Lewinia pectoralis*), while the Auckland Rail (*Lewinia muelleri*) is also regarded by some authorities as being conspecific with the latter. Furthermore, Lewin's Rail is sometimes placed in the genus *Rallus*, although its skeleton differs in several respects from the true *Rallus* type. However, its skeleton is almost identical to that of the much larger White-throated Rail (*Dryolimnas cuvieri*) of Madagascar and the Aldabra atoll, and Olson placed it too in *Dryolimnas*, regarding the genus as rather primitive and forming part of a pro-*Rallus* group.

The central South Atlantic islands served as habitat for a complex of *Rallus*-related species which presumably arose from accidental dispersal. Of these, the genus *Atlantisia* was represented by three flightless species, two of which were exterminated by introduced mammals, while the third, the Inaccessible Rail (*Atlantisia rogersi*), survives on one island of the Tristan da Cunha group. Olson considers that these species represent neotenic relict forms of ancestors of the pro-*Rallus* group *Dryolimnas-Atlantisia*.

One of the most difficult problems in rallid taxonomy concerns the proper allocation of the species included in the genera *Porzana* and *Amaurornis*. *Porzana* is a possibly polyphyletic genus and is very difficult to categorize because of differing taxonomic treatments: for example, Ripley lists 27 species but Olson only 13. The five *Amaurornis* species *akool*, *isabellinus*, *olivaceus*, *moluccanus* and *phoenicurus* form a rather basic stock from which both the *Porzana* assemblage and the gallinules could have arisen, and some *Amaurornis* species have previously been included in *Porzana* and *vice versa*. A natural group within *Porzana* is formed by five living species, *parva*, *pusilla*, *porzana*, *fluminea* and *carolina*, and the recently extinct Laysan Crake (*Porzana palmeri*). The probably extinct Kosrae Crake (*Porzana monasa*) and the Henderson Crake (*Porzana atra*) are very close

The occupation of forest habitat, and the possession of patterned natal down, are regarded as primitive characters in the Rallidae. Canirallus *is a primitive genus comprising two species of forest-dwelling rails, the Grey-throated Rail* (Canirallus oculeus) *of West Africa and the Madagascar Wood-rail. In the latter the black natal down is patterned with rufous brown, a character which it shares with the forest-dwelling* Rallina *rails endemic to New Guinea. The plumage characters relevant to racial separation in the Madagascar Wood-rail are imperfectly described, while the population of the Bemaraha Reserve, in north-west Madagascar, probably belongs to an undescribed race.*

[*Canirallus kioloides kioloides*, Madagascar. Photo: Dominique Halleux/ Bios]

The genus Laterallus *comprises nine species of small crakes from the Americas, with one confined to the Galapagos Islands. Typically birds of marsh and wet grassland, they have trilling, churring or rattling calls, they eat invertebrates and seeds, and most species are poorly known. The Red-and-white Crake is possibly the most strikingly marked member of the genus, which is perhaps one reason why it is kept in captivity more frequently than are many other small rails. It is unique in the genus, and unusual among rallids, in laying pure white eggs.*

[*Laterallus leucopyrrhus*, San Diego Zoo, USA. Photo: Kenneth W. Fink]

to the Spotless Crake (*Porzana tabuensis*) and could have been derived from it.

Amaurornis-like stock could also have given rise to the assemblage of New World rails in the genera *Cyanolimnas*, *Neocrex* and *Pardirallus*. All the species in these genera share a similar drab plumage, with the exception of the Spotted Rail (*Pardirallus maculatus*), which, however, has a similar dark morph of its juvenile plumage. The long-billed *Pardirallus* rails are often mistakenly placed in *Rallus*, from which they differ markedly in skeletal characters. Another line probably derived from *Amaurornis* comprises the Australasian genera *Eulabeornis*, *Habroptila* and *Megacrex*.

The purple gallinules, formerly separated into the three genera *Porphyrula*, *Porphyrio* and *Notornis*, are considered by Olson to form an obviously monophyletic group, as was originally suggested by E. Mayr in 1949. *Porphyrula* differs from *Porphyrio* only in its smaller size, less massive bill and more oval nostril, while the two genera share a number of specialized characters. The three species sometimes placed in *Porphyrula* are closer to each other than to *Porphyrio*, so a case could be made for maintaining them as a subgenus, but they would not seem to merit a separate genus. The Takahe (*Porphyrio mantelli*), although formerly awarded the monotypic genus *Notornis*, is now generally regarded as simply a large, flightless derivative of *Porphyrio*.

Despite the distinctive appearance of the extinct Samoan Moorhen (*Gallinula pacifica*) and both the San Cristobal Moorhen (*Gallinula silvestris*) and the Tristan Moorhen (*Gallinula nesiotis*), which previously resulted in their separation in different genera, it is now generally accepted that they are most suitably placed in *Gallinula*. Similarly, it is no longer regarded as appropriate to place the Spot-flanked Gallinule (*Gallinula melanops*) in the monotypic genus *Porphyriops*, or the Black-tailed Native-hen (*Gallinula ventralis*) and the Tasmanian Native-hen (*Gallinula mortierii*) in the genus *Tribonyx*: the skeletons of all three species show no differences which can be considered of generic significance when compared to *Gallinula*.

The coots (*Fulica*) are very similar to *Gallinula* both skeletally and in their adult and juvenile plumages, and are derived from a *Gallinula*-like stock which has become adapted for diving. Their centre of species diversity is South America and it seems likely that they originated there and later spread to the Old World. The genus is well defined and has diverged relatively little from its ancestral stock. The Hawaiian Coot (*Fulica alai*) has only recently been treated as a species distinct from the American Coot (*Fulica americana*), while the Caribbean Coot (*Fulica caribaea*) is sometimes regarded as merely a morph of the American Coot, although West Indian populations mate assortatively without evidence of crossing.

A new phylogenetic study of the Rallidae, using morphological characters, is currently being undertaken by B. Livezey, and this may well shed new light on some of the unresolved problems discussed above.

Two new living rallid species, both from islands and both flightless, have been described in the last 20 years. The Okinawa Rail was first seen on the island of Okinawa, in the Ryukyu Islands, in 1978 and was described in 1981. It is considered to belong to the superspecies containing the volant Barred Rail and the flightless New Britain Rail, and to have evolved from a progenitor of the Barred Rail. An unnamed fossil rallid from Okinawa may also be ancestral to the Okinawa Rail. The fact that the Okinawa Rail should have remained undescribed for so long may seem surprising, especially as the bird occurs on a densely populated island which is ornithologically well known, but it is found only in the largely uninhabited forests of the north, whereas most of the island's human population lives in the south.

The Roviana Rail from the Solomon Islands is known from the holotype, collected in 1977; it was first seen in the wild by an ornithologist as recently as 1994, and is known to local people on several islands in the group. It belongs to the widespread group of Pacific *Gallirallus* species that includes the volant Buff-banded Rail; it is most similar to that species and to the flightless Guam Rail and the extinct flightless Wake Rail, and is probably derived from an ancestor similar to the Buff-banded Rail.

In view of these recent discoveries, it seems highly likely that there are other forms of rallid still probably awaiting discovery by the ornithological world. For example, a hitherto undescribed chestnut rail from the uninhabited Foja Mountains in north-west New Guinea was frequently seen in October 1979 and may be either an undescribed form of Forbes's Forest-rail (*Rallina forbesi*) or a new species.

Morphological Aspects

The Rallidae are a large but rather homogeneous family of small to medium-sized terrestrial, marsh and aquatic birds. Their bodies are short, and are often laterally compressed for ease of movement through dense, low vegetation, whence the expression "thin as a rail". In the Virginia Rail (*Rallus limicola*) the very flexible vertebral column is thought to facilitate movement through dense marsh vegetation, but possibly to reduce the bird's effectiveness in flight. The neck is short to moderately long, with 14-15 cervical vertebrae.

Rails range in length from 12 cm to 63 cm and in mass from 20 g to over 3000 g. The smallest species is the Black Rail of the Americas, while the Inaccessible Rail, with a length of as little as 13 cm and a mean mass of 40 g, has the distinction of being the smallest flightless bird known to exist. The largest species is the flightless Takahe of New Zealand, males of which weigh 2250-3250 g, while the Giant Coot (*Fulica gigantea*) can reach 2500 g. In most species the sexes are very similar in size, although the male is often slightly larger than the female. Marked sexual dimorphism in size occurs in only a few rallids, and in all cases the male is the larger sex; the greatest size differences occur in the Watercock (*Gallicrex cinerea*), in which the male averages 50% heavier than the female, and the Weka, in which the male averages 42% heavier. The Dusky Moorhen (*Gallinula tenebrosa*) shows remarkable racial variation in size, nominate Australian birds averaging as much as 58% heavier than *neumanni* of New Guinea.

The wings are short, broad and rounded. There are normally ten primaries, fewer in some flightless forms, and a minute eleventh primary is present in some of the larger species. There are 10-20 secondaries, and the wing is usually diastataxic, with the fifth secondary absent. In some species the alula has a sharp, curved claw which may be used by the young, and possibly also by the adults, to assist in climbing. In volant species, flight over short distances usually appears low, weak, and generally not sustained, and the birds usually fly with dangling legs. Small crakes will often pitch or flop abruptly into cover after a short flight, almost as though they had suddenly lost the use of their wings. Notwithstanding this apparent inability to fly strongly, some species migrate or disperse over long distances and the family is renowned for its ability to colonize remote oceanic islands. In fact, in terms of their morphology and their ability to accumulate food reserves, rails are perfectly capable of sustained and very long flights, but their flight performance is relatively poor and they tend to migrate at low altitudes. The high degree of vagrancy in the Rallidae is indicative of the readiness with which the birds are apparently blown off course by unfavourable winds (see Movements).

One of the best known features of the family is the incidence of flightlessness in island taxa. Flightlessness is widespread among various avian orders, and numerous flightless forms exist, but the Rallidae show a particular proclivity to flightlessness. There are 53 rallid species living, or extinct since 1600, which are known only from islands (including New Guinea and Madagascar) and of these, 32 species (59%) are flightless or nearly so. Flightlessness has evolved many times within the Rallidae, often and repeatedly on islands without predators and probably independently each time. Selection reduces the flight muscles and pectoral girdle, probably through neoteny, and there is usually a corresponding increase in the development of the leg muscles. These modifications may involve only a few genetic changes, for example in genes controlling the relative growth rate of different body parts. The selective force involved is presumably the high energetic cost of flight and the weight burden of flight muscle: where such costs are not balanced by the benefits of dispersal and escape from predators, it is obviously to the bird's advantage to become flightless.

The frequency with which flightlessness is developed by rails suggests that they are predisposed to it, and they are certainly pre-adapted to coping with some of the restrictions which it imposes. For example, many volant species are behaviourally flightless, preferring to avoid predators by running; in common with several other groups containing flightless forms, many volant

Like most of its congeners the Grey-necked Wood-rail frequents swampy forests and coastal mangroves, but it is also found in many other habitats, including deciduous woodland, marshes and marshy thickets, rice fields, and even grassland with bushes and pools. It is normally associated with dense cover and is sometimes described as shy, skulking and difficult to see, especially when calling. However, it will forage in the open and is generally regarded as less of a skulker than most other rails. It walks with an upright carriage, flicking its short black tail, and, when disturbed, especially by dogs, may fly up to perch on a branch or tree stump. This bird has found a handy temporary perch on top of a strategically situated hornero (Furnarius) *nest.*

[*Aramides cajanea cajanea*, Argentina. Photo: Wayne Lynch/DRK]

The Tasmanian Native-hen is a large, flightless gallinule endemic to Tasmania. It inhabits open pasture, grassland, newly sown crops and cleared land around permanent or seasonal freshwater wetlands with abundant cover. Its grassland habitat may be tussocky, infested with weeds, or lightly wooded, and it breeds near water in dense vegetation such as reeds, rushes and bracken. It requires short-grazed pasture year round for foraging, and is a secondary grazer, depending on primary grazers to provide its foraging habitat. In the past suitable swards were maintained by grazing marsupials and by fire, but the job is now done by introduced rabbits, sheep and cattle.

[*Gallinula mortierii*, Tasmania.
Photo: John Cancalosi/ Bruce Coleman]

rails are temporarily flightless during wing moult, when they become particularly secretive and elusive; and the post-natal development of flight in most species is slow.

Flightlessness may evolve in a very short period of time. For example, the White-throated Rail has a volant race on Madagascar and a flightless race on Aldabra; these differ markedly in size but very little in plumage pattern and colour, and have obviously diverged very recently.

The tail contains 6-16 rectrices, normally 12. It is short, square to rounded, arched and soft, and is sometimes decomposed, especially in flightless species and flufftails. It is often raised or flicked to show the signalling colours of the undertail-coverts, which in many species are contrastingly coloured or patterned.

The structure of the bill is variable. It is sometimes quite slender, straight or slightly downcurved, and slightly longer than the head, for instance in *Rallus* and *Aramidopsis*; it is often quite short and somewhat laterally compressed, as in crakes, and most gallinules and coots; or it may be massive and deep or laterally compressed, as in some *Porphyrio* species. Long-billed rails probe in soft ground and litter, and species with small, fine bills often take primarily insects and small seeds, while species with large, stout bills may graze, dig out roots and tubers, or tear off vegetation. Many species tend to be omnivorous and therefore have unspecialized bills.

The bill is often brightly coloured, contrasting with the plumage of the head, and in some species it has a patch of a different colour at its base. Gallinules and coots have a smooth, plate-like, horny frontal shield, continuous with the outer covering of the bill, which may be coloured similarly or contrastingly to the bill. In some species, the colours of the bill and shield become duller in the non-breeding season, when the shield may also shrink. The male Watercock has the frontal shield continued into a long red horn which almost disappears outside the breeding season, while the Horned Coot (*Fulica cornuta*) has a long, extensible and erectile black proboscis with two tufts at its base; the functions of this strange appendage are unknown. The Invisible Rail (*Habroptila wallacii*) and the New Guinea Flightless Rail (*Megacrex inepta*) also have small frontal shields.

Except in *Porphyrio*, the nostrils are usually in a large depression, and they are pervious in most species, perforate in some. The olfactory process is well developed in most species, and the ample supply of nasal glands and ducts, with the relative size of the olfactory bulb of the brain, indicate that rails can easily discriminate odours, presumably a help in food-gathering. Rails of littoral habitats have adapted readily to salt water and are able to secrete salt by means of adapted nasal glands; they thus share with ducks and seabirds the ability to adapt to the absorption of sea water for drinking. The White-throated Rail, for example, drinks sea water on Aldabra.

As an adaptation to their primarily terrestrial existence, rails have well developed legs which may be rather long to quite short, are often slender but usually strong, and may be laterally compressed. The toes are often long and slender, but in fully terrestrial species of predominantly dry habitats they may be rather short and heavy. The hind toe is slightly raised, and is used as a plantar toe, helping in the balance of the foot structure. In most gallinules, and also in some crakes, notably the Yellow-breasted Crake (*Porzana flaviventer*) and the White-browed Crake (*Porzana cinerea*) the toes are particularly elongated and the legs modified for walking, jacana-like, on mud and floating or emergent vegetation. Many species can climb well: gallinules, for example, are often seen clambering around high in reeds, and the American Purple Gallinule (*Porphyrio martinica*) climbs easily in bushes and trees up to 20 m above the ground. In some species the legs and feet are brightly coloured and, as with bill colour, leg colour may be brighter during the breeding season. Leg colour may also change as birds mature, and can be helpful in determining a bird's age; for example, in the breeding season, American Coots may be aged on tarsal colour, which progresses through green at one year old; yellow-green at two; and yellow at three; to orange-red at four years or more.

Rails often walk with strong, precise strides. Being accustomed to cover, they often move continuously without long pauses for visual orientation, pausing mainly to feed. When moving through low vegetation, they slip beneath low horizontal stems or arched projecting roots, or raise the feet high to step over such obstacles, and one often gains the impression that the birds are avoiding making substantial vertical changes in the position of the body relative to the substrate. In dense cover rails are adept at walking, and even running, without causing any noise or movement of the vegetation. When reacting to alarm, they melt quietly and rapidly into cover, often lowering the head and stretching

The genus Fulica *originated in South America, where the largest coots occur on ponds and lakes in the high, arid* puna *zone of the central Andes. The Giant Coot is adapted to waters which normally lack reeds and rushes; large populations occur on lakes with extensive shallows supporting dense growths of water weeds such as* Myriophyllum, Potamogeton, Zanichellia *and* Ruppia, *on which the birds feed and from which they build their enormous nests. Lauca National Park in northern Chile holds about 12,000 Giant Coots, the largest known population of this generally scarce species. Adult Giant Coots are probably flightless, and are normally attached to both territory and nest for life, but immatures are smaller and disperse by flying between lakes at night, sometimes visiting reedy lakes at lower altitudes.*

[*Fulica gigantea*, Lake Chungara, Lauca National Park, Chile. Photo: Luiz Claudio Marigo]

The forest habitats occupied by rails are usually stable and permanently suitable for them, and forest-rails tend to be sedentary. However, species that are dependent on moist substrates and forest streams may make seasonal movements in response to dry conditions. The Red-necked Crake is one such species. An inhabitant of rain forest, swamp forest, monsoon forest and secondary growth, it forages for invertebrates in shallow streams and in leaf litter. In north Queensland it is regarded as a wet season visitor from New Guinea, leaving when the forest floor dries out in winter.

[*Rallina tricolor*, north Queensland, Australia. Photo: Hans & Judy Beste/Ardea]

out the neck, and they compress the body to allow easy passage between stems. They often walk with bobbing head and flicking tail, the head movement possibly being connected with acuity of vision, as in other birds such as pigeons and chickens: the head moves forwards relative to the surroundings and, at the end of the forward thrust, is temporarily stationary while the rest of the body catches up, this brief stationary phase being an adaptation to allow a motionless view (with the central fovea) of the bird's surroundings. The tail jerk possibly functions in visual orientation and signalling between individuals, especially when the tail is jerked and spread in alarm before the bird runs into cover; if accompanied by a short pause in forward gait, the jerk allows the bird an instantaneous clear view from a stationary position. It has also been suggested that such tail-jerking movements may act as a signal of fitness designed to deter predators (see page 460).

All rails can swim; they also dive easily and can sink, using the wings under water if necessary. Some species, such as the Striped Crake (*Aenigmatolimnas marginalis*) and the Clapper Rail, will dive and cling to submerged vegetation to escape pursuit or when wounded. In coots, which are fully aquatic, the pelvis and legs are modified for diving, and all but one species, the Red-fronted Coot (*Fulica rufifrons*), have toes with enlarged lateral lobes to aid swimming. The Spot-flanked Gallinule also has narrowly lobed toes, while those of the Common Moorhen (*Gallinula chloropus*) are somewhat emarginated.

The plumage of rails is often dull and cryptic, common colours being sombre browns, chestnut, black, blue-grey and grey; in the genus *Porphyrio*, however, the plumage is predominantly iridescent purple, blue or green. The upperparts are frequently spotted, barred or streaked, but are uniform in some species. The flanks are often strongly barred, for example in most *Rallus*, *Gallirallus* and *Porzana* species, and the vent and undertail-coverts may contrast strongly with the rest of the plumage. The Weka and the Chestnut Rail (*Eulabeornis castaneoventris*) both have different plumage morphs. In most species the sexes are alike or very nearly so: marked sexual dimorphism in plumage occurs only in the flufftails, the *Rallina* forest-rails endemic to New Guinea, the Striped Crake, the Little Crake (*Porzana parva*) and the Watercock, while several other species show much slighter differences.

With the exception of the Watercock, no species in the family shows any significant seasonal change in plumage colour or pattern. Most minor differences which exist between breeding and non-breeding plumages are difficult to see in the field, and are often caused by abrasion.

The downy plumage of rallid chicks is typically black (sometimes iridescent, or grizzled with brown or chestnut) or dark brown, and exceptions to this plumage pattern are few. In the Andaman Crake (*Rallina canningi*) the chick is rich chestnut, while in the Madagascar Wood-rail and Forbes's Forest-rail the grizzled chick has rufous colouring on the head and neck and, in the former species, a rufous stripe along the side of the body. The chick of the Chestnut Forest-rail (*Rallina rubra*) is black, grizzled with russet or chestnut, and the black chicks of the Buff-banded Rail and the Lord Howe Rail may have grey on the eyestripe or the cheek. In the Nkulengu Rail, however, the chick is distinctively patterned with brown, black and white; this presumably cryptic pattern more closely resembles that of the precocial chicks of other orders, whereas the black down of most other rails is a wide departure from that of typical precocial chicks. The natal down of the Nkulengu Rail probably represents a relatively primitive state, while the black down of typical rails appears to be a specialized, derived condition and may be an adaptation for hiding in dense vegetation.

The downy young of some rallids have distinctively coloured filoplumes or bristles, these being developed most markedly in the Common Coot (*Fulica atra*), which has red papillae on the face as well as black bristles on the crown, and yellow-tipped down on the neck and body. Downy young of the coots native to the Americas have yellow or orange bristles on the neck or throat. The Sora (*Porzana carolina*) also has orange throat bristles, while the American Purple Gallinule has grey bristles on the head, two other *Porphyrio* species have pale filoplumes on the head and body, and two *Gallinula* species have pale down-tips or plumes on the neck. *Fulica*, *Porphyrio* and *Gallinula* chicks also have brightly coloured bare skin on the head. It is thought that the bright colours of the bill and throat act as signals for feeding, and in the Common Coot this probable signal effect remains conspicuous as long as the young are totally dependent on parental care. J. Fjeldså has suggested that, in the Common Coot, the colours of the bare skin on the head have an appeasement func-

Coots are the most aquatic members of the Rallidae, occurring on fresh to brackish waters and also quiet inshore sea waters. Most species are gregarious, and both the American Coot and the Common Coot (Fulica atra) *form large monospecific flocks outside the breeding season, while during the breeding season non-breeding birds also flock near occupied territories. Both species also congregate in large flocks to undergo their post-breeding moult, when the remiges are moulted simultaneously and the birds may be flightless for up to four weeks.*

[*Fulica americana americana*, Merritt Island, Florida, USA. Photo: Arthur Morris]

tion, which may well be necessary in such pugnacious birds. The downy chicks of many rallid species, especially those which nest in dense vegetation, have brightly coloured or patterned bills and it has been widely suggested that this prominent feature serves to assist the parents in directing food to the chick's bill in the dim light conditions prevailing in dense vegetation.

Juvenile (post-natal) and immature (post-juvenile) plumages are undescribed for many rail species. Even when details are available, it is sometimes not possible to determine whether the described plumage is juvenile or immature, or whether there is, in fact, any difference between the two. In some species the juvenile plumage is similar to the adult plumage, but in others it may be paler or duller than in the adult, and less contrastingly barred or patterned; sometimes, for example in most flufftails, it is plain. The White-spotted Flufftail (*Sarothrura pulchra*) is apparently unique among rallids in having its juvenile plumage patterned like that of the strongly sexually dimorphic adult of the corresponding sex, and this makes it possible to sex the young as soon as post-natal moult starts. As far as can be determined, the immature plumage of rallids is usually almost identical to that of the adult.

Post-juvenile moult is partial, resulting in an immature non-breeding plumage. The following first pre-breeding moult is partial in some species and complete in others, and it may often follow the post-juvenile moult almost immediately, thus suppressing a distinct immature non-breeding plumage. In some cases the post-juvenile moult leads directly to the first breeding plumage. There are variations to these basic patterns: for example, in the Galapagos Rail the change from juvenile to adult-type plumage is gradual, no distinctive immature plumage being attained.

In adults, post-breeding moult is complete though its timing is variable, and there is usually a partial pre-breeding moult. In the Western Palearctic, migratory rallids moult the flight-feathers after breeding and before migrating, while sedentary species in Africa may undergo remex moult during the breeding season. In South Africa, the Red-knobbed Coot (*Fulica cristata*) has been found to replace the body and tail plumage continuously, while Striped Crakes in captivity had two complete moults per year, a pattern not known in any other rallid.

In some rallids, notably of the genera *Laterallus*, *Gallirallus*, *Rallus*, *Porzana*, *Pardirallus*, *Porphyrio*, *Gallinula* and *Fulica*, remex moult is simultaneous, resulting in a flightless period. In others, notably of the genera *Sarothrura*, *Himantornis*, *Canirallus*, *Rallina* and *Anurolimnas*, it is sequential.

Habitat

The wide distribution of the family is a reflection of the ability of rails to adapt to a very diverse range of habitat types, both natural and artificial. Rails are cosmopolitan and occur almost everywhere except in polar regions, completely waterless deserts and mountainous regions above the permanent snow-line. The greatest variety of species is found in wetlands, where rails occupy virtually all types of terrestrial, estuarine and littoral wetland habitats. Some species are found at coastal wetlands such as lagoons, bays, salt-marshes, tidal creeks and mudflats, and mangrove swamps. For example, the mangrove habitats of South America are home to four of the *Aramides* wood-rails, the other three species being found predominantly in forest. In Australia the Buff-banded Rail, which occurs in a wide range of habitat types including freshwater wetlands, forest, woodland, heathland, grassland and crops, sometimes also inhabits salt-marshes, tidal mudflats and mangroves, and it even occurs on coral cays and other offshore islands.

Rails occupy many types of freshwater wetland including swamps, peat bogs, marshes, dambos (seasonally wet drainage lines in African woodland), floodplains, permanent and seasonal pans and ponds, ditches, paddyfields and wet sugar cane fields, and the marginal and emergent vegetation of streams, rivers, canals, dams and lakes. Some species, such as the Grey-breasted Crake (*Laterallus exilis*), the Sakalava Rail (*Amaurornis olivieri*), the Yellow-breasted and White-browed Crakes, and the *Porphyrio* gallinules, have a preference for floating vegetation, and one factor responsible for the threatened status of the Sakalava Rail of Madagascar is probably the continued loss of this habitat type.

The most aquatic rallids, the coots, occupy water bodies ranging from freshwater lakes and ponds to brackish water, and bays and arms of the sea. They frequently occur alongside waterfowl (Anatidae) but, unlike some ducks, have not become adapted to a purely saltwater environment. The two largest species, the Giant Coot and the Horned Coot, frequent barren highland lakes of

the Andean *puna* zone, occurring to altitudes of over 5000 m, while the Andean Coot (*Fulica ardesiaca*) and the White-winged Coot (*Fulica leucoptera*) occur to almost as high an elevation in similar habitats. The Red-fronted Coot, which occurs at lower altitudes in South America, appears to prefer semi-open waters with much floating and emergent vegetation, and is the only member of the genus in which the lobes on the toes are not greatly enlarged as an aid to frequent and prolonged swimming.

Other rails inhabit warm forests from lowland to highland areas, including the interior and edge of primary and secondary growth, monsoon forest, swamp forest, sago swamps, gallery forest, dense riverine forest, forested ravines, partially cleared forest and dense scrub, overgrown and abandoned cultivation at forest margins, banana groves, cassava and arrowroot plantations, and dense evergreen or deciduous thickets. Forest habitats may have clear substrates with leaf litter, moist ground or mud, or may have ground vegetation. Some species, for example the Nkulengu Rail, the Grey-throated Rail (*Canirallus oculeus*) and Woodford's Rail (*Nesoclopeus woodfordi*), are typically associated with wet habitats such as forest streams, swampy areas and muddy patches, and are never far from water, whereas the four wood-rails endemic to New Guinea appear not to be associated with wet areas. Others, such as the Rufous-necked (*Aramides axillaris*) and Grey-necked Wood-rails (*Aramides cajanea*) extend their ranges from forest into deciduous woodland. The Buff-spotted Flufftail (*Sarothrura elegans*) occupies a wide range of habitat types, from stable forest habitats to deciduous thickets which may be occupied only seasonally depending on the cover and the substrate moisture, and consequently also the availability of food.

Other species are associated with predominantly grassland habitats, ranging from mosaics of hygrophilous grassland and sedge meadow, and the marginal zones of grassland savanna with pockets of marsh, to predominantly dry grassland including savanna, *pampas*, hayfields, meadows, rough pasture, alfalfa and crop fields, occasionally crop stubble, and also golf courses and airstrips; the grass may be tall or relatively short, but it is usually dense. In New Zealand, both the Weka and the Takahe occur in subalpine tussock grassland, the latter exclusively, except when forced to move down to subalpine scrub and beech forest when snow covers the grassland in winter. In Africa, the Striped Flufftail (*Sarothrura affinis*) occurs in both upland grassland and, in the south-western Cape, in mesic mountain fynbos, a macchia-type vegetation dominated by heaths (Ericaceae), proteas (Proteaceae) and the grass- and sedge-like restios (Restioanceae) on dry to seasonally waterlogged ground; it is the only rallid to occur in this habitat type. Grassland habitats may be permanently or seasonally occupied: for example, those occupied by the African Crake (*Crex egregia*) and the Streaky-breasted Flufftail (*Sarothrura boehmi*) in central and southern Africa are typically seasonally moist to wet and are frequently burned during the dry season, forcing the birds to emigrate after breeding.

The non-breeding habitats of most rails are similar to their breeding habitats, but some wetland and grassland species, especially those which migrate, may occupy different habitats in different seasons, and many species occupy a wider range of habitats outside the breeding season. During the rainy season in central and southern Africa, sedentary species such as the Red-chested Flufftail (*Sarothrura rufa*) and the African Rail move out from permanently wet reedbeds and sedgebeds to occupy peripheral seasonally wet grassland which provides good nesting habitat but may be burned in the dry season. In North America the winter habitat of the Black Rail includes smaller, more linear and more fragmented wetland patches than does the preferred summer habitat, while in some areas the Yellow Rail (*Coturnicops noveboracensis*) appears to prefer the drier portions of coastal marshes in winter, and the Virginia Rail occupies salt-marshes more widely in winter than in the breeding season. The Little, Baillon's (*Porzana pusilla*) and the Spotted Crakes (*Porzana porzana*) and also the Sora all occupy a wider range of palustrine wetland habitats outside the breeding season, while Spotted Crakes wintering in central Africa occupy very temporary habitats not used by breeding Afrotropical species. In winter, the Water Rail, when displaced by frost, may use drainpipes, rubbish dumps, open ditches and other artefacts as refuges, and it can occur in gardens. There is even a record of the threatened Austral Rail (*Rallus antarcticus*) wintering in a garden and subsequently moving back into its normal reedbed habitat. A narrower habitat tolerance in the breeding season may result from restrictions imposed by breeding-habitat requirements, and also from seasonal differences in food requirements (see Food and Feeding).

Any rallid is likely to make use of atypical habitats, often artificial and sometimes of very limited extent or with relatively poor cover, when on migration or undergoing dispersal or irruptive movements. Thus wetland species may occur at sewage ponds, flooded patches of grass or forbs, flooded thickets, and predominantly dry grassy areas such as lawns, pastures and hayfields, while species normally inhabiting freshwater sites may temporarily use brackish or saline wetlands. Grassland species may make use of airstrips, golf courses and crop fields. The highly eruptive Black-tailed Native-hen of Australia takes advantage of many wetland, grassland and scrub habitats, especially during influxes, and is also known to occur in urban areas and in arid country, sandhills, and coastal flats and scrub.

The ability to capitalize on this great diversity of habitats throughout the world indicates that the family shows great adaptive plasticity. Rails are also predominantly of generalist habits, for example many are omnivorous. These two characteristics allow many species to exploit highly ephemeral or atypical habitats. The great adaptive plasticity of rails also allows them to be successful colonists of oceanic islands. Their ability to make use of open land allows them to colonize islands where, in the absence of competitors, they can radiate to occupy almost any available terrestrial niche. They are capable of adapting to remote oceanic islands of volcanic origin, where conditions are harsh and vegetation is sparse or even almost non-existent. For example, the recently extinct *Atlantisia elpenor* lived on Ascension Island, where the terrestrial environment is hostile in the extreme, consisting mainly of bare, waterless tracts of lava and ash. This medium-sized rail, about the size of the Virginia Rail, apparently obtained its food and water from the eggs and regurgitated prey of the seabirds which formerly nested on the island in great numbers. Another *Atlantisia* species, the Inaccessible Rail, apparently occupies the niche of a mouse on its namesake island. It makes tunnels through the vegetation and forages on boulder beaches, making use of natural connecting cavities under boulders when moving around. The Spotless Crake is a good example of a species with a wide habitat tolerance which has successfully colonized islands. It normally occurs in a great variety of wetland habitats and also in ferns, heath and scrub, but on some islands it occupies dry, sterile, rocky or stony habitats with no standing water. Similarly, the nominate, Madagascar race of the White-throated Rail occurs in forest, wetlands and mangroves, but the Aldabra race, *aldabranus*, is adapted to coral scrub habitat.

The habitat requirements of few rail species have been studied in great detail, but it has been demonstrated that, for some wetland and forest species which feed chiefly on invertebrates, the structure of the vegetation and the nature of the substrate may be the most important factors influencing habitat suitability. For example, the Virginia Rail is known to avoid marshes with high stem densities or large amounts of residual vegetation, features which are common in older marshes and which impede the birds' movement, whereas vegetation height is not important as long as there is adequate overhead cover. These birds need shallow water and a substrate with a high invertebrate abundance, and are most common in areas with 40-70% upright emergent vegetation interspersed with patches of open water, mudflats or matted vegetation. When breeding, they may select those areas of the marsh with a greater abundance of emergent vegetation.

Red-chested Flufftails occur in a very wide variety of wetland vegetation types and, like Virginia Rails, avoid areas where the vegetation is very dense and moribund, such vegetation being difficult to move through and providing few good nest-sites and relatively little invertebrate food. In southern Africa they are adapted to fire-modified wetland habitats, and periodic burning results in improvement in habitat quality expressed in terms of the increased availability of vegetation suitable for occupation

During the breeding season coots are highly territorial and are notoriously aggressive, especially towards conspecifics but also to other waterbird species. The aggressive displays and fighting behaviour of most coots have been described in some detail; warning, patrolling, Charging-attack and Splattering-attack behaviour appear to be very similar in all taxa. The Splattering-attack, a high intensity threat, is shown in the upper photograph of Giant Coots. The attacking bird splatters noisily towards the intruder, running over the surface of the water aided by the flapping wings, extending the neck forwards and holding the tail down. The attacked bird flees in a similar manner, but with its head more erect (Splattering-retreat). To avoid violent confrontation, when close to the victim the attacker usually brakes sharply by closing its wings, raising its body and "churning" or treading water vigorously. In the Common Coot, as seen in the lower photograph, fighting generally follows Charging-attacks, when the antagonists swim towards each other at high speed and neither gives way. It involves violent, often prolonged, striking with the feet, clawing at the opponent's breast and stabbing with the bill; both birds usually spread and hold back the wings as they try to unbalance each other. The weaker bird is often forced onto its back or is held under water, and may escape by swimming under water or by fleeing in the Splattering-retreat. Fights may result in injury, and death has even been known to occur.

and an increase in the density of permanently resident pairs. The timing of their return to burned territories is mainly influenced by the development of adequate canopy cover (at least 55% and usually over 65% cover is required) and to the substrate water content, for they do not reoccupy seasonally wet areas until the substrate is moist or flooded; the effect of vegetation height is less important but is complementary to that of cover in that birds will return to very tall vegetation, such as *Typha*, while cover values are still relatively low.

The Buff-spotted Flufftail also occupies a wide variety of habitat types encompassing both natural forest and thickets, and also areas dominated by alien vegetation: in southern Africa it has extended its range locally by occupying exotic vegetation around human habitations. Its primary food consists of macroinvertebrates, for which it forages in leaf litter and damp earth; such prey is as abundant on substrates below exotic vegetation as on those below indigenous plants.

Although most rails inhabit wetland habitats, it does not necessarily follow that the family has an aquatic or paludicoline origin. Olson has pointed out that the most primitive living rail, the Nkulengu Rail, is a forest bird, as are the members of other primitive or unspecialized relict genera such as *Aramides*, *Canirallus* and *Gymnocrex*, while the most specialized and derived genera such as *Rallus*, *Porphyrio* and *Fulica* contain aquatic or marsh-dwelling species. Thus it would appear that the progression from generalization to specialization in the family is from forest forms to aquatic forms.

General Habits

Because of the difficulties involved in observing rails in dense cover, and the often secretive nature of the birds, the social behaviour of most species is very poorly known, and most detailed studies have been made on the larger, more obvious species such as gallinules, moorhens and coots. In general, rails are solitary or occur only in pairs, family parties or other small groups. The most gregarious species are the coots, with the exception of the Giant Coot: species such as the Common, American, Red-knobbed, White-winged and Andean Coots frequently associate in large monospecific flocks outside the breeding season, while non-breeding birds of the first two species also flock near breeding territories during the breeding season. Some flocks may be very large, numbering over 10,000 birds in the Common Coot, in which some of these agglomerations may be moulting groups. Coots tend to feed in loose flocks, often alongside ducks. In the breeding season coots are territorial and often very pugnacious, but the Horned Coot occasionally nests in loose colonies.

Some gallinules also associate in loose flocks when not breeding, examples being the Purple Swamphen (*Porhyrio porphyrio*), and the Common and Dusky Moorhens. In flocks of Common Moorhens, and in all social groups of Purple Swamphens, a social hierarchy may be seen, males being dominant to females and adults dominant to immatures. The Black-tailed Native-hen is usually gregarious and may occur in enormous flocks during its periodic irruptions, when flocks of up to 20,000 birds are recorded. It may also feed gregariously, but it breeds in isolated pairs or in small colonies of up to five nests. Populations of the Takahe are often concentrated into loose colonies, but within these, solitary pairs defend secluded territories.

Most other species are normally solitary, although population densities can be very high in some wetlands. Black Crakes (*Amaurornis flavirostris*), Lesser Moorhens (*Gallinula angulata*) and Allen's Gallinules (*Porphyrio alleni*) are known to occur and breed at high densities in the emergent vegetation of irregularly flooded river systems in the Afrotropics.

After breeding, many rails relinquish their territories and remain solitary until the next breeding season. Winter feeding territories are known to be maintained by the Water Rail, by the migrant Spotted Crake, and possibly also by the Corncrake (*Crex crex*), in their African wintering quarters, and by the African Crake, and this phenomenon is probably more widespread than is known. Some sedentary species which defend permanent territories and remain in pairs throughout the year, such as the Red-chested and White-spotted Flufftails, may allow immatures to remain in the territory throughout the non-breeding period, during which time the young birds assist with territory defence; the adults will then eject the offspring at the start of the next breeding season. Even species such as the Black Crake, which are territorial only during the breeding season, may retain a loose association between family members during the non-breeding period.

The distinctive song of the Corncrake, from which the bird's scientific and common names are derived, is a monotonous rasping call given only by the male. It may be imitated by mechanical means such as rubbing a piece of bone or wood against another with notches cut in it, or even against a comb. The call serves to proclaim ownership of a territory, to challenge conspecific intruders, and probably also to attract females. It is given most frequently early in the breeding season, when birds often call for hours on end, both day and night. The male calls from the ground, or sometimes from an elevated perch such as a wall; this bird is calling from a low bush at night.

Oxford Scientific Films]

Many rails, whether or not they are defending breeding territories, appear to be aggressive towards conspecifics, and also towards other rail and other bird species. There are few published observations of rails feeding in close proximity to other bird species, but Spotted and Baillon's Crakes, in non-breeding habitat in central and East Africa, will forage on muddy substrates alongside small sandpipers (*Tringa*, *Calidris*) and Greater Painted-snipes (*Rostratula benghalensis*), and they will also feed close to each other.

The daily activity patterns of rails have been poorly studied, but it is known that many species are active during the day and roost at night. Many species are predominantly crepuscular and most show peak activity, including intensive feeding, soon after they emerge from the roost, and again in the late afternoon and early evening. The middle of the day is often spent sheltering and resting. Some species are thought to be mainly nocturnal, but it is difficult to find solid evidence for regular nocturnal activity in more than a few species, and what is loosely described as nocturnal activity may often refer only to crepuscular activity. Some species, such as the flufftails, give advertising calls throughout the night during the breeding season but are not active in any other way at night: they remain in one spot and will not move around in response to taped playback, and they do not forage at night.

Similarly, the King Rail calls much at night during the courtship period, and to a lesser extent at other times of the year, but captive birds move little at night; nothing is known of their roosting habits in the wild. The Plumbeous Rail (*Pardirallus sanguinolentus*) gives advertising calls at night, and is also active during the night in marshes or adjacent cultivated fields. Other terrestrial and marsh species which are known to forage at night as well as by day are the Weka, the Grey-necked Woodrail, and the Chestnut, Inaccessible, Guam and Buff-banded Rails; however the last two are most active at dawn and dusk. The Weka is semi-nocturnal, becoming active in the late afternoon and being active in open habitat on clear moonlit nights. Common Coots and Common Moorhens are sometimes active on moonlit nights and on floodlit waters, and it is possible that nocturnal foraging in rallids is largely confined to species which occupy open habitats where the visibility at night is relatively good, for example coots and those species which inhabit open mudflats. Rails which forage in tidal areas must presumably be active nocturnally when low tides occur at night.

Rails usually roost solitarily, or seasonally in pairs or family groups, except in flocking species. They generally roost on the ground in dense cover, but sometimes above the ground in dense vegetation such as bushes and trees. Some forest-rails, including some flightless species, roost in trees to avoid ground predators, and the Red-necked Crake (*Rallina tricolor*) may use communal roosting platforms. The Plain Bush-hen (*Amaurornis olivaceus*) is also known to build roosting platforms, and other species roost in groups on patches of flattened vegetation. When breeding, many species roost in nests with their offspring, and some may roost in nests at other times of the year: in the New Guinea forests, Forbes's Forest-rail constructs a domed roosting nest in which up to seven adults may sleep, and the White-striped Forest-rail (*Rallina leucospila*) roosts in pairs in a roofed shelter of dried leaves and moss which, according to local people, has nothing to do with nesting and is merely a shelter from the rain, although admittedly this bird's nest remains undescribed but is possibly domed. In harsh environments shelter at night may be important, as is suggested by the case of a captive Inaccessible Rail which was inadvertently left outside in one of the island's frequent gales; although it dug a hole almost 30 cm deep near the roots of a tussock plant, it died.

When resting, rails stand, sometimes on one leg and mostly in a hunched posture with the head sunk on the shoulders, or they lie down on the belly. They often sleep with the head on the back and the bill tucked into the feathers. They bathe freely, mainly by standing in shallow water, alternately ducking the head into the water and flipping water over the back, as well as beating the half-open wings in the water; they may also move the body up and down in the water, or dip the tail. Coots sometimes bathe while swimming. After bathing, the birds leave water to oil and preen. In captive Yellow Rails, bathing activity peaked in the evening at around 19:00 hours and was less frequent in the morning. Captive Red-chested Flufftails bathed daily, always after midday and with peaks in the hottest part of the day and in the early evening, while wild Buff-spotted Flufftails bathed throughout the day, the frequency of this activity increasing during the day to a peak in the two hours before the birds went to roost; chicks also bathed regularly from the age of 10-11 days.

The Water Rail, like most rallids, is omnivorous. It eats predominantly animal matter, especially in spring and summer, consuming more plant material in autumn and winter. Its animal foods include many invertebrates, and it also eats small vertebrates such as fish, amphibians, birds and mammals, which it either kills or scavenges. It occupies many types of dense vegetation over water. On migration and in winter, especially in severe weather, it exploits a much wider range of habitats, and it may venture some distance into the open away from cover to feed, even tolerating human presence.

[*Rallus aquaticus aquaticus*. Photo: Hellio-Van Ingen/ Auscape]

The Black Crake, the commonest and most widespread crake in Africa, is relatively bold, coming more readily into the open than other crakes, and often foraging some distance from cover on floating vegetation and on open or burnt ground. It eats invertebrates and small vertebrates but also takes plant material, especially seeds of aquatic plants. It takes eggs and young birds, kills small birds caught in mist-nets, and also scavenges. When accustomed to human presence it becomes quite tame, and readily accepts artificial foods such as duck- and fish-food pellets, even taking food from the hand.

[*Amaurornis flavirostris*, Kruger National Park, South Africa. Photo: Hanne & Jens Eriksen/Aquila]

After bathing, the birds preen vigorously. When conditions permit, they will often sun themselves after bathing and preening. Many species are known to stand in a characteristic sunning posture, with partly open wings spread backwards over the sides of the tail. A similar posture, with shuffling movements, is also used to dry the wings, and is the source of reports of so-called rain-bathing. Purple Swamphens will also sometimes sun by crouching with the legs extended forwards, toes splayed and pointed forwards, and wings closed. In Red-chested Flufftails, bathing is solitary but sunbathing may be a social activity, involving a pair or a family group; the birds either crouch or lie flat on the ground with the tail spread and the wings open, drooped, raised, partially or fully extended, or with the wingtips crossed across the back; they frequently preen vigorously while sunning. In captivity, these flufftails were found to sunbathe for the longest periods, lasting 4-10 minutes, in the cool of early morning, as soon as warm sunlit patches became available on the ground or on top of dense vegetation; thereafter, they sunbathed for shorter periods throughout the day. Social sunbathing and preening are also recorded in captive Red-and-white Crakes (*Laterallus leucopyrrhus*).

Allopreening is common, between pair members (often reciprocally), adults and offspring, and siblings; it probably involves functional feather-care to some extent, as well as being of social significance. Head-scratching is direct.

Thermoregulatory behaviour has been little studied in rails. Tasmanian Native-hens often face the breeze on hot days and pant to keep cool, and when shade temperatures exceed 27°C they stop feeding in the open and seek shade or move beneath dense masses of vegetation. On small islands, the Buff-banded Rail is known to shelter in shearwater and petrel burrows and under coralline rocks during the heat of the day.

Voice

Most rails are very vocal, as is to be expected in birds which inhabit dense cover where visual contact is often very limited and communication by sound is important. Red-chested and White-spotted Flufftails, for example, are strongly territorial species which inhabit very dense vegetation, and which may indulge in prolonged bouts of territorial calling with neighbours at a common boundary without apparently being in visual contact, even though the birds may be within 1 m of each other on the ground.

The calls of rails vary from sweet to harsh, and include screams, squeals, trills, whistles, booms, rattles, trumpets, grunts and barks. The advertising and territorial calls of many species are given in rather repetitive series and are often loud. Calling may occur at any time of the day or night, but many species call most commonly in the early morning and the evening. Most species are mainly silent when not breeding, and therefore not territorial, but those that are permanently territorial call throughout the year, as do social species, many of which have loud rallying cries. Non-vocal sound signals include wing-clapping, used by Purple Swamphens to distract predators from the young and to attract relief when incubating, beating the water with the wings, used by coots and moorhens in aggressive displays and by many rails during distraction displays in defence of chicks, and slapping noises made with the feet, these characteristically being made by moorhens and coots in defence displays.

Authors describe many rail calls as harsh or monotonous, such as "tack", "kak" or "crek", and many species include a call of this type in their vocal repertoire, sometimes given in a series as an advertising call and sometimes given singly as an aggressive, alarm or warning call. The calls of some small species such as the Yellow Rail may be likened to the noise made by knocking two large pebbles together, and the birds may be induced to respond to sounds produced in this way. Other small crakes produce a sequence of notes rather like a trill, such as is made by small grebes. Some gallinules have booming calls, holding the head and neck in such a way as to produce a resonant note, smaller in volume but similar to that produced by rheas (Rheidae) and cassowaries (Casuariidae). Some of the larger rail species can scream loudly when caught.

Characteristic call types are sometimes shared by most or all members of a genus, and some examples will serve to illustrate the range of calls used. Crakes of the genera *Anurolimnas* and *Laterallus* have trilling, churring or rattling calls, flufftails have hooting advertising calls, *Rallina* crakes often have croaking or nasal calls, and *Gallirallus* species typically give screeches, whistles, squeals or grunts. The *Aramides* wood-rails, which in-

Coots are largely herbivorous, most species feeding predominantly in open water and some also on land. They employ a variety of foraging techniques, two of which are illustrated in these photographs of Common Coots. In shallow water, the Common Coot will immerse the head and neck to scrape algae from stones, stems and tree stumps under water, and to glean food items from the bottom. It may upend in water as much as 40 cm deep, occasionally immersing the whole body. It also dives, usually to 1-2 m but as far down as 6·5 m. A bird presses the air out of the feathers, leaping upwards and then tilting forwards and diving almost vertically with the neck extended. Dives are usually short, lasting up to 20 seconds, and are made to secure water weed, invertebrates and occasionally fish. Coots are less adept at diving than are other bottom-feeding birds: in a given depth of water the duration of their dives is much less, and food is brought to the surface rather than eaten at the bottom.

Clapper Rails inhabit mainly saltwater and brackish marshes. They eat invertebrates, including molluscs, crustaceans and insects, and also take small vertebrates such as fish and frogs, and sometimes, as in this photo, mice. Vegetable matter is also eaten. The race obsoletus *of central California is one of three races of this species currently considered to be endangered in the USA. It suffered first from excessive hunting and then from extensive loss of habitat, and its numbers have declined rapidly from an estimated 4200-6000 birds in the early 1970's to only about 400 in 1991. Most of its remaining population is found in San Francisco Bay, where much of its habitat has been destroyed by development.*

[*Rallus longirostris obsoletus*, San Francisco Bay, California, USA. Photo: Jeff Foott/Auscape]

habit mangroves, swamps and lowland forest in Central and South America, have a wide range of remarkably loud and far-carrying yelps, shrieks, cackles, barks, grunts and pops, which are characteristic sounds of the areas in which they occur, and which have given rise to onomatopoeic local names for the birds. The voices of the Grey-necked and the Giant Wood-rails (*Aramides ypecaha*) are particularly arresting: both species call in chorus, the former having a varied series of crazed-sounding rollicking, popping and clicking notes, and the latter congregating in groups in the evening to set up a deafening chorus of screams, shrieks and wheezes. The vocabulary of most *Porzana* crakes includes trills, rattles, purrs, chattering, knocking, grating or ticking notes; some also have whistling calls. Most *Gallinula* species emit crowing or clucking calls, and most *Fulica* species have short, explosive, aggressive calls variously rendered "pit", "hic" or "pssi".

Calling in some species is recorded as being ventriloquial, so that the position of the caller is difficult to pinpoint, and one way in which this effect is produced has been observed in the Buff-spotted Flufftail. The male gives loud, hollow, hooting "oooooooo....." notes, each lasting 3-4 seconds, usually from a completely concealed low perch in dense woody vegetation. The call is often given throughout the night and is one of the most characteristic and evocative sounds of the African forest, and has given rise to legends and superstitions (see Relationship with Man). While uttering the note the male continually turns his head slowly from side to side, possibly to broadcast the sound effectively in all directions, and this creates the impression that the call varies greatly in volume and makes the source very difficult to locate.

Duetting is reported in several genera. As normally applied to rails, the term may cover three different forms of vocalizations: true antiphonal duetting, in which a mated pair will make precisely timed alternate calls; calling in precise unison by two birds; and two or more birds calling simultaneously or in chorus, but not in unison or antiphonally. A few species are described as making calls of the second type, notably the Virginia, White-throated and Chestnut Rails and the Tasmanian Native-hen, all of which are also said to duet antiphonally. The White-throated Rail's calls are not made precisely in unison, nor is there apparently any published sonagraphic evidence that those of the other species are. Likewise, most descriptions of antiphonal singing in rails are not backed by sonagraphic evidence to show the precise synchrony of the calls and, in many instances where reasonable evidence is available, it seems that true synchrony is not achieved but that individuals may sing according to their own internally derived rhythm. Species claimed to sing antiphonally include some flufftails, the Nkulengu, New Britain, Okinawa and Water Rails, the Rufous-necked and Grey-necked Wood-rails, the Black Crake, the Rufous-tailed Bush-hen (*Amaurornis moluccanus*), the Spotted and Henderson Crakes and the Chestnut Rail; some of these species also call in chorus. The other species recorded as duetting, such as the Red-necked Crake, the Weka, the Lord Howe and African Rails and the Giant Wood-rail, call either in asynchronous duet or in chorus.

Duetting, including simultaneous song and chorus singing, in rails appears to be principally related to co-operative territorial defence and advertisement, but in some species duetting and simultaneous calling probably help to maintain and reinforce the pair-bond and may also be part of pre-copulatory behaviour. At least in the Black Crake, chorus singing may also assist in the maintenance of the extended family group during the breeding season. Much remains to be discovered about duetting in rails, especially because the calls of so many species, particularly from the tropics, remain undescribed.

Many rails have an extensive vocal repertoire, using calls to communicate in a wide variety of situations. Distinctive advertising calls are frequently uttered, both in territorial advertisement and maintenance and to attract mates. Courtship calls, pre-copulatory and mating calls, contact calls, rallying calls, aggressive calls, warning, alarm and distress calls, and food-soliciting and food-offering calls are among the many vocalizations described for the better known species. Advertis-

Display behaviour, including heterosexual behaviour, is very similar in the Common Moorhen to that found in the Common Coot (Fulica atra). *The female solicits copulation by performing the standing Arch-bow display, in which the body is held upright but the head bent down so that the bill points towards the toes. This leads to the Squat-bow, when the female crouches on bent legs in a similar posture and the male steps on to her back to copulate. The male sometimes adopts the standing Arch-bow as a post-copulatory display, and this may lead to reversed mounting, when the female mounts the male, at times a not uncommon occurrence.*

[*Gallinula chloropus cachinnans*, Florida Everglades, USA. Photo: George McCarthy/ Bruce Coleman]

ing calls are frequently far-carrying; for example, the whistle call of the Spotted Crake is audible for at least 2 km in calm weather, while the hoot of the Buff-spotted Flufftail is well audible for up to 1 km through forest and woodland and up to 2·8 km over open ground.

In seasonally territorial species, the frequency and variety of calling often peak during the establishment of the breeding territory, courtship and the early part of the breeding season, falling off after egg-laying and remaining at a relatively low level while the young are reared. In some species there may be a resurgence of territorial calling at the end of the breeding season and this has been shown, in the African Rail and probably in the Clapper Rail, to reflect inclusion of juvenile calls at this time of the year. In those species which do not hold permanent territories, advertising calling usually decreases markedly, or ceases completely, at the end of the breeding season, but species which hold permanent territories continue to make territorial advertising calls throughout the year, although usually at a reduced level outside the breeding season. The Lord Howe Rail is less vocal during its post-breeding moult, as probably are other permanently territorial species. Some species are known to call in flight when migrating, but many migrant species are described as being silent on their non-breeding grounds.

Food and Feeding

Although some species are predominantly vegetarian and some almost entirely dependent on invertebrate food, rails as a group are characteristically omnivorous and non-specialized feeders, often opportunistic, and well able to adapt to new habitats and food sources. Many species appear to feed largely on the most abundant plant or animal foods available at any time, and thus the proportions of different invertebrates in the diet, or of different seeds and vegetative parts of plants, often reflect the relative availability of these foods in the environment. While there is much information on the diet of a few well studied species, mainly from Europe, North America and Australasia and particularly the large, easily studied species such as gallinules and coots, little or nothing is known about the food and feeding habits of many others. Even for most well studied species, good quantitative analyses of diet are lacking.

Plant foods include a wide range of vascular plant material, including seeds and drupes, shoots, stems and leaves, tubers, bulbs, rhizomes and roots, as well as marine and filamentous algae, fungi and lichens. Some species take cultivated plant matter and fruit, such as young vegetables and cereal crops, fodder crops, grain (including rice and maize), tomatoes, melons, apples, drying apricots, bananas and taro. Invertebrates are an important part of the diet of many species, and include worms (Annelida and particularly Oligochaeta), nematodes, flatworms, leeches, molluscs, woodlice (Isopoda), millipedes (Diplopoda), centipedes (Chilopoda), amphipods, copepods, crabs and crayfish, springtails (Collembola), Arachnida (mainly spiders), and a wide variety of insects and their larvae. Some species take small fish and fish spawn, amphibians and their tadpoles, reptiles (lizards and their eggs, small snakes, and turtle eggs and hatchlings), the eggs and young of other birds, the droppings of gulls and ducks, rodents (mice and rats), young rabbits, carrion (ranging from small birds and rodents to the carcass of a cow), and various household items including bread, porridge, stew, dog food, chicken food, biscuits, butter and chocolate, while the Lord Howe Rail has even been known to eat rat poison, and presumably to survive!

In general, the most aquatic species, such as the gallinules and coots, are largely herbivorous, while those that inhabit terrestrial and palustrine habitats are either omnivorous or predominantly carnivorous, at least seasonally. Forest-dwelling species are relatively poorly known but they probably eat fewer plant foods than do rails in other habitats. Forest species such as the Andaman Crake and the Grey-throated, New Caledonian, Okinawa, Woodford's and Bare-eyed Rails (*Gymnocrex*

The Spotless Crake builds a cupped nest of woven dry grass, sedges or rushes, usually very well concealed in dense vegetation such as a sedge clump or a grass tussock, and often situated over water. The eggs are dull creamy brown with numerous small chestnut brown flecks and weigh about 9-9·5 g, roughly 23% of the female's mean weight. The clutch size is 2-6, typically 3-4, though clutches laid later in the season are apparently larger on average than the earlier ones, while island populations may lay smaller clutches than mainland birds. Both sexes incubate, and hatching may be either synchronous or, in larger clutches, asynchronous.

[*Porzana tabuensis tabuensis*.

plumbeiventris) are recorded as taking very little plant material, if any.

Species with long, thin bills probe for invertebrate food in shallow water, soft ground and litter, while species with small, fine bills tend to take many small invertebrates and seeds from the substrate, shallow water and low vegetation. Those with relatively unspecialized, straight bills of moderate length and depth take a wide variety of small to large food items, chiefly by probing, gleaning, digging, sifting litter, stabbing at large prey and raking in soft earth and mud. Thick-billed species tear and slice vegetation, and dig or pull up the underground parts of plants. Some gallinules graze, for example the Purple Swamphen and the Tasmanian Native-hen, as also do the coots. Only coots regularly dive for food; Common Moorhens do so rarely, and Rouget's Rail (*Rougetius rougetii*) of wetlands in the Ethiopian highlands has been seen to dive into a stream like a dipper (*Cinclus*) when foraging, while the Little and Baillon's Crakes are also said to dive. Coots and *Gallinula* species regularly upend when feeding, and other species such as the King Rail may upend occasionally when foraging in deep water.

Terrestrial species which forage in leaf litter and soil use the bill to move or toss aside leaves and debris, and to turn over small stones, while searching for invertebrates; some species also use the feet to move debris aside and scratch in the ground. The Weka and the Lord Howe Rail will pull apart bark and rotten wood to extract food, while the latter chisels harder wood and will also pull aside palm fronds to search for food beneath them. Some species, such as the Rufous-tailed Bush-hen, the Sora and the Spotted Crake, run grass heads through the bill to strip seeds from them. The White-browed Crake often feeds while swimming, floating with the neck extended parallel with the surface and suddenly reaching out with the fine-pointed bill to capture water insects.

Large, live food items are usually killed and dismembered before being swallowed. The Water Rail first paralyses frogs and fish by making vertical blows with its bill behind the prey's head and then kills the prey by repeatedly striking it with the bill, while the King Rail hacks large prey items, such as crayfish, to pieces before eating them, and the Rufous-tailed Bush-hen crushes frogs in the bill before swallowing them. Large insects, such as grasshoppers, are shaken and battered before being swallowed. The Buff-banded Rail captures live prey by stabbing with the slightly open bill, pecks large snail shells to break them, crushes fish in the bill, and holds crabs by the legs in its bill while flicking its head from side to side until the legs break off. Other species knock large prey animals on the ground to immobilize or kill them before swallowing them. Several species spear eggs with the bill and either eat the contents *in situ* or carry the egg away to deal with. Large prey may be carried into cover or, if caught while the bird is in water, brought ashore to be dealt with. Rallids often wash food in water, this behaviour being recorded in aquatic, palustrine and terrestrial genera alike.

Using the foot to grasp and manipulate food is recorded in some *Porphyrio* species, such as the Purple Swamphen, Allen's Gallinule, the Takahe, and the extinct White Gallinule (*Porphyrio albus*). The Purple Swamphen uses its powerful bill to pull out grass tillers or to nip them off at the base, and to pull out emergent plants such as *Typha* and *Eleocharis*; it then grasps them in the foot while it chews or slices off the soft fleshy bases. It also holds down *Typha* stems with the foot while stripping off leaves with the bill to eat the leaf bases. Items such as stems, water-lily buds and figs are held in the foot and lifted towards the bill, which tears off small pieces or crushes the item before swallowing; plant material is held for eating by the opposition of the hind toe to the three closed fore toes. The fore toes are also used to comb through weed dangling from the bill, to strip casing from plants, or to harvest aquatic plants for nest material, and the feet are also used to hold down large food items, such as fish and carrion, while the bird pecks at them. This same species also climbs well in reedbeds and even into low trees to take eggs and nestlings, when the feet grip whole bunches of leaves and stems to give the bird sufficient support. It also grazes clover and pasture, digs for rhizomes and roots, and moves gravel and stones with the bill to find invertebrates. It is primarily vegetarian, plant material being recorded as making up 75-90% of its diet.

The Takahe holds food items in the feet in a similar way, and also strips seeds from grasses with the bill while holding the stalks in the foot. Allen's Gallinule turns over water-lily leaves with its bill and holds them down with the feet while gleaning food items from their undersurfaces. It is also partial to developing water-lily seedheads, which it breaks off with the bill and transfers to one foot before tearing off pieces with the bill, and it sometimes carries other food items in the foot to the bill. The Weka and the Dusky Moorhen also hold down food items with the foot while pecking or hammering at them, but they do not grasp or manipulate them in the foot as do the gallinules.

All rails ingest grit or small stones to help break up food in the gizzard and in some herbivorous species, such as the Takahe, this material may be ingested in considerable quantities. The Buff-spotted Flufftail, which forages in the leaf litter of forest and thickets, frequently ingests large quantities of the small, hard seeds of common trees such as bugweed (*Solanum mauritianum*) and pigeonwood (*Trema orientalis*), probably in lieu of grit, sufficient quantities of which may be hard to find.

Coots are almost entirely herbivorous but they do take some aquatic insects, molluscs and crustaceans, and will sometimes eat eggs, fish, carrion, duck-food pellets and even food scraps from camp-sites. The Common Coot feeds both in water and on land, employing a variety of foraging techniques. It scrapes algae off stems, stones and tree stumps under water, picks food from the water surface while swimming, breaks off young emergent shoots, feeds among vegetation stirred up by other waterfowl, leaps upwards to bring down leaves, seedheads and insects, upends in water up to 40 cm deep, occasionally immersing the whole body, and dives to bring up plant material and occasionally also invertebrates and fish, subsequently eating its spoils on the surface. Dives are usually short, no more than 20 seconds long, and normally to only 1-2 m, although a depth of 6·5 m is recorded. These birds also fish for shrimps in flocks of up to 100 birds, sometimes with ducks. They graze on land in flocks, or sometimes solitarily, particularly when winds cause high waves on the water.

Rails which forage in mangrove habitats appear to feed largely on crabs, these crustaceans being the main food items recorded for species such as the Chestnut Rail and the Rufous-necked and Grey-necked Wood-rails. The Chestnut Rail probes crab burrows and catches small fiddler crabs from among mangrove prop-roots, tapping them against a root before eating them. Black Crakes are apparently unique among rails in gleaning ectoparasites from the backs of large mammals, while the Nkulengu Rail and the Grey-necked Wood-rail are the only species known to follow army ant columns, presumably to feed on invertebrates that the ants disturb; other forest-rails probably do so too.

Seasonal variations in the proportions of animal and plant food taken are reported for a number of species, and reflect seasonal changes in the availability of food, the use of different habitats when birds are on migration or in wintering areas, and the possible need for a greater consumption of protein in the breeding season to satisfy the requirements for egg-laying. Many species increase their intake of animal food in the spring and summer, and of plant food in the autumn and winter. A quantitative study on the King Rail found that, during the year at one site, animal material constituted 95% by volume of foods in spring, 90% in summer, 74% in autumn and 58% in winter. In the Virginia Rail, animal foods predominate in summer, comprising 85-97% by volume of the diet, insects accounting for nearly 62% of the diet, whereas in autumn and winter 32% and 21% respectively of the diet consists of the seeds of marsh plants.

Very little information is available on the diet of the chicks of most rail species, but it would seem that the young of most species, even of herbivorous species, are fed primarily on insects and other animal food. Thus, aquatic insects comprise 45-85% of the diet of young chicks of the American Coot. Again, invertebrates form a large proportion of the diet of Takahe chicks for 4-6 weeks, the chicks becoming predominantly vegetarian when 6-8 weeks of age. Sora chicks are fed largely on invertebrates, although plant material constitutes a large proportion of the summer diet of the adults. The young of the Dusky Moorhen are fed on annelids, molluscs and insects for the first few weeks, after which plants are taken increasingly. There are conflicting accounts of the proportion of invertebrates fed to young Common Coots, but at least some are fed chiefly on invertebrates for the first 10 days, while the vegetarian Giant Coot feeds small young on both weed and invertebrates, and the American Coot feeds large quantities of aquatic insects to its chicks during the first week after hatching.

Kleptoparasitism is recorded in coots and gallinules. The Common Coot will snatch food from conspecifics and also from swans and both surface-feeding and diving ducks. The American Coot robs Canvasbacks (*Aythya valisineria*), Redheads (*Aythya americana*) and Ring-necked Ducks (*Aythya collaris*). Conversely, it has also been seen to be kleptoparasitized by American Wigeons (*Anas americana*) and Gadwalls (*Anas strepera*) and to relinquish food passively to them, apparently to gain time to dive a second time and eat food unmolested. Allen's Gallinules will chase and rob conspecifics of water-lily seedheads, and will also snatch them from African Pygmy-geese (*Nettapus auritus*).

Few studies have been made of foraging behaviour in rails. Wekas are known to search large areas of leaf litter, loosening it to a depth of 5-8 cm with the bill and covering up to 50 m² of dry litter per day. The Lord Howe Rail forages intensively in small areas, covering about 0·5 m² in 20-30 minutes. The Water Rail, in both breeding and winter territories, uses definite paths for foraging, the course of which is fixed by the position of favourable food sources, and it repeatedly visits successful hunting spots. The Madagascar Wood-rail is said to cover ground swiftly when probing leaf litter, and sometimes to return several times to areas which have just been searched. In Kakamega Forest, Kenya, pairs of White-spotted Flufftails holding permanent territories along small forest streams foraged over part of the terri-

Some African rallids undergo regular seasonal migrations, moving both north and south away from the equator to breed during the rains. One such species is Allen's Gallinule, which often breeds at seasonally inundated grasslands and floodplains. It may be locally very numerous in such breeding habitat during seasons of good rainfall. Juveniles only 2-3 months old are known to migrate with adults, while on the Nyl floodplain, South Africa, a newly arrived population included birds in all plumages from full juvenile to adult, suggesting that breeding may take place throughout the year. This species is well known for its vagrancy, and is unique in being the only Afrotropical bird species which straggles to Europe.

[*Porphyrio alleni*. Photo: Clem Haagner/ Ardea]

tory each day, one pair with two chicks using about 20% of the territory area each day and changing this foraging area every 2-4 days, the timing apparently depending on the availability of food and the amount of shallow streamside habitat available for foraging. Also in Kenya, Baillon's Crakes, feeding on plentiful invertebrates at drying shallow pools on mud in tall reedbeds, intensively searched small pools, up to about 4 m² in area, for up to 30 minutes and sometimes returned to the same sites several times per hour.

Breeding

Detailed studies have been made of the social organization, mating systems and breeding of only a few rallid species in the wild, notably some of those in the genera *Sarothrura*, *Gallirallus*, *Rallus*, *Crex*, *Porzana*, *Porphyrio*, *Gallinula* and *Fulica*, and in captivity of some of these species plus others such as the Yellow Rail and the Striped Crake. Unfortunately, little is known about the breeding of many other rails and the list of those species for which the nest, eggs and young are not even described is depressingly long.

Available evidence suggests that rails are seasonally or permanently territorial, living either in pairs or family groups, and that the majority form monogamous pair-bonds of at least seasonal duration. Monogamy is to be expected as the predominant mating system in the group because, although rail chicks are precocial or semi-precocial, they need intensive parental care at an early age, when they do not feed themselves but follow the parents and are fed, guarded and brooded by them. Some form of non-monogamous mating system is known to occur in the wild in only five rail species, the Corncrake, the Purple Swamphen, the Common and Dusky Moorhens and the Tasmanian Native-hen; in captivity it occurs in the Yellow Rail and the Striped Crake, and in the latter probably also in the wild. Although only a few species are involved, the strategies used are fascinating in their variety and complexity, and are worth examining in detail.

The Corncrake was formerly assumed to be monogamous, with the pair-bond lasting throughout the breeding season, but early observations indicated that it sometimes formed polygynous associations: males did not regard additional females as territorial intruders, closely neighbouring broods and clutches were sometimes associated with several birds, only one of which was a male, and chicks were often brooded and fed by the female alone. All these are indicative of polygyny, and recent work has shown that, although monogamy does occur, serial polygyny is regular in this species: males occupy shifting and overlapping home ranges and mate with two or more females; each female incubates the clutch and rears the young. In the congeneric African Crake, an association of one male and two females has also been observed in the breeding season. Serial polygyny has been recorded too in captive Yellow Rails, in which one male became dominant over others, claimed the entire enclosure as his territory and then paired with a female, seeking to mate with a second female when the first began to incubate; the male took no part in incubation or in caring for the young.

The reverse situation has been seen in captive Striped Crakes, which show serial polyandry. The sexes are rather different in plumage, and it is the female that makes advertising calls and establishes a breeding territory, mating with two or more males in succession and taking no part in incubation or in the rearing of the chicks. Evidence from limited observations of wild birds suggests that males normally incubate, indicating that polyandry may occur, although monogamy is also possible. One case of possible polyandry has also been reported for the Henderson Crake, in which a female made four nesting attempts with one male and one interim attempt with a male from an adjacent territory.

Monogamy is usual when both parents are needed to rear the young successfully. In situations where less parental care is needed, for example when the young are precocial and nidifugous, and especially if they can find their own food, it may not be necessary for more than one parent to tend the young. Breeding habitats such as wetlands and lush grasslands are structurally simple and may be highly productive, with food concentrated in a narrow spatial range. In such conditions it may be possible for males to control territories in which two or more females can breed, relegating less successful males to sub-optimal territories, or to none at all. This situation may apply to the Yellow Rail, and possibly also to the Corncrake. Polyandry in the Striped Crake, an Afrotropical migrant which often breeds in unpredict-

The Madagascar Flufftail is unusual among wetland and grassland Sarothrura *species in building a domed, rather than a cup-shaped, nest. Like other flufftails, it lays white eggs. Although only the female is known to incubate, this photo shows the male leaving the nest. This species is very similar in plumage to the Striped Flufftail* (Sarothrura affinis) *of Africa, and likewise it occurs in grassland, but it also uses habitats, such as forest edge, bush, cultivation and marshes, which in Africa are occupied by other* Sarothrura *species. Unlike African flufftails it lacks a hooting song, but its advertising call resembles the Striped Flufftail's territorial call.*

[*Sarothrura insularis*, Madagascar.
Photo: Dominique Halleux/ Bios/Foto Natura]

The nests of coots are normally built either within emergent vegetation, in some species with little attempt at concealment, or in open water. The Red-knobbed Coot's nest is a typical bulky platform of leaves and stems of water plants, lined with finer material and usually with a ramp at one side. When situated within emergent vegetation, such as the Schoenoplectus *sedges in the photograph, the nest is often constructed on a foundation of bent and trampled stems. It is built by both sexes, sometimes with the help of immatures; it is rearranged and added to during incubation; and it is built higher if the water level rises. Red-knobbed Coots occur on many types of open fresh water ranging from large natural lakes to small artificial farm dams, and can breed on waters 1 ha or less in extent; in some areas they have benefited considerably from the proliferation of artificial water bodies.*

[*Fulica cristata*, Lake Naivasha, Kenya. Photo: Alan Root/ Survival Anglia/ Oxford Scientific Films]

ably ephemeral wetland habitat, may have evolved in response to the great variability in breeding conditions and the availability of abundant food in the breeding habitat. The situation may be comparable with that seen in some waders which breed in the far north or in montane areas and have "rapid, multi-clutch" mating systems which enable them to increase their reproductive output when conditions suitable for breeding are short-lived. In these species, such as Temminck's Stint (*Calidris temminckii*) and the Eurasian Dotterel (*Charadrius morinellus*) the female either lays two or more clutches in quick succession for different males or lays two clutches, one of which is incubated by the male and the other by herself.

The social structure and mating systems of the promiscuous *Porphyrio* and *Gallinula* species are more complex. The Common Moorhen normally forms monogamous pair-bonds, usually for the breeding season only but sometimes for up to several years; it tends to be solitary and territorial when breeding. Immatures from earlier broods, and sometimes one or more additional mature birds, often help to tend and feed chicks. Polyandrous trios, where a female forms pair-bonds with two males, also occur at a low frequency. Co-operative nesting also occurs, in which two females, sometimes more, are paired to the same male and lay in the same nest, subsequently sharing parental care. In a recent study by S. McRae, most co-operative breeding groups consisted of a core pair and their previous offspring; in many cases a daughter laid in a communal nest with her mother and, if there was only one male in the group, he gained full paternity of his daughter's offspring, which had a low survival rate. Furthermore, brood parasitism regularly occurred: females laid eggs in neighbours' nests, often in addition to laying their own clutches. It was considered that co-operative breeding might be the only breeding option for first-year females that hatch late and overwinter on their natal territories, and that brood parasitism was a highly opportunistic reproductive strategy used by females that could produce more eggs than they could rear, or by those whose nests had been destroyed, or by "professional parasites" which achieved little reproductive success.

The flightless Tasmanian Native-hen defends a permanent territory and is either monogamous or polygamous, in the latter case usually polyandrous. The breeding unit consists of an adult pair or a trio of two males, often brothers, and a female; however, there may be up to five members, rarely including two females, always sisters. Adults normally associate for life. All males copulate with all females in the group, and the females all lay in one nest. Nest building, incubation and parental care are shared by all adults, sometimes assisted by young of an earlier brood or by young of the previous year which have not yet left the group. This strategy is believed to have arisen as a result of an unequal

Black-tailed Native-hens usually build a well concealed nest in low, dense vegetation, but they sometimes nest on the ground. Clutch size is usually 5-7 and hatching is normally asynchronous. The newly hatched chick has a white egg tooth and a black bill with a pink base to the upper mandible and a small greyish saddle, all of which features are visible here. Occurring over much of Australia, the species is dispersive and highly irruptive, and breeds opportunistically, sometimes arriving in an area in large numbers shortly after heavy rain and breeding in colonies, when laying is probably synchronous throughout the colony. It may nest in any month.

[*Gallinula ventralis*, Byro, West Australia. Photo: Babs & Bert Wells/ Oxford Scientific Films]

sex ratio in the species, as there is an excess of males among immatures, and it is cited as an example of kin selection.

The Dusky Moorhen is either sedentary or dispersive and is territorial only during the breeding season, when birds form breeding groups of 2-7 apparently unrelated birds in which the sex ratio usually favours males. Individuals sometimes switch groups between seasons. Simultaneous promiscuity occurs, all males copulating with all females, which all lay in one nest, and all members of the group defend the territory and share all breeding tasks; older siblings also sometimes help to care for the young. No explanation has been forthcoming for the evolution of this strategy in this species.

In Western Palearctic populations, the Purple Swamphen maintains a monogamous pair-bond, but in New Zealand the species has a complex social structure and mating system. Most birds occur in communal groups of up to 12 birds; stable groups, in which the birds remain together all year, usually consist of kin, while unstable groups are non-kin. Stable, communally breeding, groups which maintain permanent territories are polygamous and usually consist of 2-7 breeding males, 1-2 breeding females, and up to seven non-breeding helpers, which are offspring from previous matings. Unstable groups may be considered promiscuous, are characterized by much aggression and many male members, and are usually unsuccessful. Within the stable group mate-sharing is total, incestuous matings are common and homosexual matings also occur. Some males are dominant, but multiple paternity is prevalent. Only the most dominant females breed, laying in a common nest or a twin-bowl nest, and all birds in the group, including young from previous broods, care for the young. Most offspring remain as non-breeders before eventually becoming breeders. In this environment, habitat saturation and a shortage of prime breeding territories appear to be responsible for the communal breeding strategy.

A further ten species are known to live in extended family groups, at least during the breeding season, and to receive assistance, from other adults or young in the group, in feeding and rearing the chicks. This situation is normal in the Black Crake, which is territorial only in the breeding season, though it may associate in loose family groups at other times, and is multi-brooded, young of early broods helping to rear chicks of later broods; in some cases, young from one season remain with the family in the following season, when they also assist in rearing chicks. Cases of young birds helping to rear chicks of later broods are also reported in the Red-chested Flufftail, the Lord Howe Rail, the American Purple Gallinule, the Tristan Moorhen, the Common Coot and, in captivity, the Rufous-sided Crake (*Laterallus melanophaius*), while in the Weka, both large young and an extra adult have been seen to help. Some Henderson Rail territories were found to contain one or two extra birds of either sex which assisted with the defence of the chicks; it is not known whether these additional birds were fully adult, or whether they were related to the breeding pair. The Takahe is monogamous, maintains a permanent pair-bond, holds a territory during the breeding season, and breeds in family groups: older young, and sometimes offspring up to two years old, help to rear the chicks. In some of these cases, habitat saturation and a potential shortage of prime breeding territories may be reasons why mature offspring remain in the natal territory as opposed to establishing their own breeding units.

Little or no information on breeding seasonality and timing is available for many species, but most rails appear to breed seasonally, during the spring and summer in temperate regions and in or near the wet seasons in the tropics. There are exceptions to this generalization, however, most of them involving species of tropical or subtropical regions which may have extended or ill-defined breeding periods. Thus, some flufftails breed seasonally in central and southern Africa but have an indeterminate breeding season near the equator, while the African Rail breeds in both the wet and dry seasons in the tropics but is mainly restricted to summer breeding in southern Africa. Many forest species are reported to breed during, or at the start or end of, wet periods, but the Roviana Rail is reported to breed in the dry season, when excess water is not a problem on the forest floor in its habitat.

Some species may breed throughout the year if conditions remain suitable, examples from Africa being the Black Crake; the Common Moorhen in western Cape Province, South Africa, and in Zimbabwe; and the Red-knobbed Coot in Transvaal, South Africa. Elsewhere, breeding throughout the year is reported in the Guam Rail, the Lord Howe Rail, and the Giant Coot of high altitude lakes in the Andes. Over some of its range, the Buff-banded Rail is also known to breed throughout the

The brightly coloured bill found in chicks of some rallid species is thought to function as a signalling device, encouraging and assisting the adult to present food to the chick. In the Sora chick, this signalling is enhanced by contrastingly coloured bare skin on the crown, as is also found in coots and some gallinules, and, again as in coots, coloured throat bristles. When begging for food, Sora chicks crouch, and alternately gape and bow the head. These actions draw attention to the bill colours, the chrome-orange throat down, and the contrasting bluish skin over the eyes and reddish skin on the crown.

year, while the Weka of New Zealand has a variable breeding season, the start and duration of which are influenced by climate, food supplies and population size, and which may continue throughout the year in periods when its populations are expanding.

A study of the breeding seasons of waterbirds in south-western Australia showed that for the rails the laying period was best correlated with increasing day length, increasing temperature and, in most cases, peak rainfall. The timing of vegetation development is often important to the initiation of nesting in rails of marshy habitats, and migratory or seasonally displaced species may not be able to colonize wetlands, or to begin nesting, until the vegetation has developed to a suitable height and density. In the USA, peak nest initiation of the Common Moorhen occurs when the height of *Typha* is 45-100 cm and its growth rate is greatest, and the nesting of American Purple Gallinules is delayed in some habitats until the plant density is adequate. The breeding season of the Tasmanian Native-hen is determined by rainfall, as it depends on fresh young plant growth. Flooding conditions may also influence the start of breeding: for example, the breeding of the Spotless Crake in Australia may be delayed by flooding by up to six weeks, while the period of laying is correlated with water depth. Breeding timing may also vary with altitude, as a result of the later development of suitable conditions at higher altitudes: in Natal, South Africa, the start of breeding in the Buff-spotted Flufftail may be 1-2 months earlier in coastal regions than at altitudes above 1200 m.

The establishment of the breeding territory and the initiation of breeding activity are usually marked by greatly increased calling. Communication by sound is important and many species have loud and distinctive advertising and territorial calls, which are often uttered most frequently and continuously at the start of the breeding season (see Voice). Pair-forming and courtship behaviour are poorly known and little studied except in the larger, more conspicuous and less secretive species such as gallinules, moorhens and coots, but it is clear that sexual display has a limited repertoire in the family. Courtship feeding and allopreening are common, and aggressive-looking courtship chases often lead to copulation. Courtship displays are usually simple and in some species, such as the Buff-banded Rail and Baillon's Crake, copulation occurs with no preceding display at all. In some other species, the male's courtship display involves bowing, with head down and tail up, and either raising the wings, as in the Water Rail, or spreading them and holding them down, as in the Corncrake. The males of the King and African Rails walk around the female with the tail raised and the white undertail-coverts fanned, while the male Virginia Rail runs around the female with raised wings, stretched neck and a high-stepping gait. Male flufftails invariably vibrate their tails rapidly from side to side during courtship displays, which may involve a bowing or an upright stance, and the head and neck feathers are always raised. Courtship displays often involve the display of bold flank patterns or contrastingly coloured undertail-coverts, or both. Calling often accompanies courtship displays.

The male Purple Swamphen has upright, horizontal and hunched display postures, and also presents waterweed in his bill to the female, bowing repeatedly, while the American Purple Gallinule has billing, bowing, swaying and "Squat-arch" displays in pairing and courtship. Coots and moorhens share similar components in their courtship displays, including a "Bowing-and-nibbling" ceremony, in which one bird is submissive while the other preens it, and also an upright stance with neck arched and head down, the "Arch-bow". In coots, the threat display is very similar to pairing behaviour, showing a parallel repertoire between display elicited by the excitement of sexual stimulation and the desire to ward off strangers from the territory. Although coots and moorhens may display in water, even coots usually copulate out of water, on land or on specially built platforms.

Most species nest solitarily and are generally well separated, but in some wetland habitats, especially where nesting habitat is scarce or territories are small, nests may be very close together. For example, nests of the Little Crake may be as little as 10-15 m apart and those of the Common Moorhen as close as 8 m, while in Nigeria four nests of the Lesser Moorhen were recorded within a radius of 20 m. In restricted habitats some species such as the Purple Swamphen, may nest in loose colonies, while the nests of the Australian Crake (*Porzana fluminea*) are sometimes clumped, with up to 30 nests reported in a group. Populations of the Takahe are normally concentrated into loose colonies but with spaced-out territories within these, while the Black-tailed Native-hen

breeds in isolated pairs or in colonies of 5-500 nests or more, with nests 7-10 m apart.

In many species the nest-site is selected by the male, but sometimes it may be chosen either by the female or by both members of the pair together. Nests are usually concealed in thick vegetation, often near water or in it, but some species nest on the ground far from water or in forest, or up to 10 m high in trees when they may use old nests of other birds. Nest materials are usually gleaned from any available vegetation, and nests are often built by both sexes, though sometimes by the male or the female alone. The nest is usually cup-shaped and well lined, and often fairly deep. It is domed in some species, notably the White-spotted and Buff-spotted Flufftails, the Chestnut Forest-rail, the Russet-crowned Crake (*Anurolimnas viridis*), the Inaccessible Rail, and *Coturnicops* and *Laterallus* species. Some nests of the Henderson Crake are also domed, but others are open cups. Domed nests of forest species are often made of leaves but that of the Russet-crowned Crake is a ball of dead grass with a side entrance, sometimes with a ladder-like entrance ramp, hidden about 1 m up in branches of shrubs, or in coarse herbage, in dense vegetation. *Laterallus* nests are also woven balls placed in grass, reeds or bushes, but the Black Rail has a bowl-shaped nest with a woven canopy.

Nests in grass, and in emergent vegetation such as reeds, often have the surrounding and overhanging vegetation pulled down or woven into a canopy for concealment from above, while nests in wetlands often have pathways or ramps up to the bowl. Some species build nests that float or are attached to aquatic vegetation, and nests on water may be substantial structures to cope with flooding, or may be built up rapidly as the water level rises. Non-functional nests are often found in gallinules and moorhens, and in some other species; these and many other species build nursery nests in which the family members roost.

The Giant Coot builds an enormous permanent nest of aquatic vegetation which forms a raft up to 3 m long projecting 50 cm above the water. The nest is in water about 1 m deep, and large nests usually rest on the bottom; the original structure compacts into peat in the centre. The Horned Coot also builds an enormous nest of water weed, but this is usually placed on a conical mound of stones, up to 4 m in diameter at its base and about 60 cm high, ending just below the water surface in a platform about 1 m across. The weight of the stone structure has been estimated as about 1·5 t! Each stone weighs up to 450 g and both adults collect stones from the lake bed in shallow water and carry them to the nest-site in the bill. Sometimes the nest is built on a large stone just above the water level, while, in very shallow water, nests may be built on natural hillocks on the muddy bottom, but in lakes with very dense vegetation the birds build a floating platform of water weeds. After the coot's breeding season, the nest-site may be used by other birds such as ducks, grebes and gulls. Even the Horned Coot lines its nest well with water weed and tends to have a waterway slide of dried and decaying weeds on the entrance side of the nest.

Rail eggs are blunt oval, smooth, and usually fairly glossy. The ground colour is off-white to dark tan, usually more or less blotched or spotted with red-brown, grey, mauve, black and so on. *Rallina* and *Sarothrura* species lay unmarked white eggs, as also do the Russet-crowned and Red-and-white Crakes. Clutch size varies from 1-19 eggs, but most frequently numbers 5-10; dumping or laying by more than one female in the same nest may complicate the estimation of the clutch size laid by an individual. It has been said that, of semi-precocial birds, only the family Rallidae has clutch sizes which approach those of fully precocial birds such as galliformes and anatids, which do not feed their young, and that particularly large clutch sizes in species such as the King Rail may reflect the unpredictability of their freshwater habitats.

The laying interval between successive eggs is usually of 24-48 hours, but of 48-72 hours in the Takahe. Incubation is usually performed by both sexes but in some species only the female incubates, whereas in the polyandrous Striped Crake only the male does so. In many species the male incubates by day and the female by night. The incubation period is 13-31 days per egg, usually 15-19, and the start of incubation varies from the time of laying of the first egg to that of the last egg, so that hatching may be synchronous or asynchronous according to the species. The Sora has a large clutch size and asynchronous hatching, which may be advantageous by distributing the high energetic cost of feeding the young over a longer period. Eggshells are often removed but they may be left in the nest.

The Chestnut Forest-rail is unusual in that it lays only one large egg, which is equivalent to about 27% of the mean adult weight; incubation is at least 34 days, and possibly over 37 days,

As well as brightly coloured bills and contrastingly coloured bare skin on the head, the chicks of the Common (Gallinula chloropus) *and Dusky Moorhens also have bright bare skin on the wings; all these areas are prominent in the chicks' begging display. Dusky Moorhen chicks are fed intensively until they are four weeks old, and then with decreasing frequency for a further five weeks. The chick approaches an adult, extends its neck, waves its wings, which have conspicuous orange-yellow patches on the leading edge, and emits a high, piping call. It then further stimulates the adult to present food by pecking at the yellow tip of the adult's bill.*

the longest of any rallid. Incubation is by both sexes and the incubated egg is often left to become cold.

Rail chicks hatch covered in down, and are precocial or semi-precocial. The young stay in or near the nest until all have hatched, and they usually leave the nest within 1-3 days of hatching. They may return to the "egg nest" to be brooded at night by the parents, but in many species they roost in nursery nests. Chicks are brooded at night and in poor weather while small: they rapidly become chilled if not brooded at night, and suffer from exposure if left out in rain. Newly hatched young may swim and dive in case of need but all, even those of coots, are prone to wetting and rapidly become chilled in water. They are therefore reluctant to stay long in water during their first days of life, except in emergency situations.

Chicks are at first fed bill to bill and they become self-feeding only after a period varying from a few days to over eight weeks. The young are normally tended by both parents, sometimes by one parent only and, in a few species, also by adult helpers or the offspring of previous broods, or both. The parents may split broods for foraging and brooding. Some species, such as the Virginia Rail, may carry young in the bill; both this species and the Buff-banded Rail will also carry eggs in the bill, moving the clutch to an alternative nest if the original site is disturbed. The American Purple Gallinule has been seen to carry young in its bill when in flight, and the Red-chested Flufftail will brood a small chick under one closed wing, lifting the chick off the ground in doing so, and even sometimes carrying it like this for short distances.

In general, the fledging period of rails is 4-8 weeks, although in the Giant Coot it is about four months. The chicks' legs and feet grow rapidly, reaching full size before the rest of the body; in contrast, the growth of the wings is generally much retarded. The first body feathers begin to appear after 6-15 days, usually about 7; the tail develops quite late in the sequence, and the down on the head and neck is often the last to be replaced. A recent study of the Buff-spotted Flufftail showed that full juvenile plumage was attained in 27-32 days, mean adult mass was reached at about 45 days, the bill attained full length after 16-17 days, the tarsus after about 26 days, the tail after about 40 days and the wings not until about 90 days; the young made their first short flights at 19 days of age, an early age for small rallids, when the wings were 79% grown and the mass 74% of the mean adult mass. Soras and Virginia Rails show a comparable rate of development, the tarsus being fully grown, and full juvenile plumage attained, at 28 days. Spotless Crake chicks were found to reach asymptotic weight at one month, with fully grown tarsi at 27-28 days.

The young usually become independent as soon as they are fully fledged, occasionally before and sometimes after fledging. The time of independence varies from 3-4 weeks, for example 20-21 days in the Buff-spotted Flufftail, to 15 weeks in the Weka and the Henderson Rail. The chicks may be ejected from the territory as soon as they are independent, after which the parents may nest again immediately. In other cases the young may stay in the natal territory for the rest of the breeding season, often helping to rear chicks of subsequent broods, before leaving at the end of the season or later. In the Sora, a migratory species, the family group disperses from the home range when the young are 16-22 days old.

Usually one or two broods are reared, and replacement laying may occur up to three times after egg loss. In species with extended breeding seasons several broods may be reared, and many species have the capability to extend the breeding season, or to raise more broods per breeding period, when food is plentiful or conditions remain favourable for longer than normal. The adaptive plasticity of rails allows some species to exploit breeding habitats as and when they appear, and to cope with sudden changes in habitat conditions. For example, American Coots in Colorado adapted well to artificial alteration of water level in a marsh, rapidly deserting areas when habitats deteriorated and recolonizing them when habitats improved. The birds were not tied to a strict seasonal breeding cycle, so could colonize ephemeral nesting sites, and when conditions changed could quickly relocate and produce a replacement brood. The Black-tailed Native-hen of Australia is widely dispersive and irruptive, and often appears in great numbers after local rain to begin breeding immediately; birds will breed continuously throughout the winter and summer if conditions remain favourable.

The age of first breeding is usually one year, but sometimes less. The Lord Howe Rail, and the White-throated Rail of Aldabra, attain sexual maturity at nine months, whereas the Guam Rail can breed at only 16 weeks old, a feature which has consider-

Clapper Rail chicks leave the nest immediately after hatching, and follow their parents in search of food. They can swim at one day old, and are adept at hiding in dense marsh vegetation. They are fed and cared for by both parents for 5-6 weeks, after which they become independent. As in other rails, the legs and feet grow fast, reaching full size long before the chick is fully grown, while the remiges develop late: the young are not able to fly until they are 10 weeks old, by which time they are fully grown and have moulted from the plain, greyish juvenile plumage into immature plumage, which is almost identical to that of the adult.

ably helped the captive breeding programme of this threatened species.

Movements

Rails have a wide variety of movement and dispersal patterns. Some species are long distance migrants, many are dispersive, some are strongly irruptive, some nomadic, and others show limited local movements in response to changing environmental conditions. The movement patterns of many species are unknown, or at best poorly known, due to a combination of factors such as the birds' tendency to move at night and the difficulty involved in locating birds when they are not breeding, when their silence and secretive behaviour render them easily overlooked; in this way, reported absences are sometimes more supposed than real.

Migrating rails fly at night and at low altitudes, usually singly or in small groups, with the exception of highly sociable species such as the coots. Virginia Rails often follow the courses of rivers in low, level ground, and may fly less than 1 m above the ground. Both they and Soras gather in numbers in marshes before moving, but there is no evidence that they migrate in groups. Migrating rails are frequently attracted to lights of many kinds, from lighthouses and floodlights to lighted house windows, and they often strike towers, buildings, overhead power lines, telephone wires, fences and other obstacles.

Most Holarctic species undertake substantial migrations and winter further south in Africa, southern Asia and South America. In the Western Palearctic, seven of nine breeding species are wholly or largely migratory, five crossing the Sahara to winter to the south and one, the Water Rail, wintering far into the Sahara; only the Purple Swamphen and the Red-knobbed Coot are mainly resident. The Water Rail migrates on broad fronts and crosses mountains such as the Alps. The Corncrake's main routes into Africa are in the west, between Morocco and Algeria, and in the east via Egypt; few cross the Mediterranean between these two flyways. It overflies North Africa and the Mediterranean region on its return passage, which is more rapid than the southward passage, unlike the migratory *Porzana* species which overfly these regions in the autumn and not the spring. The Common and American Coots are the only rallids known to have a specific moult migration, and particularly large flocks of flightless Common Coots are recorded from the Black Sea in August.

All rails breeding in North America are to some extent migratory, with at least some populations wintering to the south of the breeding range, although the Clapper Rail is largely resident. The Yellow Rail and the American Coot do not winter as far south as Central or South America. Some species, such as the Black and Yellow Rails, are known to move over a broad front, while the Sora apparently migrates along the coast and is prone to drift in strong winds, sometimes being recorded far out to sea. Migrant Clapper Rails fly overland and also along the coast.

Relatively little is known about the migrations of those species which breed from India east across Asia to China and Japan and occur south through the Oriental Region. Many are known or suspected to be at least partially migratory, evidence suggesting that they are either predominantly winter visitors to the southern parts of their range, as in the case of the Watercock, or that resident populations in the south are augmented by visitors from the north in the winter. A typical example is the Red-legged Crake (*Rallina fasciata*), which is both resident and migratory over its normal range but is largely a winter visitor to the southern regions, and is probably also dispersive. The Slaty-legged Crake (*Rallina eurizonoides*) is both a resident and migrant species in India, and moves at the beginning and end of the south-west monsoon. The Slaty-breasted Rail has local movements in India during drought or flood, and may make migratory movements elsewhere in its range. The Band-bellied Crake (*Porzana paykullii*) is a recognized migrant, but even it has an imperfectly known winter distribution.

Less is known about the movements of South American rails than about those of any other continent or subcontinent, but the great majority of the species known or suspected to be migratory or dispersive are inhabitants of palustrine wetlands or wet grassland, habitats which have apparently received relatively little attention from ornithologists. For a few of the more obvious species, such as the coots, there is sufficient evidence to show that movements do occur: thus immature Giant Coots are known to disperse widely at night, while the Horned Coot has altitudinal movements or displacements in harsh weather. At least local movements are recorded for the Spotted Rail. Species such as the Ocellated (*Micropygia schomburgkii*), Colombian (*Neocrex colombianus*) and Grey-breasted Crakes are suspected to have migratory or dispersal movements only because individuals have flown into lighted windows at night. The Ash-throated Crake (*Porzana albicollis*) is suspected of having seasonal movements in Colombia because appearances in different parts of the country occur at different periods.

Much more is known about the movements of African rallids, but even this knowledge is very incomplete. Some species, such as the Striped and African Crakes, the Streaky-breasted Flufftail and Allen's Gallinule, move away from the equator to breed during the rains. However, such species are not necessarily always migratory: where conditions remain suitable, the African Crake may remain after breeding, while the Streaky-breasted Flufftail is sedentary in Gabon. Other species, such as the Black Crake and the African Rail, are normally regarded as sedentary but may be locally migratory in some parts of their range, appearing with the rains and disappearing in the dry season, and they may occupy temporary wetlands anywhere within their range. The Buff-spotted Flufftail has complex and poorly understood movements which are related to its wide habitat tolerance: it is largely sedentary in stable forest habitat but of seasonal occurrence in habitats, such as deciduous thickets, which are only suitable in the rains. The Striped Flufftail has seasonal altitudinal movements in Natal, South Africa, moving to lower altitudes after breeding; in some cases the distance moved may be as little as 30-40 km.

A typical dispersive and adaptable species is the Buff-banded Rail of South-east Asia and Australasia. It has a very wide habitat tolerance and is able to colonize small islands, it eats a wide range of food, and it can breed throughout the year. It may move in response to availability of water, switching from dry to wet areas depending on rainfall. The Spotless Crake is known to be a highly dispersive species which has spread widely across the Pacific. The Rufous-tailed Bush-hen is possibly nomadic in Australia, where it moves into some regions with the onset of rain and may retire to areas with permanent water in the dry season. Similar behaviour is recorded for the Dusky Moorhen, which is dispersive or nomadic in Australia but does not undergo large-scale irruptive movements. The Black-tailed Native-hen, however, is a classic dispersive and regularly irruptive species which breeds opportunistically whenever and wherever it can. Its irruptions are probably associated with a period of favourable breeding conditions which allows a population build-up and which is followed by harsh conditions that force the birds to move.

Irruptions and movements also occur in flightless species. In New Zealand, the Weka can move for significant distances: immatures may move more than 9 km from the natal area; subadults can walk more than 4 km in a day; while the greatest recorded natural movement is of 35 km, by an adult male. Rivers and lakes are apparently no barrier to the bird's movements. Mass migrations, associated with the disappearance of many populations on North Island, have occurred for unknown reasons, while rapid increases in populations are also recorded, apparently due to short-term changes in food supply. The Weka's homing ability is also remarkable, the longest return being recorded as 130 km. Also in New Zealand, the Takahe undergoes altitudinal movements of 5-10 km, possibly up to 30 km, when winter snow covers its grassland feeding territories, while chicks are recorded moving 400-800 m within a few days of hatching. Immature Tasmanian Native-hens disperse widely and are recorded as moving up to 40 km. Both adult and juvenile Lord Howe Rails make altitudinal movements over short distances.

A lack of knowledge of the distribution and status of many species sometimes makes it difficult to judge whether isolated occurrences are indicative of long distance movements, or whether movements are primarily eruptive or migratory. For example, recent distributional data suggest that the Speckled Rail

The Weka normally lays 2-4 eggs, and the young are cared for by both parents. Some young are able to feed independently at 21-40 days, and all parental care ceases after 40-108 days; most young have dispersed from their parental territories by 4-6 months after independence. Although flightless, normally sedentary and often permanently territorial, Wekas can move over significant distances: they walk up to 1 km from the territory to feed; young birds may disperse 9 km or more from the natal territory; and mass migrations and rapid local population increases are recorded, possibly due to changes in food supply. Some individuals show a remarkable homing ability, and one bird returned "home" after relocation some 130 km away!

[*Gallirallus australis australis*, Golden Bay, South Island, New Zealand. Photo: Tui de Roy/ Oxford Scientific Films]

Small crakes of dense vegetation in grassland and terrestrial wetland habitats are particularly vulnerable to the effects of fire, which may cause direct mortality, may expose them to predation, and may result in increased mortality as a result of habitat destruction and consequent forced emigration. The Ocellated Crake, a near-threatened species of dense grasslands in South America, is caught in numbers for food by local people who set fire to grassland and catch birds which are overcome by the smoke. At the same time, the vulnerable birds are often preyed upon by Aplomado Falcons (Falco femoralis).

[*Micropygia schomburgkii chapmani*, Das Emas National Park, Goiás, Brazil. Photo: Luiz Claudio Marigo]

(*Coturnicops notatus*) is unlikely to have regular migrations in South America, while a lack of knowledge of its distribution means that the possibility of its undergoing random long distance eruptions can not be confirmed; the best that can be said is that it must undergo post-breeding dispersal. The enigmatic White-winged Flufftail is known only from wetlands in Ethiopia and South Africa, and the morphological similarity between these two populations suggests that migration may occur between the centres of distribution. However the paucity of records from intervening regions, with a very few acceptable records from only Zimbabwe and Zambia, and an overlap in occurrence dates make this unlikely, and it is thought that in both regions it may undergo periodic long distance dispersal when numbers are high, allowing gene exchange between the two populations.

Although most forest habitats are stable and permanent, some species dependent on moist conditions may have to move at least locally if conditions become dry. In New Guinea, both the Red-necked Crake and the Bare-eyed Rail move out of some forests when the ground dries out seasonally, the former possibly migrating to north-east Australia, where it is a wet season visitor to the Cape York Peninsula, leaving again when the forest floor dries out. In Africa, the White-spotted Flufftail may move locally in response to drought conditions and habitat disturbance.

The widespread occurrence of rails on oceanic islands provides ample evidence of these birds' powers of dispersal and their tendency towards vagrancy. The available evidence shows that the phenomenon of dispersal to islands, or to continental habitats far from their home range, is widespread in rallids, and a large number of living, recently extinct and fossil taxa have been found on islands. All types of rail are involved in long distance vagrancy, and the high degree of vagrancy in the family is indicative not only of the birds' dispersive ability but also of the readiness with which they are apparently blown off course by unfavouable winds, as a result of their relatively poor flight performance. Long distance vagrancy, especially involving ocean crossings, is often associated with bad weather and prevailing winds. An example is the occurrence of American Purple Gallinules in South Africa, whereas there are no instances of African migrant rallids occurring in the Americas because the prevailing winds are against the crossing. Another factor relevant to rallids landing on oceanic islands and surviving is that they are virtually forced to do so: to leave would mean their having to reorientate themselves from a completely unfamiliar location, and to accumulate sufficient food reserves to sustain them in a long return crossing, probably against prevailing winds. In such a situation they are well served by their ability to adapt to marginal habitats and to colonize open areas, and their tendency to omnivory. They may not be the only types of bird to reach remote islands by accident, but they are certainly amongst the best survivors in such hazardous situations. They also have the potential for rapid breeding to establish a viable population.

One of the most notable vagrants in the family is the American Purple Gallinule, which occurs from the USA south to Argentina, its northernmost and southernmost populations being migratory. This species is regularly reported from the island of Tristan da Cunha, some 3800 km from the South American mainland, has also occurred on St Helena, about 6400 km from South America, and is of almost annual occurrence in south-west Cape Province, South Africa. Of 21 vagrants to the south-western Cape, almost all have occurred from late April to early July and most were juveniles. It appears that birds starting north from Buenos Aires Province, Argentina, or from Uruguay, are caught in strong westerly winds and carried across the Atlantic, to appear in South Africa exhausted and emaciated. The majority of vagrant individuals are immatures, suggesting that adults are not inclined to stray so far off course. Another inveterate wanderer, Allen's Gallinule of sub-Saharan Africa and Madagascar, has occurred in North Africa, in Europe north to Denmark, and on offshore islands in the Atlantic Ocean as far away as the Azores, Ascension Island and St Helena, 1900 km from the African continent, and also in the Indian Ocean in the Comoros and on Rodrigues, 1500 km east of Madagascar. The Corncrake, which breeds in Eurasia and winters mainly in sub-Saharan Africa, has a remarkable range as a vagrant, having been recorded as far afield as North America, the Bahamas, India, Sri Lanka, the Seychelles and Australia.

The process of dispersal is continuous and an example of the recent colonization of islands by a rail species is that of the nominate race of the Paint-billed Crake (*Neocrex erythrops*) in the Galapagos. This race, which was formerly known only from coastal Peru, was first recorded from the Galapagos in only 1953, but it is now an abundant breeding bird on Santa Cruz, and is also recorded from Santa Maria. It had not been found by expeditions which had

By 1987 the Guam Rail had become extinct in the wild. Its decline is one of the most spectacular examples of the damage caused by an introduced species, in this case the brown tree snake (Boiga irregularis)*, which has caused dramatic declines and extinctions in Guam's native forest birds. A programme of captive breeding, set up in 1983, has been very successful: the original birds showed good genetic diversity, and captive numbers have grown rapidly because the birds breed throughout the year and are sexually mature at only four months. The species has been introduced to the nearby snake-free island of Rota, where it recently bred for the first time.*

[*Gallirallus owstoni*, San Diego Zoo, USA. Photo: Kenneth W. Fink]

made extensive collections of the Galapagos avifauna in the previous hundred years, and is thus likely to be a very recent colonist, although it has been suggested that the species was possibly overlooked for some time before its discovery. The Paint-billed Crake is not known to have regular migrations, but the nominate race has also been recorded as a vagrant in Texas, USA; there are many instances of the race *olivascens* occurring outside its normal range in South America and even occasionally in Central America, and once (probably *olivascens*) in Virginia, USA. Too little is known about this bird's status and distribution to ascertain to what extent it is migratory or has vagrant habits.

Relationship with Man

Unlike many other groups of wetland birds, including members of the Pelicaniformes, Ciconiiformes and Anseriformes, the Rallidae have had no significant association or relationship with man and have no special place in art or in popular legend and myth. Virtually the only superstitions or legends which exist about rails are local ones, such as those held by certain groups of people in Africa to explain the source and meaning of the birds' strange calls heard, often at night, from forest or marsh. The remarkable song of the Buff-spotted Flufftail, one of the most evocative sounds of the African rain forest, has been the object of much superstition and speculation. It is believed to be the wail of a banshee, has been attributed to snakes, lizards, snails and mammals, and is also said to be the noise made by a chameleon in the agonies of giving birth and the sound of a chameleon mourning for his mother, whom he killed in an argument over some mushrooms. The probably extinct Kosrae Crake of the Caroline Islands remains a legend among the islanders to this day, since it had been regarded as a sacred bird before the onslaught of Christian missionaries upon the indigenous religion. The species rapidly became extinct after the islands were overrun by rats from the whaling ships which began to visit the islands from the 1830's.

A very few cases are recorded in which rails are used by man. In the Cocos (Keeling) Islands, the Buff-banded Rail is said to be used when on the nest to hatch out chicken eggs in place of domestic hens. In Bangladesh, the Watercock is used as a fighting bird on which wagers are placed, as in cockfighting. It is said that people collect the eggs from nests and hatch them using the heat of their own bodies, the eggs being placed in a half coconut shell tied against the belly with a cloth and carried like this until they hatch after 24 days. In South America, the Giant Wood-rail is often kept in captivity, and individuals are sold commonly in village shops. If allowed to run about with chickens, however, they soon dominate the flock and become a nuisance by stealing eggs.

Although they are not now regarded as being of economic importance, rails have long been hunted for food in many parts of the world and, in some regions such as the USA and Europe, for sport, although it is difficult to see what sport or skill there can be in shooting flying rails other than coots, except perhaps the skill involved in actually inducing the more secretive species to fly. The Common Coot, much hunted in the past, is still heavily shot in Mediterranean countries today, for both sport and food, while in Pakistan, Afghanistan and neighbouring countries these coots are still eaten by fishermen on the larger lakes or *jheels*. In Europe, the Corncrake was commonly hunted for food in the past, and its flight-feathers used to be regarded as excellent for the manufacture of flies for the angler. It is still caught in Egypt during the ancient practice of quail-netting. The Water Rail and the smaller crakes were also formerly hunted with dogs in Europe. In the USA, the non-threatened larger rails may still be hunted legally, but interest by hunters is often low. In J. J. Audubon's time, Soras and Clapper Rails were popular with hunters: Soras were killed at night by being knocked on the head when they approached a light suspended from a pole on a boat, while Clapper Rails were shot indiscriminately and in large numbers.

Rail eggs are regarded as highly palatable, as indeed are the rails themselves, and Common Moorhens were formerly extensively exploited for their eggs in Asia, over 100,000 eggs being collected per year. The Giant Coot is also exploited for its eggs, many of which are taken at some sites. Forest-rails are often trapped or netted by people in Africa, southern Asia and Latin America, or hunted with dogs as in New Guinea, the Solomon Islands and New Caledonia, while marsh rails are widely hunted in southern Asia.

The larger rails may occasionally damage crops or pasture. The Common Moorhen is thought to cause damage to growing crops in the Low Countries of Europe. The Tasmanian Native-hen has been accused of damaging livestock pasture and young oat crops by grazing, although this is not the case, but the species was

Although widespread in highland areas of Ethiopia and Eritrea, and formerly regarded as common to locally abundant, Rouget's Rail is now considered near-threatened because recent visits to areas where it was formerly not uncommon have yielded very few sightings. This rail inhabits marshy situations in montane grassland and moorland, and sometimes forages in open meadows. The reasons for its apparent decline are thought to be habitat destruction as a result of increased grazing pressure in marshes and along streams, coupled with the ploughing up of grasslands for cereal growing. Recent droughts have probably also caused reductions in numbers.

[*Rougetius rougetii*, Bale Mountain National Park, Ethiopia. Photo: Michel Gunther/ Bios]

at one stage declared vermin. The Purple Swamphen is said to do considerable damage to growing rice crops in India and Bangladesh, but such damage is likely to be highly localized. In New Zealand this species is known to dig up potatoes, pull out young maize plants and eat maize cobs. It eats eggs and ducklings and on some islands it is considered a pest in taro and yam crops, and in banana groves. The American Purple Gallinule is regarded as a pest in some parts of the Neotropics where it occurs in rice plots.

The flightless Weka of New Zealand has a remarkable ability to exist alongside man in rural and urban areas. Wekas are inquisitive and curious, and their propensity for snapping up bright and shiny objects sometimes apparently leads them to be regarded as a nuisance. They are sometimes considered a pest because they pull up seedling crops, kill chickens and young ducks, and spear hen and duck eggs with the bill, but they also eat pest insects. They were formerly hunted extensively for food, but are currently protected in most places.

Status and Conservation

Current evidence indicates that 33 (25%) of the 133 listed rallid species are globally threatened, while the subspecies *tuerosi* of the Black Rail, sometimes considered a distinct species, is equally in serious danger. A further seven species are classed as near-threatened, and four more as Data Deficient. Thus the survival of 44 species (33%) of possibly extant rallids gives cause for concern. Indeed, two of the 33 can almost certainly be added to the list of extinct species: the Bar-winged Rail (*Nesoclopeus poeciloptera*), not definitely recorded since 1890; and the Kosrae Crake, with no records since its discovery in 1827/28.

Flightless species are particularly vulnerable, and 13 of the 18 surviving flightless or virtually flightless species are threatened: the Guam Rail is Extinct in the Wild; the New Caledonian Rail and the Zapata Rail (*Cyanolimnas cerverai*) are Critical; five species are Endangered and another five Vulnerable. A further three species are near-threatened or Data Deficient and, amongst the flightless species, only the New Britain Rail and the Tasmanian Native-hen are currently not globally threatened. However, even the New Britain Rail should not be regarded as completely safe: it has a restricted distribution confined to New Britain, there is no current estimate of its status, and it is known to be trapped and eaten by local people. The Tasmanian Native-hen is apparently still very numerous, despite some drastic local declines in recent years, thought to be a result of disease. It has a history of persecution which continues today: it is traditionally regarded as an agricultural pest, though most claims are unsubstantiated; nevertheless, thousands were killed in the 1950's, when the species was declared a pest. It is not protected, is still controlled by shooting and round-ups, and is attacked by feral cats and dogs.

Of the 20 rallid taxa which have probably become extinct since 1600 (see Table), 18 (90%) were flightless. The extinction of these flightless island rails provides a classic example of the particular vulnerability of island endemics, which arises as a result of their long isolation from predators and competitors, and is one of the major factors involved in island extinctions. The worst period for recorded extinctions since 1600 was the late nineteenth and early twentieth centuries, when many oceanic islands were rapidly developed and altered. The factors which led to these extinctions are worth examining, as some of them are still applicable to threatened rails today.

The principal causes of extinctions among island rails were introduced mammalian predators such as cats, dogs, rats, mongooses and pigs, indiscriminate hunting by the first people to visit the islands and, to a lesser extent, habitat destruction by introduced goats, rabbits and fire. Hunting wiped out the larger flightless species very quickly, the White Gallinule, the Mauritian Red Rail (*Aphanapteryx bonasia*), Leguat's Rail (*Aphanapteryx leguati*) and the nominate race of the Tristan Moorhen (*Gallinula nesiotis*) all being destroyed in this way. Introduced predators have probably been responsible for more extinctions than any other single cause, although some species have been wiped out by a combination of this factor and the destruction of habitat. The Laysan Crake (*Porzana palmeri*) is an example of this, and also of a lost opportunity. It was common and fearless at the time of the arrival of the first Europeans in 1828, and was not molested by the guano diggers, but in 1903 rabbits were introduced and by 1923 had destroyed the grass and thickets in which the crakes lived and nested. They survived on two tiny islets on the Midway Atoll, to which they had been introduced. They were known to hop on to the laps of sailors stationed on Midway during the Second World War and to forage for crumbs around the tables in the mess; they were treated,

The largest living rallid, the flightless Takahe of New Zealand is also one of the most threatened members of the family. Formerly widespread on both North and South Islands, its grassland habitat was reduced by the spread of forests in the late Pleistocene-Holocene, although in the past it probably also inhabited forest ecosystems. In addition, its numbers were reduced by hunting and, more recently, by competition from, and predation by, introduced mammals. It was thought extinct by the 1930's but was rediscovered in Fiordland, South Island, in 1948. Since then its population has experienced a steady decline and now stands at about 190 birds: 150 in Fiordland, occupying apparently suboptimal habitat of alpine tussock grassland; and 40 on four islands to which it has been introduced. Extensive conservation efforts are being made on its behalf, and the Takahe Recovery Plan aims to increase the Fiordland population to 500 birds and to establish populations on at least three predator-free islands.

[*Porphyrio mantelli hochstetteri*, South Island, New Zealand. Photo: Paul H. Reinsch/ Aquila]

affectionately, as pets. But in 1943 rats invaded the islands from a naval craft, and by 1944 they had exterminated the rails. Unfortunately, no-one had thought to reintroduce them to Laysan, where the rabbits had been eliminated by 1924.

The Guam Rail was brought to extinction in the wild by another type of predator. Although the rail was taken by local people with dogs and snares, and despite the presence of introduced predators such as cats and pigs, it held its own on Guam until the spread of the accidentally introduced brown tree snake (*Boiga irregularis*), which has caused a precipitous decline and extinction among Guam's native forest birds. The snake is nocturnal and arboreal, and probably did not prey significantly on adults but took mainly eggs and chicks. This is the first time that a snake has been implicated as an agent of extinction.

Hunting is still a threat to some endangered species with very small populations. The San Cristobal Moorhen, Critically Endangered and possibly already extinct, has suffered from hunting by local people with dogs, and has also probably been affected by introduced predators such as cats. A similar situation affects the Invisible Rail, but it is also threatened by habitat destruction.

Several island species which are currently holding their own, having stable populations in secure habitats, are still at risk from the possible accidental introduction of mammalian predators to their islands. The Gough Island race *comeri* of the Tristan Moorhen is one such case, although precautions have been taken to minimize the chances of accidental introductions occurring. The Inaccessible Rail is another, and it is also vulnerable to fire and agricultural development, as long as Inaccessible Island continues to lack protected status. Similarly, the survival of the Auckland Rail (*Lewinia muelleri*) depends on the continued exclusion of mammalian predators. The Henderson Crake is another in this situation, and it was recently threatened by human impact when a millionaire sought to make the island his home. The Okinawa Rail, which is threatened by deforestation, is also vulnerable to the effects of the brown tree snake, which has been seen on Okinawa.

Habitat destruction, in many forms, is certainly a major threat to many continental rail species, although its impact on threatened island rails is less clear at present. The Zapata Rail is restricted to the Zapata Swamp in Cuba, where its habitat is under serious threat from dry season burning, although introduced rats and mongooses are also a serious problem for this almost flightless species. The Plain-flanked Rail (*Rallus wetmorei*) has a very restricted distribution in coastal Venezuela, where its mangrove and lagoon habitats are being destroyed by housing development, oil exploration and dyking, and the one wildlife refuge in which it occurs is also under threat. The White-winged Flufftail is under severe threat from wetland habitat destruction and modification in both of its centres of occurrence, the principal problems being damming, draining, overgrazing and afforestation, although disturbance by birdwatchers is a problem in South Africa, where only four sites regularly hold these birds and they are vulnerable to disturbance and trampling.

Great efforts have been made to save some threatened species, involving captive breeding and reintroduction of birds into the wild, habitat management and predator control. After it had been written off as extinct, but was subsequently rediscovered, the Takahe has undergone a steady decline in numbers, and its population currently stands at about 150 individuals. It has been the subject of extensive conservation efforts, including: brood manipulation, involving the transfer of eggs to other nests so that all nesting pairs have one viable egg; artificial rearing, originally to establish a captive population, and recently also to provide yearlings for release into the wild; and establishment of birds on four offshore islands, which now hold 19% of the total population. The offshore island populations are breeding successfully, and the survival rate of yearlings is good. The Takahe Recovery Plan aims to establish a self-sustaining population of over 500 birds on the mainland, to establish populations on three or more predator-free islands, and to promote public awareness.

A captive breeding programme was set up for the Guam Rail in 1983, four years before the species became extinct in the wild. The captive population has grown rapidly, because the birds attain sexual maturity at only four months of age and breed throughout the year. By 1991 there were over 180 rails in captivity on Guam and in 14 zoos in the USA, and efforts are being made to establish a self-sustaining population on the snake-free island of Rota, the intention being to eliminate the brown tree snake from Guam before reintroducing the rail to its former range. The first release on Rota was unsuccessful, birds being killed by cats and by vehicles on roads, but successful breeding was reported in 1996 and further releases are planned at sites with less traffic, while efforts are being made to control feral cats.

Many rails seem to be undergoing a continuous population decline, largely through loss of forest, marsh and grassland habitats. The continued wholesale and enormous destruction of indigenous forests is a severe threat to some species, especially in South-east Asia and South America. The Bald-faced Rail (*Gymnocrex rosenbergii*) and the Snoring Rail (*Aramidopsis plateni*) are both threatened by forest destruction. However, the forest-rails of New Guinea, including six endemic species, seem relatively secure because no major threats to their habitats are apparent at present.

Palustrine wetlands are under threat everywhere in the world and are disappearing at an alarming rate. It is only in recent years

RAIL TAXA EXTINCT SINCE 1600

Species			
Mauritian Red Rail	*Aphanapteryx bonasia*	1675-1700	Mauritius
Leguat's Rail	*Aphanapteryx leguati*	c. 1730	Rodrigues I (Mascarenes)
Wake Rail	*Gallirallus wakensis*	1945	Wake I (N Pacific)
Tahiti Rail	*Gallirallus pacificus*	post-1844 (?)	Tahiti
Dieffenbach's Rail	*Gallirallus dieffenbachii*	c. 1842	Chatham Is
Chatham Rail	*Gallirallus modestus*	c. 1900	Chatham Is
Sharpe's Rail	*Gallirallus sharpei*	date unknown	perhaps Indonesia (?)
Ascension Rail	*Atlantisia elpenor*	1656	Ascension I
Tahiti Crake	*Porzana nigra*	post-1784 (?)	Tahiti
Laysan Crake	*Porzana palmeri*	1944	Laysan I (Hawaiian Is)
Hawaiian Crake	*Porzana sandwichensis*	1884	Hawaii
White Gallinule	*Porphyrio albus*	c. 1834	Lord Howe I
Samoan Moorhen	*Gallinula pacifica*	1874	Savai'i (Western Samoa)
Mascarene Coot	*Fulica newtoni*	c. 1863	Mauritius and possibly Reunion
Almost certainly extinct			
38. Bar-winged Rail	*Nesoclopeus poecilopterus*	c. 1973 (?)	Fiji
95. Kosrae Crake	*Porzana monasa*	1828 (?)	Caroline Is
Subspecies			
[45. Buff-banded Rail]	*Gallirallus philippensis macquariensis*	1880	Macquarie I
[74. Uniform Crake]	*Amaurolimnas concolor concolor*	c. 1890	Jamaica
[61. White-throated Rail]	*Dryolimnas cuvieri abbotti*	pre-1937	Assumption I (Mascarenes)
[116. Tristan Moorhen]	*Gallinula nesiotis nesiotis*	1861	Tristan da Cunha
Probably extinct			
[59. Lewin's Rail]	*Lewinia pectoralis clelandi*	c. 1932	SW Australia

Rallidae has probably lost more species in historical times than any other bird family. This is clearly due in part to the high incidence of flightlessness among rails: all of the species now reckoned extinct were island endemics, and probably succumbed to predators introduced by man. If one looks further back in time the list grows steadily. An interesting case is that of the Takahe (Porphyrio mantelli), *which was known as a subfossil species before it was ever found to survive as an extant species; indeed, the nominate race is still known only from subfossils, whence its absence from the table.*

[Table: Barry Taylor]

To the surprise of the ornithological world, a new rail species was discovered on Okinawa in 1978, in the largely uninhabited northern forests of this otherwise densely populated island. The Okinawa Rail is considered Endangered: its population is estimated at about 1800 birds and it is threatened by continuing deforestation within its very small range. It is almost flightless, but has strong legs and runs swiftly to escape from predators. It is normally difficult to observe, and is most visibly active in the morning and late afternoon, when it visits pools to bathe. At night it roosts in large trees, standing on sloping trunks and branches.

[*Gallirallus okinawae*, Knigami, Okinawa, Ryukyu Islands. Photo: Kouzô Maki/ Photo Library Myojo]

that the threats to these habitats have been fully appreciated and the great importance of these wetlands realized, and, even now, there is only limited appreciation of the significance to rallids and other birds of small palustrine wetland patches. Many rails which inhabit these wetlands are threatened by habitat loss and modification. In Asia, Swinhoe's Rail (*Coturnicops exquisitus*), a migratory species which is considered Vulnerable because of its apparent rarity, is threatened by the destruction and modification of wetlands in both its breeding and wintering areas. In South America the Rufous-faced Crake (*Laterallus xenopterus*) is also considered Vulnerable, although it may be more widespread than is currently known; wholesale destruction of wetland habitats in Brazil by drainage and adjacent afforestation with *Eucalyptus* plantations may have serious effects on hitherto undiscovered populations of this poorly known species. All the savanna and *páramo* marsh habitats of the Bogota Rail (*Rallus semiplumbeus*) in Colombia are seriously threatened in many ways, for example by drainage, encroachment, pollution, tourism, hunting, burning, trampling, and fluctuating water levels. In Madagascar, the Endangered Slender-billed Flufftail (*Sarothrura watersi*) requires small wetland patches adjacent to rain forest; although its habitat may be widely distributed, the totally inadequate protection of wetlands in Madagascar gives no cause for optimism regarding this bird's long-term chances of survival.

Small crake species, such as the Black Rail, which inhabit the edge regions of marshes are generally more threatened by habitat destruction, and, for example, by disturbance from grazing or agriculture, than are other marsh rallids which live in the interiors of palustrine wetlands or alongside open water.

Prime grassland habitats are also disappearing and their rail populations are under threat. A typical example of the threats facing rails in these habitats is that of the Striped Flufftail of eastern and southern Africa. In South Africa its distribution is fragmented and its grassland habitats are disappearing rapidly as a result of agriculture and, increasingly more importantly, widespread commercial afforestation.

Another grassland species, the Corncrake, is the only globally threatened rail for the conservation of which any kind of international effort is being made. The species breeds in 31 countries and is threatened mainly on its breeding grounds, where mechanized hay mowing causes heavy losses of breeding birds, eggs and young. All large populations of Corncrakes with over 10,000 males now occur in countries where hand mowing of hay remains a common practice. A Birdlife International European Workshop on the Corncrake was held in Poland in October 1994, to discuss the extent of its decline and possible measures to prevent further population decreases. In Britain, a major research project of the Nature Conservancy Council and the Royal Society for the Protection of Birds in the mid-1980's, and subsequent studies, identified the main reasons for the decline, and a draft action plan to halt the decline was produced in 1989. An important conservation effort was then initiated, involving government, conservation and farming bodies in the UK, Ireland and France. As a result of the implementation of conservation management measures, Corncrake numbers in Britain have recently shown a modest increase.

So little is known about many rails that their status and even their distribution can not be established with any degree of confidence. In order to address this problem, a considerable amount of work needs to be done urgently in many parts of the world. Particularly poorly known genera include the South American *Anurolimnas* and *Laterallus*, and other typical examples are to be found among the *Aramides* species. The Little Wood-rail (*Aramides mangle*) is a poorly known species of potentially restricted distribution, with habitat preferences that have not yet been properly established. The Slaty-breasted (*Aramides saracura*) and Red-winged Wood-rails (*Aramides calopterus*), although not regarded as globally threatened, are potentially at risk because of the destruction of forest habitats, and their status is in urgent need of investigation. These few examples indicate that, unless appropriate steps are taken, the lengthy list of threatened rallids is highly likely to continue to grow; serious efforts are already required to prevent the lengthy list of extinct rallids from following such a pattern.

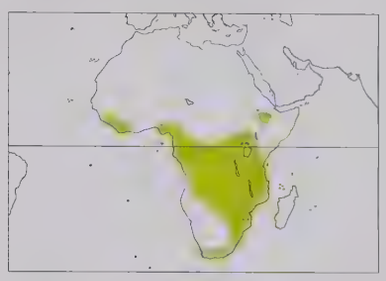
Genus *SAROTHRURA* Heine, 1890

1. White-spotted Flufftail

Sarothrura pulchra

French: Râle perlé **German**: Perlenralle **Spanish**: Polluela Pulcra

Taxonomy. *Crex Pulchra* J. E. Gray, 1829, Sierra Leone.
Genus sometimes merged into *Coturnicops*, which is more likely to be a derivative of *Sarothrura* stock. Birds of W Cameroon highlands formerly awarded race *tibatiensis*, but now reckoned to be synonymous with nominate; *batesi* has sometimes been considered synonymous with either *zenkeri* or *centralis*. Four subspecies normally recognized.
Subspecies and Distribution.
S. p. pulchra (J. E. Gray, 1829) - Gambia and S Senegal E to SW Niger, Nigeria (except extreme SE) and N & C Cameroon; possibly extreme SW Mali.
S. p. zenkeri Neumann, 1908 - extreme SE Nigeria, coastal Cameroon and Gabon.
S. p. batesi Bannerman, 1922 - interior S Cameroon.
S. p. centralis Neumann, 1908 - Congo and N Angola E through Zaire to extreme S Sudan, W Kenya extreme NW Tanzania and extreme NW Zambia.



Descriptive notes. 16-17 cm; 39-53 (46) g. Tail short, not noticeably fluffy. In male, white-spotted black upperparts and red tail diagnostic. Female unlike that of any other flufftail: foreparts as male; body blackish, barred reddish buff; tail chestnut, barred black. Immature almost identical to adult but duller. Juvenile unique in genus in showing adult pattern; areas chestnut and red in adults are dark brown, as are underparts; upperparts blackish brown with pale brown to buff markings, with some whitish spots on wings of male. Races separated on: relative width of black and reddish buff bars in female; richness of plumage colours, *zenkeri* brightest; and size, *zenkeri* and *batesi* smaller. Voice. Vocal repertoire extensive. Characteristic call of male, given all year, a series of 3-14 short, hollow "goong" notes, reminiscent of call of Golden-rumped Tinkerbird (*Pogoniulus bilineatus*); double notes "gui", rising in pitch, often included; call series often repeated for several minutes; weaker version given by female. Also gives series of 4-8 shorter, faster notes. Other calls include rapidly repeated "ker", high-pitched "ki" and ringing "klee" notes, and growls, grunts, gulps and hisses. Does not call at night.
Habitat. Mainly lowland rain forest, usually in association with water, e.g. forest swamps, streams and pools, and riverbanks. Also occurs on forest floor away from water: population in disturbed forest at Malava, W Kenya, 2 km from nearest stream. Not usually deep inside primary forest away from water. Also occupies dense shrubbery and cassava plantations in almost completely cleared areas. Follows rivers and streams out into gallery forest, dense thickets, shrubby growth, neglected cultivation and other rank herbage. Exceptionally in papyrus and other vegetation by lakes. Occurs up to 1600 m in some areas but does not frequent montane forest. Requires dense cover over foraging areas of leaf litter, mud, sand, gravel or shallow water.
Food and Feeding. Diet consists chiefly of invertebrates: earthworms, nematodes, small leeches, small gastropods, myriapods, spiders and many insects, including ants, beetles, bugs (Hemiptera), flies and small moths; takes terrestrial and aquatic insect larvae, including those of chironomids, mayflies, beetles and Lepidoptera; also small frogs. Occasionally consumes a little vegetable matter, including small seeds. Takes much food from surface of humus, mud and water; also probes with bill and turns over leaf litter. Feeds in water up to 2 cm deep; rarely immerses head; stirs up muddy stream bed with one foot to disturb prey. Searches low-growing plants for insects, chases flying insects, and digs blowfly larvae out of cowpats. In Kenya feeds largely on the most abundant suitable invertebrate prey available at any time. Forages throughout day, with peaks in early morning and late afternoon; changes foraging area within territory every 2-4 days; one pair with 2 chicks foraged over c. 20% of territory each day.
Breeding. Seasons poorly known: in most areas breeds during rains, probably more seasonally in S areas with a marked rainy season, but in W Kenya lays Jan-Mar, in months of low rainfall; lays in Liberia, Sept; in Nigeria, Sept, breeding condition Jun, Aug, Dec; in Cameroon, Sept-Oct, breeding condition Apr, Jun; in Gabon, Mar; in Zaire, Apr-May, Nov; in Uganda Mar-Apr; nest building in Gambia, Aug. Monogamous and permanently territorial, forming strong permanent pair-bond. Nest in forest, in leaf litter on damp ground, or by pool, or on rotten tree root in shallow water in swamp; oval mound of dry or wet dead leaves, 10 cm high x 23 cm long, sometimes concealed by covering of dead leaves; lined with dry leaves, grass, etc.; entrance is slit at side. Eggs 2; incubation 14 days, by both sexes; black downy chick has black bare parts; chicks precocial and nidifugous; fed by both parents but tend to follow parent of same sex; capable of feeding themselves from early age, but remain in close association with parents until fully grown and feathered at 6-7 weeks, when post-juvenile partial moult begins; this is complete at 14-16 weeks. In W Kenya some young disperse at c. 3 months old; others may remain in parental territory for up to 9 months, disappearing by start of next breeding season. Juvenile mortality probably low; age of first breeding 1 year; adult mortality low. In W Kenya, only 1 brood per season.
Movements. Normally entirely sedentary and permanently territorial, but there is some evidence for local movements occurring in Sierra Leone, and also in W Kenya in disturbed and unusually dry habitats.
Status and Conservation. Not globally threatened. Common to locally abundant over most of range. In W Kenya distribution along streams essentially linear, one pair per 100-130 m of stream, mean territory size 0·85 ha. Catholic in choice of habitat and well adapted to forest disturbance, as long as suitable cover remains or develops: successfully colonizes cleared areas in forest, and remains along streams after forest clearance. However numbers must be decreasing with continuing large-scale destruction of forest habitat.
Bibliography. Benson *et al.* (1971), Brosset & Érard (1986), Chapin (1939), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Field (1995), Gore (1990), Grimes (1987), Jackson & Sclater (1938), Keith *et al.* (1970), Lippens & Wille (1976), Mackworth-Praed & Grant (1957, 1962, 1970), Pinto (1983), Pye-Smith (1950), Serle (1957), Short *et al.* (1990), Snow (1978), Taylor (1994), Taylor & Taylor (1986), Urban *et al.* (1986), Wacher (1993).

2. Buff-spotted Flufftail

Sarothrura elegans

French: Râle ponctué **German**: Tropfenralle **Spanish**: Polluela Elegante

Taxonomy. *Gallinula elegans* A. Smith, 1839, near Durban, Natal, South Africa.
Genus sometimes merged into *Coturnicops*. Possible races *buryi*, *loringi* and *languens* known from single localities in Somalia, Kenya and Tanzania respectively, and not nowadays accepted. Two subspecies recognized.
Subspecies and Distribution.
S. e. reichenovi (Sharpe, 1894) - Sierra Leone E to Zaire and Uganda, and S to N Angola.
S. e. elegans (A. Smith, 1839) - S Ethiopia; extreme S Sudan and W Kenya S through Zambia and Tanzania to E & S South Africa.

Descriptive notes. 15-17 cm; 40-61 (47·3) g; wingspan 25-28 cm. Tail short, not fluffy. Distinguished by spotted plumage and wooded habitat from all other *Sarothrura* except *S. pulchra*, from which male is separable by buff spots on upperparts, black-banded tail and lack of chestnut on mantle; female almost golden brown with small black-edged buff spots on upperparts, spotted and barred underparts, and barred tail. Immature very similar to adult but duller; female darker brown. Juvenile almost plain sepia brown, paler on face and belly, with relatively dull buff bars and spots on growing remiges. Male of race *reichenovi* darker above, with larger, coarser spots. Voice. Vocal repertoire very extensive. Remarkable and unique song of male a series of hollow, hooting "ooooooo..." notes, like tuning fork, each of 3-4 seconds and given 5-8 times per minute. Usually calls at night, in morning and evening, and in overcast or rainy weather; may call continuously for 12 hours or more; call audible for 1 km through dense forest. Mating calls of male include low-pitched hoot followed by high-pitched whine: "mooooo-eeeee". Both sexes have a quiet, low-pitched "ooo" contact call, a rapidly-repeated, loud, nasal "né" of aggression, and various other hoots, gulps, grunts, growls, squeaks and moaning and whining notes.
Habitat. Occupies wide range of habitats associated with forest or thick bush, from sea-level to 3200 m. Occurs in interior and at edges of many forest types; particularly favours clearings, secondary growth and scrub. Occurs widely outside forest in dense evergreen and deciduous thickets; also frequents banana groves, arrowroot plantations, neglected cultivation and, in South Africa, dense exotic cover in suburban and farm gardens. Not typically associated with water, but in Gabon frequents floors of muddy valleys, in Sudan swampy patches in forest areas, and outside range of *S. pulchra* sometimes associated with forest streams. In winter in Natal, South Africa, sometimes feeds in marshes adjacent to normal forest habitat. Requires dense, low overhead cover (e.g. secondary growth or thickets), usually some dense ground cover, and clear ground or leaf litter for foraging. On migration occurs in atypical habitats.
Food and Feeding. Studies in Natal show that species takes wide variety of invertebrate prey, principally earthworms, Amphipoda, Isopoda, Diplopoda, small ants, termites, beetles, bugs and flies, but also small gastropods, Chilopoda, Nematoda, Collembola, spiders, ticks, cockroaches, Lepidoptera, grasshoppers and crickets. Larval insects taken frequently. Grass seeds eaten occasionally and hard, rough seeds of trees such as bugweed (*Solanum mauritianum*) and pigeonwood (*Trema orientalis*) frequently taken, probably to assist in grinding food in gizzard. Food items 1-32 mm long (earthworms up to 100 mm); given good selection of prey sizes, birds appear to select larger available items. Daily energy intake of adults c. 170 kJ. Forages throughout day, mostly during morning and late afternoon. Forages most frequently in leaf litter; also on open ground and mossy rocks, in short grass, dense ground cover in forest, and garden flower beds. Turns over dead leaves, digs and probes with bill, scratches with feet, and readily takes prey from shallow water.
Breeding. In S Africa breeds during rains (Sept-May), but few data from other regions: Cameroon, May, Sept, Oct; Zaire, Sept; Kenya, breeding condition Feb, Apr, May. Monogamous and territorial; pair-bond maintained at least throughout breeding season. Nest placed on ground, often in small excavated depression, usually well hidden in dense ground vegetation, tangled cover or under leaves of large plant. Most nests domed, with entrance hole at one end; made of dead leaves or grass, often with moss, twigs, roots and bark, and lined with fine grass, rootlets, moss or leaf fragments; external length 16-19 cm, width 13-20 cm, height 8·5-10 cm; nest chamber length 8-10·5 cm, width 8 cm, height 6-7·5 cm; some nests are open shallow cups with roofing cover of low vegetation; built by male. Eggs 3-5, laid at daily intervals; incubation 15-16 days, male by day, female at night; chicks precocial and nidifugous, leave nest after 1-2 days, fed by both parents; black downy chicks have black bare parts; body feathers and remiges begin to appear at 6-7 days; body almost fully feathered at independence; independent at 19-21 days, when driven off by parents; young can fly at 19 days; fully grown at 6 weeks. Adults often renest immediately after independence of young. Post-juvenile moult begins at 3-4 weeks, complete by 10 weeks. Age of first breeding 1 year; adult mortality probably high. Clutch losses low; juvenile mortality high. Up to 4 broods per season, Natal; interval between clutches 30-40 days (mean 36 days).
Movements. Poorly understood: seasonality of occurrence and extent of movements highly complex and imperfectly known (not shown on map). Normally regarded everywhere as sedentary but throughout range there are isolated records indicative of both vagrancy and migration; probable vagrants recorded in N Somalia (Wagar Mts), N Kenya (L Turkana), N Botswana (Maun) and Namibia (Omateva and Oranjemund). In some habitats, such as deciduous or exotic thickets, occurrence may be confined to the rains, when sufficient food and cover exist. In Natal some birds remain throughout year wherever suitable conditions persist, but strong evidence for regular movements, both altitudinal and coastal, possibly over long distances and involving more first-year birds than adults. In Natal, immatures disperse from vicinity of parental territory when c. 7 weeks old.
Status and Conservation. Not globally threatened. Widespread; locally common, especially in South Africa. Although forest destruction must have adversely affected its numbers in some areas, species probably holding its own by virtue of its ability successfully to colonize degraded forest habitats, overgrown cultivation and exotic vegetation in suburban gardens. In Natal, has extended its range locally in

recent past, following the creation of habitats associated with human habitation. However, in residential areas it suffers heavy predation from domestic cats, which may have serious local effects on its numbers.

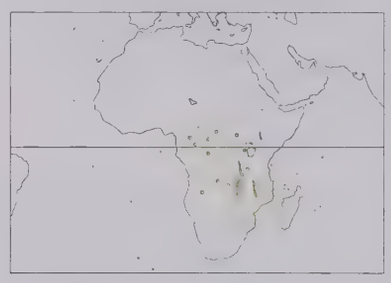
3. Red-chested Flufftail

Sarothrura rufa

French: Râle à camail **German**: Rotbrustralle **Spanish**: Polluela Rufa

Taxonomy. *Rallus rufus* Vieillot, 1819, Cape Province.
Genus sometimes merged into *Coturnicops*. Race *ansorgei* proposed for birds of Angola. Three subspecies recognized.
Subspecies and Distribution.
S. r. bonapartii (Bonaparte, 1856) - scattered records from Sierra Leone E to Nigeria; more continuously in Cameroon, Gabon and Congo.
S. r. elizabethae van Someren, 1919 - Ethiopia; Central African Republic and NE Zaire E to Uganda and W Kenya.
S. r. rufa (Vieillot, 1819) - C Kenya through Tanzania, S Zaire and Angola to South Africa.



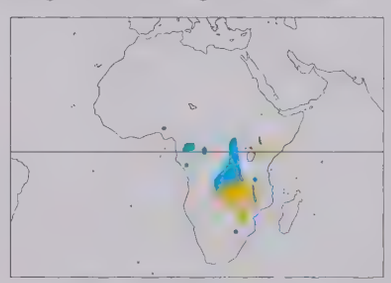
Descriptive notes. 15-17 cm; 29-47 (37·4) g; wingspan c. 25 cm. Tail noticeably long, often fluffed out. In male, chestnut extends to mantle and lower breast; tail black, spotted white. Female paler, more golden brown, than females of other wetland or grassland flufftails; spots and bars predominantly buff. Immature resembles adult but in male chestnut is duller and white markings fewer, mostly spots, female very dark brown with paler, less numerous spots on upperparts and more extensive markings on underparts. Juvenile has upperparts dull black, underparts dull grey-black except for whitish chin, throat and centre of belly. Males of races *elizabethae* and *bonapartii* have longer white streaks on upperparts and white streaks, not spots, on tail; upperparts of female *elizabethae* mainly barred, of female *bonapartii* mainly crescent-shaped; *bonapartii* smaller. Voice. Vocal repertoire very extensive. Song of male a series of high-pitched short hoots "woooo", 0·5-0·8 seconds long, repeated every 0·5-1 seconds and often continuing for several minutes; hoot sometimes rises in pitch "wooaa"; given during breeding season, both day and night. Common territorial call of male a series of loud notes, each rising in pitch at end, "dueh"; notes become more strident and lower-pitched as aggression increases; female has similar call. Gulps or grunts may accompany these and other calls. Has loud territorial "kevic" call and sharp "ki" and "ker" calls of alarm; also wide variety of other hooting, squeaking, rattling, moaning, hissing, humming, buzzing, bubbling and ticking notes.
Habitat. Wide range of wetland vegetation types, from seasonally wet hygrophilous grassland and sedge meadow as short as 55 cm to permanently flooded reedbeds up to 3 m tall, including papyrus swamp; normally avoids deeply flooded vegetation. In forested areas of W Africa also occurs in dry grass, sometimes near human habitation. Requires dense cover and foraging areas of mud, firm ground or short vegetation. In South Africa widespread from sea-level to 2100 m, above which altitude suitable cover does not grow; occurs up to 2700 m in Kenya.
Food and Feeding. Takes wide variety of invertebrate prey, including earthworms, small gastropods, spiders, and adults and larvae of many insects, including termites and small ants. Seeds, mainly of grasses, eaten frequently, but not fed to chicks, and may form large part of diet in non-breeding season. Daily energy intake of adults 140-150 kJ. Forages throughout day, with peaks in early morning and late afternoon. Searches low-growing plants for insect prey; forages on dry to wet substrates, digging with bill among roots, moss and in soft ground; takes active prey on and below surface of shallow water.
Breeding. Season indeterminate in equatorial regions; Sierra Leone, May, Jul; Nigeria, Dec; Cameroon, Mar-Jul; Gabon, Nov-Dec, Mar; Zaire, Jan-Feb, May, Jul-Aug; Angola, breeding condition May; Uganda, Oct; Kenya, May; Pemba Jan-Apr; Tanzania, Feb, Mar, breeding condition Apr, Jul; normally breeds during rains (Nov-May) in S Africa but Aug-Dec nesting recorded in SW Cape, under winter rainfall regime (Apr-Sept). Monogamous and permanently territorial, forming strong permanent pair-bond. Nest is a cup of grass or dead plants, sometimes with slight dome; well hidden in or under clump of grass or herbs 8-30 cm above ground or water surface; often nests in damp to shallowly flooded grass at edge of marshy areas; external diameter 13 cm, internal diameter 8·9·5 cm, depth of cup 3-4 cm. Usually 2-3 eggs (2-5), laid at daily intervals; incubation usually 16-18 days (14-18), male by day, female at night; chicks precocial and nidifugous, leave nest after 2-3 days, fed by both parents; black downy chicks have pronounced fluffy tail and black bare parts, bill with white tip and pink base; body fully feathered at 23 days; normally independent after 3-4 weeks, but may solicit food until 8-9 weeks old; remiges and rectrices fully grown at 6 weeks, when young fly; post-juvenile partial moult then begins, complete at 10-11 weeks. Age of first breeding 1 year; adult mortality low. Clutch losses, from predation or flooding, sometimes high; juvenile mortality possibly low. Usually 1-3 (1-4) broods per season; interval between clutches 4½-9 weeks; in captivity, in Zimbabwe up to 6 clutches laid Aug-May. Young may help feed chicks of subsequent broods; young of last brood often remain in parental territory during non-breeding season, being ejected by start of next breeding season.
Movements. No evidence for regular movements; pairs entirely sedentary and permanently territorial when conditions permit. Very local movements occur in non-breeding season when habitat is drastically reduced, e.g. by burning or drying out. Immatures disperse widely outside breeding season.
Status and Conservation. Not globally threatened. Widespread, sometimes locally common; occurs at densities of 2-6 pairs/ha in Natal, South Africa; a successful colonist of artificially created, sometimes very small, habitat patches. However, overall numbers must be decreasing with the continual destruction of wetland habitats throughout its range.
Bibliography. Ash (1978b), Benson (1956), Benson & Benson (1975), Benson *et al.* (1971), Broekhuysen *et al.* (1964), Brosset & Érard (1986), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Hopkinson & Masterson (1984), Irwin (1981), Keith *et al.* (1970), Lippens & Wille (1976), Liversidge (1968), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Pakenham (1943, 1979), Pinto (1983), Short *et al.* (1990), Steyn & Myburgh (1986), Taylor (1994), Taylor & Hustler (1993), Urban *et al.* (1986), Wintle (1988).

4. Long-toed Flufftail

Sarothrura lugens

French: Râle à tête rousse **German**: Ugallaralle **Spanish**: Polluela Cabecirroja
Other common names: Chestnut-headed Flufftail

Taxonomy. *Crex lugeus* [sic] Böhm, 1884, Ugalla District, Tanzania.
Genus sometimes merged into *Coturnicops*. Two subspecies recognized.
Subspecies and Distribution.
S. l. lugens (Böhm, 1884) - Cameroon to Zaire, Rwanda and W Tanzania.
S. l. lynesi (Grant & Mackworth-Praed, 1934) - C Angola and Zambia.
Specimen from Nyanga, Zimbabwe, is immature female *S. rufa*; recent sight and sound records from Zimbabwe and Malawi probably also referable to *S. rufa*.



Descriptive notes. c. 15 cm. Tail even longer than in *S. rufa*, often fluffed out. Male has rich chestnut on head down to hindneck and malar region; chin and throat off-white; tail black, spotted white; upperparts finely streaked white; underparts with broad white streaks. Female distinctive, streaked chestnut and black where male is chestnut; body is dark brown-black with broader white streaks than in male; wings predominantly spotted or barred. Immature resembles adult but duller, with fewer streaks on upperparts; female streaked buff, not chestnut, on head and more heavily streaked on underparts. Juvenile blackish with dingy white chin. Race *lynesi* smaller. Voice. Poorly known. Song of male a series of moaning, rather guttural hoots "whooo", repeated with hardly a pause for up to 1 minute; speed and pitch variable. Call a series of loud, rapid, far-carrying, pumping "koh" notes, given for up to 45 seconds and often in crescendo, dying away to a grunt; sometimes calls in asynchronous duet.
Habitat. Patches of savanna in lowland forest; grass-grown marshes in savanna; lakeside marshes; rank grass and sedges in dambos (wet drainage lines in woodland). In forest of NE Gabon, also inhabits moist post-cultivation growth dominated by *Aframomum* and arrowroot plants. Prefers dense, lush vegetation 0·7-1·5 m high. Often occurs alongside *S. rufa*.
Food and Feeding. Little known. Stomach of adults contained insects and seeds; of a chick, small black ants.
Breeding. Laying months, derived from young birds and collected females containing eggs: Cameroon, Apr, Jul, Sept; Zaire Mar, Apr; Zambia, Mar, Dec. Nest and eggs undescribed; black downy chick has black bill with white base and tip.
Movements. Unknown; probably entirely sedentary, with perhaps very local displacement outside breeding season following habitat reduction by burning, etc.
Status and Conservation. Not globally threatened. Generally uncommon, but locally common in NE Zambia. Has been described as a relict species in unsuccessful competition with *S. rufa*. In view of its fragmented distribution, the fact that it appears to be generally uncommon, and the continual destruction of wetland habitats, species should perhaps be considered Vulnerable.
Bibliography. Benson & Benson (1975), Benson *et al.* (1971), Brosset & Érard (1986), Chapin (1939), Dowsett & Forbes-Watson (1993), Gibbon (1989), Keith *et al.* (1970), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1957, 1962, 1970), Pinto (1983), Roux & Benson (1969), Short *et al.* (1990), Snow (1978), Taylor (1994), Taylor & Hustler (1993), Urban *et al.* (1986).

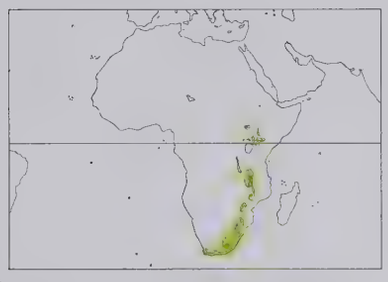
5. Streaky-breasted Flufftail

Sarothrura boehmi

French: Râle de Böhm **German**: Boehmralle **Spanish**: Polluela de Boehm
Other common names: Boehm's Flufftail

Taxonomy. *Sarothrura böhmi* Reichenow, 1900, Likulwe, Haut Luapula, SE Zaire.
Genus sometimes merged into *Coturnicops*. Proposed race *danei* known only from type specimen taken at sea. Monotypic.
Distribution. Imperfectly known. Scattered localities from Nigeria and Cameroon E to Kenya, and S through NE Zaire to E Angola and N South Africa.

Descriptive notes. 15-17 cm; 31-42 (35·8) g, 1 female (juvenile?) 21 g, 1 juvenile 27 g. Tail short, not fluffy; outer web of outermost primary white. Male has chestnut paler than in *S. rufa* and extending only to hindneck and upper breast; tail black, streaked white; white streaks on upperparts longer than in *S. rufa*. Female dark, with mainly scallopy off-white markings on upperparts. Immature resembles adult but duller, with fewer, less pronounced upperparts markings. Juvenile is dull sooty black, with white chin, throat and centre of belly; male has faint white markings on upperwing-coverts. Voice. Song of male a deep, hollow, hooting "hooo", repeated every 2 seconds. Also a short, higher-pitched pumping toot "oo" or "oe", repeated every 0·5-0·7 seconds, each note preceded by a low grunt; series sometimes trails off into softer agitated "wu" notes. Annoyance call a repeated low "cuk".
Habitat. Breeding habitat in E & S Africa is short grass, temporarily inundated during rains, such as that at edges of rivers, drainage lines and marshes; also grass flats and pans. In Zambia occurs in grass 30-70 cm tall, on ground flooded to maximum depth of 10 cm. Often occurs alongside *Aenigmatolimnas marginalis*; prefers shorter, less dense and often drier vegetation than *S. rufa*; however, in W Africa occurs alongside *S. rufa* in dry grassland, in NE Gabon frequenting areas with large tussocks of tall grass scattered in continuous cover of shorter grass.
Food and Feeding. Poorly known. Stomach contents were small seeds, especially grass seeds, and small insects; in captivity eats much less seed than *S. rufa*. Chicks fed on insects.
Breeding. Breeds during rains: in S Africa Nov-Mar, possibly May-Jul in Kenya. Monogamous; apparently territorial; captive males have primitive communal display. Nest often in relatively short or sparse grass; a pad or shallow bowl of grass, c. 2·5 cm thick, placed in grass tuft, with growing blades pulled over it in dome; usually 2·5-7·5 cm above wet to dry (not flooded) ground. Usually 3-5 eggs (2-



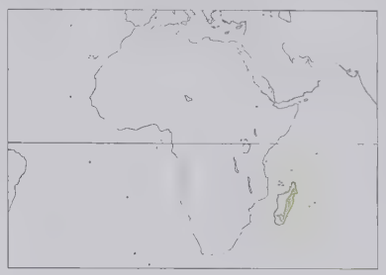
5); incubation 16-18 days, male by day, female at night; chicks leave nest after 1-3 days, fed by both parents; black downy chicks have black bare parts; feathers begin to grow at 7 days; young fully grown and able to fly at 5 weeks, when post-juvenile partial moult begins. Clutch losses from predation often high. Some breeding records must be treated with caution because of confusion with *S. rufa*.
Movements. Imperfectly known. Apparently sedentary in NE Gabon, though breeding not yet recorded; in E & S Africa migrates, breeding mainly in S tropics and retreating towards equatorial regions in dry season when much of habitat dries out and is grazed and burnt. Recorded in Kenya May-Sept, and from Zambia and Angola southwards only in Nov-Apr. At Mufindi, S Tanzania, migrants attracted to lights at night in May-Jun: all were exhausted and were probably moving N after breeding. A presumed off-course migrant was taken at sea in Jun, 150 km off coast of Guinea. May migrate when only 5-6 weeks old: one in juvenile plumage flew into a building at night in Kenya, Jul.
Status and Conservation. Not globally threatened. Status difficult to assess because, like other flufftails, species is frequently overlooked. Often uncommon but may be locally numerous in good rainfall years: 100+ calling males were heard on a grass plain in Zambia in Jan 1978. Locally common in NE Gabon (Makokou), where it occurs in similar numbers to *S. rufa*. Numbers in E & S Africa must have been adversely affected by habitat loss resulting from overgrazing and the damming and draining of wetlands.
Bibliography. Baker *et al.* (1984), Benson & Benson (1975), Benson *et al.* (1971), Brosset & Érard (1986), Brown & Britton (1980), Chapin (1939), Dowsett & Forbes-Watson (1993), Farmer (1979), Ginn *et al.* (1989), Hopkinson & Masterson (1984), Irwin (1981), Keith *et al.* (1970), Lippens & Wille (1976), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Neuby Varty (1953), Pinto (1983), Short *et al.* (1990), Snow (1978), Taylor (1987, 1994), Urban *et al.* (1986), Wintle (1988).

6. Striped Flufftail

Sarothrura affinis

French: Râle affin **German**: Streifenralle **Spanish**: Polluela Estriada
Other common names: Red-tailed/Chestnut-tailed Flufftail

Taxonomy. *Crex affinis* A. Smith, 1828, Cape Province, South Africa.
Genus sometimes merged into *Coturnicops*. Forms superspecies with *S. insularis*. Two subspecies recognized.
Subspecies and Distribution.
S. a. antonii Madaràsz & Neumann, 1911 - extreme S Sudan S to E Zimbabwe.
S. a. affinis (A. Smith, 1828) - South Africa.



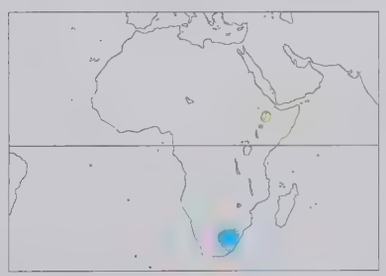
Descriptive notes. 14-15 cm; male 25-30 (28·5) g; wingspan 23-24 cm. Tail short and fluffy; upperparts heavily streaked whitish with yellowish wash. Normally the only flufftail in its habitat; male distinguished from sympatric wetland species by chestnut tail; female by chestnut and black barring on tail and orange-brown wash on face. Immature resembles adult; in race *antonii*, male has white streaks on mantle and almost no chestnut on upper breast, while female has deeper chestnut wash to upperparts streaks, fewer spots on belly, and streaks, rather than spots, on breast. Juvenile dull blackish, paler on underparts. Race *antonii* larger; chestnut on head of male extends to upper breast. Voice. Vocal repertoire extensive. Song of male a hoot, lower-pitched than that of *S. rufa*, lasting c. 1 second and given at intervals of 1·5-2 seconds for up to 10 minutes, often continuing intermittently throughout night; also calls during day. Territorial call of male a series of loud, rapidly repeated, sharp, tinny "ki" notes, usually followed immediately by similarly loud and rapid series of lower-pitched strident "ker" notes; either series may be repeated or given without the other; female has a quiet, faster version of this call. Also various gulps, rattles, barks, low-pitched short hoots, and ticking, buzzing and bubbling notes.
Habitat. Under existing climatic conditions, distribution essentially discontinuous and relict. Over most of range typically inhabits dry upland grassland, sometimes with bracken, brambles or *Protea*, or near forest edges; also occurs in crops, e.g. lucerne, millet. In South Africa, where descends to sea-level, found in *Psoralea-Osmitopsis* fynbos in extreme SW Cape. Although frequently associated with small streams and marshy patches in grassland, no convincing evidence that species occupies larger wetland areas alongside *S. rufa* except under severe drought conditions. Requires dense cover with clear ground for foraging; in Natal, South Africa, occurs in grass 35-100 cm tall and avoids rocky areas and steep or convex slopes. Ascends to 3700 m in Kenya, 2300 m in C Africa, and 2100 m in South Africa.
Food and Feeding. Takes insects, including beetles, bugs, adult and larval Lepidoptera, ants, termites, grasshoppers, crickets and flies; also earthworms, small spiders, grass and sedge seeds and some vegetable matter. Forages throughout the day; searches clear ground, very short vegetation, low-growing plants and bases of grass tussocks; moves aside dead plant material; catches small ants around nests; probably also forages on wet substrates and in shallow water.
Breeding. Normally breeds during the rains. Sudan, breeding condition May; Kenya, May; Tanzania, Jan; Zambia, breeding condition Jan; Malawi, Apr; Zimbabwe, Jan; South Africa Dec-Mar, but SW Cape Sept (end of winter rains). Four clutches reported from South Africa are referable to other species. Monogamous; apparently permanently territorial, with permanent pair-bond when sedentary. Nest a bowl of dry grass or rootlets built into grass tuft. Usually 4 eggs, sometimes 5; incubation probably 15 days, by both sexes; black downy chicks have black bare parts; chicks precocial and nidifugous; may leave nest within a day of hatching; cared for by both parents.
Movements. Normally regarded as sedentary, with local movements when grassland habitat becomes too dry or is burnt. In Natal, sedentary at lower altitudes, where cover and food remain at suitable levels all year, but in upland areas (over 1400 m) departs Apr-Jun and returns Oct-Jan, exodus associated with drop in invertebrate numbers and arrival with increasing invertebrate numbers and development of cover after burning; movements probably altitudinal, possibly over as little as 35-40 km, to altitudes below 1000 m.
Status and Conservation. Not globally threatened. Uncommon in some parts of range, and classed as Rare in South African Red Data Book. Race *antonii* has not been recorded in Sudan for over 50 years; now rarely recorded in Kenya, although 70 years ago was considered locally common; in Zambia, may be locally common; in Zimbabwe, may be more widespread than is known. In South Africa grassland habitats of nominate race have disappeared at alarming rate and are now severely restricted in extent; very few birds are found in farming areas, where grazing renders vegetation too short and sparse for occupation, and disturbance is too intense; however, species still locally common at some protected or well managed grassland and fynbos sites. In view of continuing habitat loss, future of species is not secure.
Bibliography. Anon. (1995g), Benson & Benson (1975), Benson & Holliday (1964), Brooke (1984a), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Hockey, Underhill & Neatherway (1989), Irwin (1981), Kakebeeke (1993), Keith *et al.* (1970), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957, 1962), Maclean (1993), Masterson & Child (1959), Short *et al.* (1990), Snow (1978), Tarboton, Kemp & Kemp (1987), Taylor (1994), Urban *et al.* (1986).

7. Madagascar Flufftail

Sarothrura insularis

French: Râle insulaire **German**: Hovaralle **Spanish**: Polluela Malgache

Taxonomy. *Corethrura insularis* Sharpe, 1870, Nossi Vola, Madagascar.
Genus sometimes merged into *Coturnicops*. Forms superspecies with *S. affinis*. Monotypic.
Distribution. Madagascar, mainly in E.



Descriptive notes. 14 cm. Tail short and fluffy. Male distinctive, with rich chestnut head, neck, breast and tail; black body with yellowish streaks on upperparts and white streaks on underparts. Female also distinctive, with dark upperparts streaked and barred buff to chestnut; ochraceous underparts with black spots on breast and bars on rest of underside; deep chestnut tail with black bars. Immature male probably resembles adult; immature female similar to adult but duller, with spotting of underparts extending to belly. Juvenile male probably almost entirely dark sooty brown. Voice. Common call, probably given by both sexes, a characteristic, loud, high-pitched, ringing series of rapidly repeated single "kee" and double "keekee" notes, given in various combinations but often with several monosyllabic notes at beginning and end of series; volume diminishes towards end of call, which may be preceded by short trills "drr" and terminated by repeated "kik" or rapidly repeated "ki" notes, or both. Other calls include short versions of, or excerpts from, the full call.
Habitat. Tolerant of wide variety of habitats: grassland of edges and clearings of undisturbed and degraded forest; secondary bush, including that comprising large ferns, thick grass, and *Philippia* (Ericaceae); dense cultivation, although not recorded from cassava fields; also seen on forest floor, and occurs in marshes with long grass, reeds and sedges, and sometimes rice paddies. Recorded from sea-level to 2300 m.
Food and Feeding. Only insects and seeds recorded.
Breeding. Poorly known. Lays Oct, probably also Sept. Probably monogamous; apparently territorial at least while breeding and possibly also in non-breeding season. Nest a ball of broad grass blades, thickly lined with finer plant material; external length 17 cm, width 12 cm; internal length and width 8 cm; built on ground in dense grass. Eggs 3-4; incubation by female only; chicks have sooty down; young may remain with parents after start of post-juvenile moult.
Movements. Unknown; probably none.
Status and Conservation. Not globally threatened. Widespread, apparently common over most of its range, especially in E region; seems to adapt readily to degraded environments.
Bibliography. Albignac (1970), Benson *et al.* (1976-1977), Dee (1986), Delacour (1932), Dowsett & Forbes-Watson (1993), Keith (1973), Keith *et al.* (1970), Langrand (1990), Milon *et al.* (1973), Rand (1936), Snow (1978), Wilmé & Langrand (1990).

8. White-winged Flufftail

Sarothrura ayresi

French: Râle à miroir **German**: Spiegelralle **Spanish**: Polluela Especulada

Taxonomy. *Coturnicops ayresi* Gurney, 1877, Potchefstroom, south-west Transvaal, South Africa.
Sometimes placed in genus *Coturnicops*, normally with, but on occasion without, other flufftail species. Ethiopian birds first described as *Ortygops macmillani*. Forms species pair with *S. watersi*. Monotypic.
Distribution. Ethiopia, Zimbabwe and South Africa; to date only one reliable record from Zambia (Chingola); sound records from Rwanda questionable, apparently referable to Grey Crowned Crane (*Balearica regulorum*).

Descriptive notes. 14-16 cm. Small flufftail; unlike other species, often easy to flush and has strong, direct flight on more pointed wings. Both sexes easily identified by white secondaries, which form conspicuous white wing-patch in flight, and distinguished from all other marsh and grassland *Sarothrura* species except female *S. affinis* by chestnut and black bars on tail; outermost long primary has prominent white outer web. Sexual dimorphism less marked than in other *Sarothrura* species. Immature resembles adult, but male has upperwing-coverts spotted white (streaked in adults), mantle feathers with broader dark tips, almost no chestnut on face, less extensive white on underparts and less chestnut on sides of breast; female has browner upperparts with duller, less distinct pale markings and fewer spots on upperwing-coverts, is duller on head, neck and breast and whiter on chin and throat. Juvenile male predominantly dull grey-brown, paler on underparts, with small white spots on upperparts and white throat and centre of belly; female blackish brown with small tawny and white spots on upperparts, whitish flecks on breast, and white throat and centre of belly; juvenile tail as adult. Voice. Common call a low-pitched, short "oop" note, repeated every second and continued for up to 3 minutes; often given in asynchronous duet, the second bird having a higher-pitched note. In South Africa, calling usually occurs only briefly, at dawn and dusk. Very similar to a roosting call of *Balearica regulorum* which, however, is louder, usually a double note or a more complex series of calls, and often given by several birds together. Other calls, rarely heard, include deep mooing notes and high-pitched short and long hoots.
Habitat. Ethiopian breeding habitat is shallowly, sometimes seasonally, flooded short, dense grassland or marsh. In Zambia, one bird found in a pan-like marsh with emergent grass. In Zimbabwe habitat varies: grass 50-100 cm tall on dry to moist ground; also muddy to shallowly flooded marshy ground with grass and sedge cover. Non-breeding birds in South Africa occur for short periods along-

side breeding *S. rufa* in dense grass, sedges and rushes averaging 1 m tall, on moist to shallowly flooded substrates, and for up to 4½ months in dense sedges, reeds (*Phragmites*) and reedmace (*Typha*), 1-2 m tall, on moist to deeply flooded ground not commonly inhabited by *S. rufa*.

Food and Feeding. Stomach contents included water insects, grain seeds and vegetable mush. No information on foraging habits.

Breeding. In Ethiopia breeds during rains, Jul-Aug; despite claims to contrary, no acceptable evidence that species breeds in South Africa. Nest and eggs undescribed, but 2 clutches of 3 eggs found on seasonally flooded ground at Mazowe, Zimbabwe, in 1950's (probably Feb) may be of this species; nests were shallow cups of grass built in reedy vegetation 10-12 cm above water 30 cm deep, with growing vegetation pulled over them in a dome.

Movements. Lack of subspeciation suggests that migration may occur between centres of distribution in Ethiopia and South Africa but paucity of records from intervening regions, and overlap in occurrence dates, makes this unlikely. C Ethiopian highland breeding habitat, where birds recorded Jun-Sept, is unsuitable in non-breeding season, when birds may migrate SW to lower altitude permanent marshes, and recorded at Kaffa in May. In South Africa, where species may be purely nomadic, recorded Aug-Mar and May; in both regions may undergo periodic long distance dispersal when numbers are high, allowing gene exchange between N and S populations; records from Zambia and Zimbabwe may reflect such dispersal.

Status and Conservation. ENDANGERED. One of rarest and least known of African endemics. Total population probably very small, habitats under severe threat from damming, draining and overgrazing, and its future is precarious. In Ethiopia seen only once since 1957, with 1 bird at Sululta swamps in 1984, until small numbers found again at Sululta in Aug-Sept 1995. In Zimbabwe recently recorded only in 1977 and 1979. Since early 1980's, 4 sites in South Africa have held small numbers, 3 of them annually in 1990-1992, when regular observations were made; reliable counts of 1-17 birds. In South Africa, the lack of recent records from coastal localities suggests that species is now confined to higher altitude wetlands.

Bibliography. 9. Slender-billed Flufftail

Sarothrura watersi

French: Râle de Waters **German**: Lemurenralle **Spanish**: Polluela de Waters
Other common names: Waters's Flufftail

Taxonomy. *Zapornia watersi*, Bartlett, 1880, south-east Betsileo Country, Madagascar.
Genus sometimes merged into *Coturnicops*. Forms species pair with *S. ayresi*. Monotypic.
Distribution. Madagascar.

Descriptive notes. 14-17 cm; 1 male 26·5 g. Tail short, slightly fluffy; bill long and slender. Male has distinctive, relatively plain plumage with dull chestnut head, neck, breast and mantle, whitish chin and throat; dull dark brown upperparts with rather indistinct darker streaks; ashy brown unmarked underparts; tail chestnut with black feather tips. Female also plain, with chocolate brown upperparts; pale supercilium; pale brown face; whitish chin, throat and centre of breast; rest of underparts plain dark brown; tail black with narrow white and broader chestnut bars. Immature male undescribed; female duller than adult, with small white spots scattered over upperparts, wings and sides of breast. Juvenile undescribed. VOICE. Muffled, solemn call, uttered during the day and over long periods without break; described as consisting of 2 or 3 notes repeated every 0·3-0·4 seconds, the 2-note version with first syllable accentuated "goo goo"; calls vary in pitch.

Habitat. Small elevated wetlands with *Cyperus* sedges, and adjacent dense, grassy terrain or even rice paddies, near rain forest. Altitudinal range 950-1800 m. It has been suggested that this species may replace the common *S. insularis* at higher altitudes, and that temperature may control its montane distribution; however, its distribution is more probably determined by that of the rain forest.

Food and Feeding. No information available.

Breeding. Unknown; possibly breeds during rains. Male and female in breeding condition Andapa, Sept; male called Ranomafana, Oct and Nov. Adult and juvenile reported near Antananarivo, May, but occurrence there disputed.

Movements. No evidence for any movements.

Status and Conservation. ENDANGERED. Known only from five localities in E Madagascar: "SE Betsileo", "near Andapa", Antananarivo, Périnet Analamazaotra and Ranomafana. Was considered rare, possibly a relict species on its way to early extinction, until its uncorroborated discovery in the 1200 km² area around Antananarivo in 1970/71, where it was reported from three sites and was suspected to occur in all suitable marshes at density of 1 pair per 2 ha; doubt has been cast on these observations and species not reliably recorded elsewhere between 1930 and 1986. Considering only the reliable records, its distribution appears coincident with that of the much-pressurized eastern rain forest; its particular microhabitat is widely but patchily distributed in small blocks over a broad forest zone and is presumably becoming increasingly rare, but suitable habitat also possibly occurs at 9 other localities. The Madagascar system of protected areas, which includes wetlands only occasionally, incorporates only one known site of occurrence; in view of the need to expand rice cultivation, it is unlikely that wetlands will be included in new protected areas. There is an urgent need for distributional and population surveys at all sites of occurrence, and for an evaluation of sites suitable for protection.

Genus *HIMANTORNIS* Hartlaub, 1855

10. Nkulengu Rail

Himantornis haematopus

French: Râle à pieds rouges **German**: Rotfußralle **Spanish**: Rascón Nkulengu

Taxonomy. *Himantornis haematopus* Hartlaub, 1855, Dabocrom, Ghana.
Has been placed in its own subfamily (Himantornithinae) on basis of primitive skeletal characters, which suggest link with trumpeters of family Psophiidae (see page 108). Sometimes divided into three races, with recognition of *petiti* of Gabon to C Zaire, and *whitesidei* of SC & E Zaire, but in view of great individual variation in plumage within ranges of all three proposed races, and overlap of characters between "races", species probably best treated as monotypic until more extensive studies made. Monotypic.
Distribution. Sierra Leone E to W Uganda and S to coastal and C Zaire.

Descriptive notes. 43 cm; 1 female 390 g. Variably scaly or mottled plumage pattern more reminiscent of francolin than rail, but overall shape, leg length and behaviour are obviously rallid. Easily separated from other forest rails by large size, heavy bill and red legs. Plumage very variable, particularly in extent of grey scaling on underparts. Sexes alike. Immature similar to adult but upperpart feathers have dark centres and tawny margins; underparts pale grey-brown, with whitish chin, throat and belly; eye, legs and feet duller than in adult. Voice. Call a rhythmical, antiphonal duet; described as series of phrases of 6 notes "ko-káw-zi-káw-hu-hóooo", each lasting c. 1·5 seconds and repeated in quick succession for several minutes. Notes are loud, raucous and far-carrying; reminiscent of monkey calls or even of "men cutting trees". Calls throughout year, mainly at night, especially at full moon, and most often just before dawn.
Habitat. Lowland rain forest, usually dense primary or old secondary growth, where inhabits rank vegetation along streams and rivers, on islands and sometimes in swampy or marshy areas; occasionally in mangroves. Also found in forest away from water, and in areas disturbed by logging.
Food and Feeding. Snails, millipedes, insects including ants and beetles, small amphibians and hard seeds. Probably takes larger prey, and forages on drier substrates, than does sympatric *Canirallus oculeus*. Forages on ground, usually in groups of 2-3 (once 8), searching for prey among dead leaves and sticks. In Gabon, seen with large parties of insectivorous birds in dry season, and also in bird parties following driver ant columns. Most active in morning and evening but also feeds during day.
Breeding. Almost unknown. Breeding recorded Cameroon, Sept; Gabon, fresh nest Feb; Zaire, Feb, probably also Mar and Sept. Probably monogamous and territorial; characteristic antiphonal duet given for long periods at dusk and during night from high in tree, and by day from ground. Only 2 nests described: 1 in Gabon was substantial structure of coarse tangled twigs and leaves, 35 cm wide and deep, placed 1·2 m above ground on heap of brushwood in undergrowth of plateau forest far from water; another nest was said to be placed in a tree. 1 clutch of 3 eggs found. Unlike most rails, downy young distinctively patterned: broad blackish brown stripe from forehead over head and back to tail; lores to ear-patch black; stripe over eye, side of head, chin, throat and underparts creamy white; brown band across breast; rest of body dull light brown; eye dull brown; legs and feet dull pink; upper mandible blackish; lower mandible grey.
Movements. Apparently sedentary.
Status and Conservation. Not globally threatened. Frequent to common throughout most of its range; in Gabon, spacing of singing birds suggested density of 3 pairs per 200 ha. No recent records in Nigeria; in 1990, was thought to be widespread in Bwamba Forest, W Uganda, whence there was only 1 previous record. Widespread destruction of its forest habitat must have reduced its numbers in many areas and species sometimes trapped for food by local people.
Bibliography. Brosset & Erard (1986), Chapin (1939), Chappuis (1975), Dowsett & Dowsett-Lemaire (1991), Dowsett & Forbes-Watson (1993), Dowsett-Lemaire *et al.* (1993), Elgood *et al.* (1994), Field (1995), Gatter (1988), Grimes (1987), Lippens & Wille (1976), Mackworth-Praed & Grant (1970), Olson (1973b), Pinto (1983), Sharpe (1907), Snow (1978), Thiollay (1985), Urban *et al.* (1986).

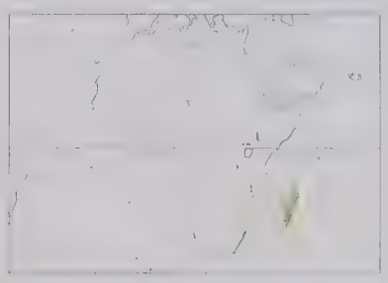
Genus *CANIRALLUS* Bonaparte, 1856

11. Grey-throated Rail

Canirallus oculeus

French: Râle à gorge grise **German**: Augenralle **Spanish**: Rascón Carigrís

Taxonomy. *Gallinula oculea* Hartlaub, 1855, Rio Butri, Ghana.
Birds from Cameroon eastward sometimes treated as separate race, *batesi*, but differ too little from other populations to merit subspecific status. Monotypic.
Distribution. Sierra Leone E across N Zaire to W Uganda and SW to coastal Congo. Occurrence in N Central African Republic (Manovo-Gounda-Saint Floris National Park) doubtful.
Descriptive notes. 30 cm. Plumage unlike that of any other rail in its habitat. White spots on remiges, and pale spots or bars on wing-coverts, would be obvious in flight but species is unlikely to flush; underwing also boldly spotted white. Sexes alike. Immature has forehead, face and throat brown instead of grey, upperparts with russet wash and underparts dark reddish brown. Voice. Song lasts 2-3 minutes; starts with hollow notes like double drumbeats; after 20 seconds intersperses soft "dou" or "douah" notes, which increase towards end of call as drumbeats fade; far-carrying and ventriloquial; given both day and night, with peak at dawn. Also loud, explosive booming of 3-6 notes on descending scale of half-tones "oue-oue-oue...", lasting 0·5-1 seconds. Probable alarm calls rendered "ptik-ptik-ptik..." , "douk-douk-douk..." and muffled "thouk-thouk...".



Habitat. Primary and secondary lowland rain forest, occurring in ravines and along creeks and forest streams overhung by trees and bordered by rank undergrowth; also flooded or swampy forest, including areas with mud, tall arrowroot plants and tree ferns, and marshes within forest regions (Ghana). Records from "floodplain" in savanna-park zone of N Central African Republic very doubtful.
Food and Feeding. Skinks, snails, slugs, small crabs, millipedes and insects including ants, caterpillars and other larvae, and beetles. Seen foraging on half-dry bed of small forest stream by removing dead leaves with jerking movements of the bill.
Breeding. Breeds during rains: Cameroon, Feb, Apr, Jul; Zaire, breeding condition Sept, Nov, Dec. 2 nests described: one, of broad grass leaves, on a stump in swampy bottom of ravine among *Raphia* palms and *Canna*-like plants; the other among roots of uprooted tree over stream bank. Eggs 2; downy chicks blackish brown.
Movements. None recorded.
Status and Conservation. Not globally threatened. Regarded as locally numerous only in Congo, elsewhere apparently uncommon or rare; however, its extreme secretiveness, and lack of familiarity of most observers with its calls, render it very easy to overlook and make its abundance difficult to assess. Forest destruction must have affected its numbers over much of range; species probably extinct in Nigeria and has not been recorded in W Uganda in recent years.
Bibliography. Bates (1927), Brosset & Erard (1986), Chapin (1939), Demey & Fishpool (1994), Dowsett & Dowsett-Lemaire (1991), Dowsett & Forbes-Watson (1993), Gatter (1988), Grimes (1987), Lippens & Wille (1976), Mackworth-Praed & Grant (1957, 1970), Olson (1973b), Serle *et al.* (1977), Snow (1978), Thiollay (1985), Urban *et al.* (1986).

12. Madagascar Wood-rail

Canirallus kioloides

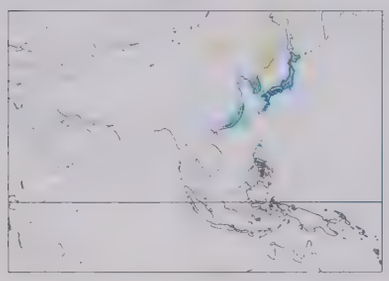
French: Râle à gorge blanche **German**: Graukehlralle **Spanish**: Rascón Kioloide
Other common names: Kioloides Rail, Grey-throated Wood-rail

Taxonomy. *Gallinula kioloides* Pucheran, 1845, Madagascar.
Formerly placed in monospecific genus *Mentocrex* on basis of imperforate nostrils (those of *C. oculeus* are perforate), but this character is not now considered generically important. Birds from Bemaraha apparently differ sufficiently in plumage coloration to be regarded as a further, as yet undescribed, race. Two subspecies currently recognized.
Subspecies and Distribution.
C. k. kioloides (Pucheran, 1845) - E half of Madagascar.
C. k. berliozi (Salomonsen, 1934) - Sambirano, NW Madagascar.

Descriptive notes. 28 cm; 258-280 (269) g. Sexes alike. Distinguished from sympatric and vaguely similar *Dryolimnas cuvieri* by smaller size, colour of head and upperparts, dark undertail-coverts, and short bill. Immature duller than adult; less extensively grey on head; yellow spots on undertail-coverts. Race *berliozi* slightly larger and paler; grey on forehead and white on throat more extensive; mantle pale greenish olive. Voice. Rather vocal and easily located by its common call, a series of loud, piercing whistles with rising inflexion. Feeding birds constantly emit muffled, throaty chortles reminiscent of contact call of Brown Lemur (*Lemur fulvus*), very brief, sharp metallic notes and staccato "nak" notes sometimes speeded up into rattle. Also utters muffled "hub" notes and harsh clucks.
Habitat. Undisturbed rain forest; slightly degraded contiguous secondary growth with fairly sparse herbaceous ground cover; woodland water courses; edges of ponds and marshes with reeds and papyrus; also seen in dry deciduous forest. Occurs from sea-level to 1550 m.
Food and Feeding. Only insects, amphibians and seeds recorded. Normally forages in pairs. Secretive; covers ground swiftly in underbrush, stops suddenly to probe litter and then moves on, sometimes returning several times to area just searched.
Breeding. Lays May, Jun, Nov; breeding condition Oct. Nest a bowl of grass and leaves, placed 2-3 m above ground in bush or tangle of creepers. Eggs 2. Downy chick has black head and upperparts, except for light rufous brown stripe along side of back and rump, and rufous brown forehead, supercilium, ear-coverts, throat and sides of neck; wings black, flecked tawny; upper breast rufous brown; lower breast black, flecked rufous brown; belly rufous brown; all brown down on head, neck and underparts is tipped black, giving mottled appearance to these regions; iris, legs and feet black; bill grey-black, tipped whitish.
Movements. None.
Status and Conservation. Not globally threatened. Race *kioloides* confined to E and High Plateau; regarded as common in 1929-1931 but by 1970's much of habitat on coastal plain had been destroyed; at present, common at middle altitudes but affected by the general and serious continued destruction of forest habitat, chiefly by slash-and-burn itinerant cultivation and exploitation for firewood. Race *berliozi* apparently still fairly common in Sambirano Domain but forest habitats in this relatively small area are severely threatened, principally by clearing for rain-fed rice growing and coffee, and have been much degraded outside reserves. It occurs in Special Reserve of Manongarivo, the forest of which is still largely intact. It is not known which subspecies occurs on nearby Tsaratanana massif, which includes large forest blocks and a Strict Nature Reserve; *berliozi* should be regarded as near-threatened due to habitat destruction, unless its occurrence there is confirmed. Birds from Bemaraha, perhaps belonging to an undescribed subspecies, restricted to humid forest in the Tsingy foothills; this population may be small but is relatively safe because the whole of Tsingy is legally protected.

On following pages: 13. Swinhoe's Rail (*Coturnicops exquisitus*); 14. Yellow Rail (*Coturnicops noveboracensis*); 15. Speckled Rail (*Coturnicops notatus*); 16. Ocellated Crake (*Micropygia schomburgkii*); 17. Chestnut Forest-rail (*Rallina rubra*); 18. White-striped Forest-rail (*Rallina leucospila*); 19. Forbes's Forest-rail (*Rallina forbesi*); 20. Mayr's Forest-rail (*Rallina mayri*).

Bibliography. Benson *et al.* (1976-1977), Dee (1986), Delacour (1932), Dowsett & Forbes-Watson (1993), Keith (1978), Langrand (1990), Milon *et al.* (1973), Olson (1973b), Rand (1936), Ripley (1977), Snow (1978).



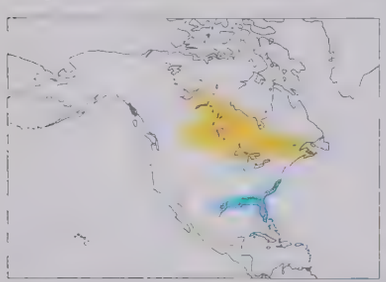
Genus *COTURNICOPS* G. R. Gray, 1855

13. **Swinhoe's Rail**

Coturnicops exquisitus

French: Râle de Swinhoe **German**: Mandschurensumpfhuhn **Spanish**: Polluela Exquisita
Other common names: Swinhoe's Yellow/Siberian Rail

Taxonomy. *Porzana exquisita* Swinhoe, 1873, Yantai (Chefoo), Shandong, China.
Sometimes considered conspecific with *C. noveboracensis*, with which forms Holarctic superspecies. Monotypic.
Distribution. SE Transbaikalia and S Ussuriland and E Heilongjiang (Manchuria). Winters from Japan and Korea through Ryukyu Is to S China.



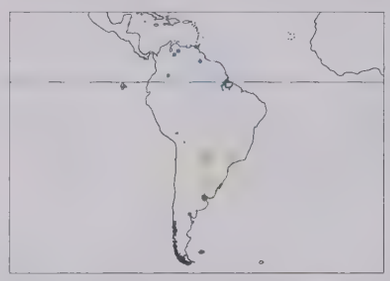
Descriptive notes. 13 cm. Sexes alike. Differs from markedly larger *C. noveboracensis* by greyer face, with close dark speckling and less distinct stripe through eye; feather edges of upperparts darker, more rufous-tinged; foreneck and sides of breast reddish brown with dusky bars; more extensive white on lower breast and belly; flanks barred deep reddish brown; legs brownish flesh. A very small rail, easily separable from all sympatric rallids by white secondaries. Immature and juvenile not described. VOICE. Not recorded; presumably similar to that of *C. noveboracensis*.
Habitat. Breeds in wet meadows and short grass marshes; habitat probably similar to that of *C. noveboracensis*. On migration and on wintering grounds frequents marshes, wet meadows and rice fields.
Food and Feeding. Nothing recorded: presumably similar to *C. noveboracensis*.
Breeding. No information available. Breeding habits probably similar to those of closely related, possibly conspecific *C. noveboracensis*.
Movements. Migratory, wintering S to SE China (Fujian and Guangdong); rare winter visitor to Japan, occurring on Hokkaido, Honshu, Shikoku and Kyushu; regarded as transient or wintering in N & S Korea and Ryukyu Is (Miyako-jima, and Amami-oshima or Okinawa). Recorded in Japan between early Aug and mid-May; most records Oct-Apr.
Status and Conservation. VULNERABLE. Regarded as very rare in SE Siberia and rare in Japan. Known from only a few breeding localities; recently recorded at Zhalong Nature Reserve, Heilongjiang, and Khanka L, N of Vladivostok. Seldom recorded on passage or in winter, recent records being of small numbers on autumn passage at Beidaihe (E China), and 1 at Poyang L (S China) in 1989. Species presumably threatened by destruction and modification of wetlands, which are occurring in both its breeding and wintering ranges.
Bibliography. Austin (1948), Austin & Kuroda (1953), Brazil (1991), Cheng Tsohsin (1987), Collar & Andrew (1988), Collar *et al.* (1994), Etchécopar & Hüe (1978), Flint *et al.* (1984), Knystautas (1993), Meyer de Schauensee (1984), Potapov & Flint (1987), Scott (1989), Sonobe (1982), Williams, M.D. (1986), Williams, M.D. *et al.* (1992).

14. **Yellow Rail**

Coturnicops noveboracensis

French: Râle jaune **German**: Gelbralle **Spanish**: Polluela Amarillenta
Other common names: American Yellow Rail

Taxonomy. *Fulica noveboracensis* Gmelin, 1789, New York.
Forms superspecies with *C. exquisitus*, with which sometimes regarded as conspecific. Two subspecies recognized.
Subspecies and Distribution.
C. n. noveboracensis (Gmelin, 1789) - SC & SE Canada to NC & NE USA, with isolated population in NW USA; winters in S & SE USA.
C. n. goldmani (Nelson, 1904) - marshes of R Lerma, C Mexico.



Descriptive notes. 16-19 cm; male 52-68 (59) g, female 41-61 (52) g. Easily distinguishable from all other North American rallids on size and plumage; similar to *Porzana flaviventer*, which is smaller, lacks white on secondaries and has white-streaked upperparts. Sexes alike, but male slightly larger than female; bill of breeding male corn yellow, of female and non-breeding male dark olivaceous to black. Two conflicting descriptions of immature plumage: either much darker than adult, with buffy white supercilium, entire upperparts black margined tawny and barred or spotted with narrow white lines, lower neck, breast and sides darker buff; or lighter and more buff overall than adult, with crown to upper back more brownish and buff, appearing striped, back to rump as adult but with less white barring and wider buff feather edges, upperwing-coverts browner than adult, throat buff-white, breast unmarked light buff, flanks barred brown, and belly white. Juvenile plumage not properly described. Race *goldmani* larger, with blackish crown and black stripes on nape. VOICE. Breeding-season song of male 4-5 metallic clicks, like 2 stones tapped together. Calls mostly at night, sometimes by day. Also gives cackles, clunks and croaks when breeding, and squeaks and wheezes in hostile encounters. Young peep and bark.
Habitat. Breeding habitat comprises the higher, drier margins of fresh- and brackish-water marshes dominated by sedges and grasses; also swampy meadows, sedge meadows dominated by *Carex lasiocarpa*, and occasionally wet, cut-over hay fields; rarely found in *Typha* stands. In autumn also found in hay and grain fields, and wet meadows; winters in coastal marshes, favouring drier parts of cordgrass (*Spartina patens*) marshes. Encroachment of woody vegetation in the absence of fire decreases quality of breeding habitat. Race *goldmani* recorded up to 2500 m in Mexico.
Food and Feeding. Earthworms, small freshwater snails, crustaceans (including Isopoda), spiders, beetles, cockroaches, bugs, grasshoppers, crickets, ants and fly larvae; also seeds of sedges, rushes (*Scleria*), grass (*Setaria*) and *Polygonum* in autumn and winter. Probably only diurnally active, foraging in areas with shallow water concealed by dense vegetation. Takes food from ground, from vegetation and from water, sometimes from 3-4 cm below water surface. Sometimes feeds while swimming.
Breeding. In USA, lays May-Jul; Mexico, flightless juvenile Sept. All further information for nominate race. Presumed territorial and monogamous but activity areas of breeding males overlap, suggesting gregariousness, while serial polygyny observed in captive birds, and nests of 2 females once located in territory of one male. Allopreening and courtship feeding observed in captive pairs. Nest a cup of fine sedges and grasses; external diameter 7-12 cm, depth 3-9 cm, thickness 2·5-4 cm; cup diameter 7 cm; covered with canopy of dead vegetation; built in sedges, rushes or grass on damp ground; placed on ground, or up to 15 cm above it, beneath dead, procumbent vegetation. Both sexes hollow out crude scrapes in vegetation but female builds nest; 1 or more extra nests sometimes used as brood nests. Mean 8 eggs (5-10), laid at daily intervals; incubation 17-18 days, by female; chicks leave nest after 1-2 days; downy chicks all black except for bright pink bill, which becomes black as juvenile plumage grows, legs and feet grey-brown; young largely feathered at 18 days of age; fed and brooded by female for 3 weeks; can fly at 35 days; age of independence not known. Normally one brood per season; may renest after failure.
Movements. Occupies breeding areas from late Apr or May to Sept-Oct. Thought to migrate over broad front; at least some move in groups; sometimes strikes towers, suggesting nocturnal migration. In Michigan, young depart from natal site late Sept to early Oct. Also recorded in summer from SE Alaska, S British Columbia and Colorado; on migration recorded Arizona and New Mexico, and irregularly in most of USA E of Rocky Mts; vagrant to Grand Bahama (1 record).
Status and Conservation. Not globally threatened. Nominate race is local breeder over wide area of Canada and N USA. Breeding range has decreased: formerly bred in N California, and possibly also in NE USA, S to c. 40° N; in 19th century described as resident in Florida and S Louisiana. Local breeding population in S Oregon, thought extirpated, was rediscovered in 1982. Drainage of wetlands probably responsible for loss of southernmost breeding areas during present century; in Canada many suitable wetlands lost since 1950 to drainage and possibly also after building dykes and barriers. Ditching and draining have destroyed several summering sites in Oregon since 1985. Grazing pressure probably adversely affects marsh-edge habitat, but mowing may help perpetuate breeding habitat. Race *goldmani* known only from Mexico, where formerly a local resident in upper R Lerma Valley; has not been seen since 1964 but may still survive, despite the fact that much of the area has been drained.

(1975), Howell & Webb (1995a), King (1978/79), Martin, A.C. *et al.* (1951), Martin, E.M. & Perry (1981), Peabody (1922), Pulich (1962), Reid (1989), Reynard (1974), Robert & Laporte (1993, 1994), Small (1994), Stalheim (1974), Stenzel (1982), Stern *et al.* (1993), Terrill (1943), Walkinshaw (1939, 1991).

15. **Speckled Rail**

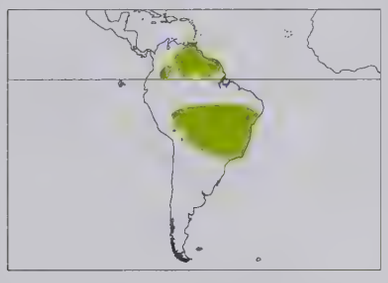
Coturnicops notatus

French: Râle étoilé **German**: Darwinralle **Spanish**: Polluela de Darwin
Other common names: Darwin's Rail

Taxonomy. *Zapornia notata* Gould, 1841, Rio de la Plata, Uruguay.
Monotypic.
Distribution. S Brazil to N Argentina; also Colombia, Venezuela and Guyana; status uncertain in much of apparent range, e.g. probably breeds in province of Córdoba, Argentina.

Descriptive notes. 13-14 cm; unsexed 30 g. Sexes alike. White on secondaries distinguishes from all sympatric rallids. *Laterallus jamaicensis* is similar in size and overall colour but lacks white markings on head, neck and breast, has prominent white bars only from flanks and lower belly to undertail-coverts, and has olive brown to blackish brown legs and feet. *Porzana spiloptera* is another very dark small wetland crake but has white spots and bars of upperparts confined to upperwing-coverts and remiges, white barring on underparts only from belly and flanks to undertail-coverts, and brown legs and feet. Easily distinguished from all other sympatric small rallids by very dark plumage with white spots and bars. Probable immatures have fewer spots on upperparts, some tending to be barred rather than spotted; white streaks and mottling, rather than roundish white spots, on lower throat and breast; undertail-coverts mostly sandy cinnamon rather than olive brown barred with white. Juvenile undescribed. VOICE. Vocalizations unobtrusive; easily masked by other marsh sounds. Has "kooweee-cack" call, first syllable high and brief, second louder and drier; also whistling "keeee" of alarm and high "kyu". Although diurnal, a captive bird called frequently at night.
Habitat. Grassy savanna, dense marshy vegetation, swamps, rice and alfalfa fields; also crop stubble and humid woodland edges. Inhabits lowlands up to 1500 m.
Food and Feeding. One stomach contained 80% small grass seeds, 15% arthropod remains and 5% fine gravel.
Breeding. Uruguay, brood of 3 young in Dec, in wheat stubble; Venezuela, breeding condition Aug; Brazil, breeding condition Dec.
Movements. Speculated to undertake migrations between N & S South America, but unlikely in view of occurrence in Apr-Aug in E Brazil (Taubaté) and Apr-Jun in Paraguay and Uruguay, and enlarged gonads of an Aug Venezuela specimen. One from Colombia (Mar 1959), and 2 from ships at sea have led to suggestion that birds occasionally erupt large distances randomly from centres of distribution in tropical savannas of N & E South America, but no proper evidence that centres of distribution are in tropical savannas and range may be wider and more continuous than currently known. Twice taken on ships at sea, the holotype being collected on the Beagle in 1831 at mouth of R de la Plata, while one flew aboard ship off Cabo Santa María, Uruguay, in Nov or Dec 1875; such records probably indicative at least of post-breeding dispersal. Also possible record from Falkland Is, Apr 1921, probably a straggler.

Status and Conservation. Not globally threatened. Data Deficient. Occurs over very large area but records very sparse, with few in any country, and species normally described as very rare. However, apparent occurrence throughout the year at Taubaté, Brazil, where it is not common but not rare, was taken to indicate that species is difficult to find rather than scarce; this may well be so, but, until further evidence is forthcoming, best considered genuinely rare.
Bibliography. Arballo (1990), Blake (1977), Canevari *et al.* (1991), Chebez (1994), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Hayes (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Meyer de Schauensee (1962), Meyer de Schauensee & Phelps (1978), Nores & Yzurieta (1980), Olivares (1959), de la Peña (1992), Rutgers & Norris (1970), Sick (1985c, 1993), Snyder (1966), Teixeira & Puga (1984), Wege & Long (1995).



Genus *MICROPYGIA* Bonaparte, 1856

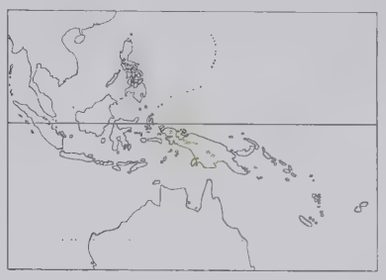
16. **Ocellated Crake**

Micropygia schomburgkii

French: Râle ocellé **German**: Schomburgkralle **Spanish**: Polluela Ocelada
Other common names: Ocellated Rail, Dotted Crake

Taxonomy. *Crex Schomburgkii* Schomburgk, 1848, interior of Guyana.
Sometimes placed in *Coturnicops* but differs in vocalizations, nest construction and some anatomical details. Two subspecies recognized.
Subspecies and Distribution.
M. s. schomburgkii (Schomburgk, 1848) - Costa Rica, Colombia, Venezuela and the Guianas; also SE Peru and Bolivia (racial affinities not clear).
M. s. chapmani (Naumburg, 1930) - C to SE Brazil.

Descriptive notes. 14-15 cm; male 40 g, female 24 g, unsexed 32 g. Distinctive small crake; tail quite well developed, despite genus name. Sexes similar but female usually has head more spotted; rich colour of forehead and crown less extensive. Overall colour and pattern easily distinguish species from all other small wetland rallids of region except perhaps *Porzana flaviventer*, which has distinctive face pattern and heavily barred flanks. Immature has grey-brown upperparts with spots only on wing-coverts, scapulars, side of neck, and sometimes on crown; underparts more extensively white or cream than adult, with pale, diffuse ochraceous breast band and flanks; sides and flanks barred grey. Juvenile not described. Race *chapmani* larger and has paler, more orange-brown, upperparts with reduced spotting; rump and uppertail-coverts often unmarked. Voice. Song a sequence of clear, strong "pr-pr-pr" notes, lasting 20-30 seconds. Calls most frequently at dawn and dusk. Alarm call a harsh whirring, likened to sound of oil sizzling in frying pan.
Habitat. Variety of dense grassland habitats, both well drained and seasonally flooded, from almost pure open grasslands to those with abundance of shrubs and small trees; sometimes occurs near marshes or forest borders. Ground may be muddy or shallowly flooded. Grass height ranges from c. 1 m to very tall grass along drainage channels. Uses tunnels of rodents, e.g. *Cavia*, in dense vegetation. Occurs in lowlands up to 1400 m.
Food and Feeding. Beetles (Carabidae, Scarabaeidae), stoneflies, grasshoppers (Acrididoidea), cockroaches and many ants. One caught in trap baited with oatmeal. Forages on ground, usually in grass or low scrub but occasionally in the open.
Breeding. Brazil, Oct-Mar; Costa Rica, probably during rainy season; Colombia breeding condition Mar. Monogamous; territorial, possibly throughout year. One nest was ball of dry grass with large side entrance, 50 cm above ground, completely concealed in dense wet grassland near palm (*Mauritia flexuosa*) grove. Nest was angled upwards at 45°; external length 20 cm, width 14 cm, height 17 cm; nest cavity length 11 cm, width 7 cm, height 9 cm. Eggs 2; incubation by female.
Movements. None recorded, but occasionally flies into lighted open windows at night. Doubtful record of vagrant in Galapagos.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Regarded as scarce and locally distributed in many areas, probably existing in small populations, but this assessment of status may reflect the difficulty experienced in locating and observing the birds rather than actual scarcity. Apparently widespread and numerous in grasslands of N & C Bolivia, and locally common in C Brazil. Local people catch many for food by setting fire to grasslands and catching birds overcome by smoke; at such times Aplomado Falcons (*Falco femoralis*) often take the crakes.
Bibliography. Blake (1977), Dickerman (1968b), Graham *et al.* (1980), Hellmayr & Conover (1942), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Negret & Teixeira (1984a, 1984b), Parker *et al.* (1991), Ripley (1977), Sick (1985c, 1993), Snyder (1966), Stiles & Skutch (1989), Tostain *et al.* (1992).



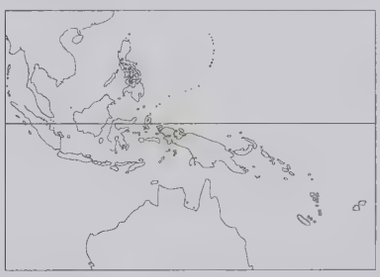
Genus *RALLINA* G. R. Gray, 1846

17. **Chestnut Forest-rail**

Rallina rubra

French: Râle marron **German**: Kastanienralle **Spanish**: Polluela Castaña
Other common names: New Guinea Chestnut Rail

Taxonomy. *Rallicula rubra* Schlegel, 1871, northern peninsula of New Guinea.
The four *Rallina* species of New Guinea show marked sexual dimorphism and therefore sometimes retained in *Rallicula*. Possible race *subrubra* merged with *klossi* because of overlapping measurements and lack of significant colour differences. Three subspecies recognized.
Subspecies and Distribution.
R. r. rubra (Schlegel, 1871) - W New Guinea, in Arfak Mts.
R. r. klossi (Ogilvie-Grant, 1913) - WC New Guinea, from Weyland Mts to Oranje Mts.
R. r. telefolminensis (Gilliard, 1961) - C New Guinea, in Victor Emmanuel and Hindenburg Mts and Tari Gap.



Descriptive notes. 18-23 cm; 3 male *klossi* 84-91 (87·7) g, 2 male *telefolminensis* 71 and 76 g. Smallest *Rallina*. Reddish chestnut plumage of male makes confusion possible only with very similar but allopatric male *R. mayri*, which is darker, with indistinct narrow black bars on tail. Female has back and upperwings black with small buff spots; resembles females of *R. forbesi* and *R. mayri* but has spotted upper mantle and lacks blackish barring on underparts; very similar to female *R. leucospila* but lacks narrow black tail bars of this and the other two species. Subadult male has grey base to black bill, and dark wine-brown legs and feet; juvenile not described. Races separated on: colour of nape, tinged black in *rubra*; overall colour, *klossi* palest chestnut; and biometrics, *telefolminensis* smallest. Voice. Shrill, sharp "krill" or "keow", often repeated many times; sometimes more squeaky. Duetting recorded, when calls may become more rapid and sharper, "kee" or "kek".
Habitat. Inhabits floor of montane forest interior, at 1500-3050 m. At Tari Gap found in mossy mixed lower montane beech forest. In areas of sympatry with *R. forbesi*, present species occurs at higher altitudes.
Food and Feeding. No information available.
Breeding. Lays Oct-Nov, and either Aug or Sept, i.e. at end of period of highest rainfall. Apparently monogamous. Two adult males responded to one female's alarm call at nest, suggesting possibility of co-operative breeding. Nest a large domed structure of moss, grass, leaf skeletons, fibres and fern fronds; lined with fine fibres, rootlets and fragments of fern fronds; base extended at one side into ramp leading up to side entrance. Nest typically placed c. 2 m up between frond bases in *Pandanus* palm crown. Mean overall length 38·5 cm (ramp 15 cm) and height 25·5 cm; mean nest chamber length 21·5 cm and height 13 cm. Lays 1 egg only, large (27% of adult weight); incubation at least 34 days, possibly over 37 days, the longest of any rallid, performed by both sexes, egg often left to become cold; 2 newly hatched chicks weighed 13·4 and 14·4 g and had black down grizzled with russet or chestnut, dark brown iris, blackish legs and feet and blackish bill with white tip and egg tooth. One young chick possibly killed by torrential rain at night.
Movements. None recorded.
Status and Conservation. Not globally threatened. Widespread in Irian Jaya, where races *rubra* and *klossi* apparently abundant; race *telefolminensis* apparently uncommon in the vicinity of Telefomin in the Victor Emmanuel and Hindenburg ranges, but the population common in Tari Gap forests is presumably also of this race.
Bibliography. Andrew, P. (1992), Beehler *et al.* (1986), Coates (1985), Frith & Frith (1988, 1990), Gilliard & LeCroy (1961), Rand & Gilliard (1967), Ripley (1964, 1977).

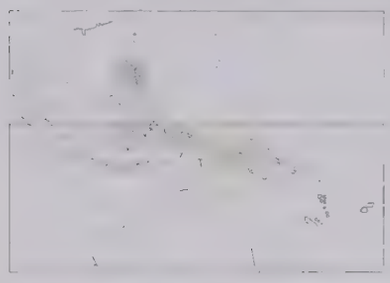
18. **White-striped Forest-rail**

Rallina leucospila

French: Râle vergeté **German**: Strichelralle **Spanish**: Polluela Listada
Other common names: White-striped Chestnut Rail

Taxonomy. *Corethrura? leucospila*, Salvadori, 1875, Arfak Mountains, New Guinea.
Sometimes placed in *Rallicula*. Forms superspecies with *R. forbesi* and *R. mayri*. Monotypic.
Distribution. Tamrau, Arfak and Wandammen Mts of Vogelkop, NW New Guinea.

Descriptive notes. 20-23 cm; 2 males 114, 125 g. Fine white streaks on black upperparts easily separate male from the other *Rallina* species of New Guinea. Female spotted rather than streaked, and closely resembles female of smaller *R. rubra* but has narrow black tail bars and less extensive chestnut on upper mantle; females of *R. forbesi* and *R. mayri* have extensive unspotted chestnut on upper mantle and latter species is generally darker, duller and more uniform. Immature and juvenile not described. Voice. Gives chuckling notes "ko..ko..ko"; contact call a low mewing note.
Habitat. Floor of montane forest interior at 1350-1850 m.
Food and Feeding. No information available.
Breeding. Nothing known. Pairs roost in roofed shelters of dried leaves and moss, so breeding nest may also be domed structure, as in *R. rubra*.
Movements. None recorded.
Status and Conservation. Not globally threatened. Data Deficient. Shy, secretive and apparently uncommon. No recent information available on status, but there is no reason to expect species to be threatened, as its montane forest habitat is likely to be secure, although local hunting with dogs occurs throughout the Vogelkop.
Bibliography. Andrew, P. (1992), Beehler *et al.* (1986), Collar *et al.* (1994), Frith & Frith (1990), Rand & Gilliard (1967), Ripley (1977).



19. **Forbes's Forest-rail**

Rallina forbesi

French: Râle de Forbes **German**: Nymphenralle **Spanish**: Polluela de Forbes
Other common names: Red-backed Forest-rail

Taxonomy. *Rallicula forbesi* Sharpe, 1887, Owen Stanley Range, New Guinea.
Sometimes retained in *Rallicula*. Forms superspecies with *R. leucospila* and *R. mayri*. Population occurring in Foja Mts, NC New Guinea, may be referable to present species or to new, as yet undescribed, form. Four subspecies recognized.

Subspecies and Distribution.
R. f. steini (Rothschild, 1934) - C New Guinea, from Weyland Mts E to Bismarck Mts.
R. f. parva Pratt, 1982 - NE New Guinea, on Mt Mengam (Adelbert Range).
R. f. dryas (Mayr, 1931) - NE New Guinea, on Huon Peninsula.
R. f. forbesi (Sharpe, 1887) - SE New Guinea, from Herzog Mts to Owen Stanley Mts.

Descriptive notes. 20-25 cm; male 78-106 (88) g, female 65-96 g, 1 subadult female 81 g. Male distinguished from other mountain forest *Rallina* species by unpatterned black or dark brown lower mantle, back and upperwings; *R. tricolor*, of moist forest at low altitudes, is larger with a more extensive and more solid area of dark brown covering most of upperparts and tail, more extensive underpart barring, green or yellow bill and dark olive legs. Female has black-margined buff spots on upperparts; distinguished from female *R. rubra* and *R. leucospila* by extensive chestnut upper mantle; similar to, but considerably brighter than, female of *R. mayri*, which does not occur within range of present species. Subadult blackish to dark olive brown on back and wings; dull reddish or greyish brown below, barred with black; bill black with grey tip; some immatures have dark olive brown back and wings; juvenile not described. Races separated on biometrics, especially tail length; *parva* smallest, and also has dark olive brown back, finely and obscurely barred in both sexes, with small spots in female. Voice. Utters a low, frog-like "quaaak", slowly repeated; also a rapid "ko..ko..ko", as well as other chuckling notes.
Habitat. Floor of primary mid-montane and montane forest at 1100-3000 m. In areas of sympatry with *R. rubra*, mostly occurs at lower altitudes.
Food and Feeding. Takes mostly insects; also some seeds. Usually seen in small parties; forages deliberately in dry leaves, calling quietly.
Breeding. Social and sexual behaviour unknown; roosting nests may contain pairs or 3-7 adults of both sexes. One roosting nest a domed structure of leaf skeletons and moss, placed 2·75 m up in *Pandanus* palm crown. Breeding nests thought to be similar, and located on ground or in tree ferns, *Microsorium* cane or epiphytic ferns, but the only one described was a thick platform of dry vegetable fibre and leaf skeletons, external measurements 18 x 25 cm, placed 5-6 m up on horizontal fork of small tree in primary forest. Thought to lay 4-5 eggs; chicks have black down with rusty tips and rusty crown, face and throat.
Movements. None recorded.
Status and Conservation. Not globally threatened. Not uncommon locally in E New Guinea but apparently scarce or rare in W half of range, where overlaps with *R. rubra*. Recently-described race *parva* known only from single locality. Species regularly trapped for food. A hitherto unnamed chestnut rail from uninhabited Foja Mts, NC New Guinea, frequently seen in Oct 1979, may be either this or a new species.

Bibliography. Andrew, P. (1992), Beehler (1978), Beehler *et al.* (1986), Coates (1985), Diamond (1972b, 1985), Gilliard & LeCroy (1961), Majnep & Bulmer (1977), Mayr & Gilliard (1954), Pratt (1982), Rand & Gilliard (1967), Ripley (1977), Ripley & Beehler (1985), Schmid (1993).

20. Mayr's Forest-rail

Rallina mayri

French: Râle de Mayr **German**: Zyklopenralle **Spanish**: Polluela de Mayr
Other common names: Black-tailed Forest-rail

Taxonomy. *Rallicula rubra mayri* Hartert, 1930, Cyclops Mountains, New Guinea.
Sometimes retained in *Rallicula*. Forms superspecies with *R. leucospila* and *R. forbesi*. Two subspecies recognized.
Subspecies and Distribution.
R. m. mayri (Hartert, 1930) - Cyclops Mts, NE Irian Jaya.
R. m. carmichaeli (Diamond, 1969) - Torricelli and Bewani Mts, NW Papua New Guinea.

Descriptive notes. 20-23 cm; male 123-136 (128) g, 3 females 112-123 (118) g. The only *Rallina* species of montane forest within its range. Predominantly reddish chestnut plumage of male similar to that of brighter male *R. rubra*, which lacks bars on tail. Female has dark chestnut brown back and upperwing with large black-margined buff spots; similar to female *R. forbesi* and *R. leucospila*, both also having indistinct blackish bars on belly and thighs, but present species considerably duller; female *R. rubra* lacks well defined bars on underparts and tail, and has spotted upper mantle. Immature and juvenile undescribed. Races separated on overall colour, *carmichaeli* darker brown. Voice. Unknown.
Habitat. Floor of montane forest, at 1100-2200 m.
Food and Feeding. No information available.
Breeding. Nothing known.
Movements. None recorded.
Status and Conservation. Not globally threatened. Data Deficient. Although range restricted to three isolated coastal mountain ranges, species was apparently common in secure habitat in late 1980's; however, not found more recently on visit to Cyclops Mts. In view of its localized and highly specific habitat, total numbers are probably small.

Bibliography. Andrew, P. (1992), Beehler *et al.* (1986), Coates (1985), Collar *et al.* (1994), Diamond (1969), Rand & Gilliard (1967), Ripley (1977).

21. Red-necked Crake

Rallina tricolor

French: Râle tricolore **German**: Dreifarbenralle **Spanish**: Polluela Tricolor
Other common names: Red-necked Rail

Taxonomy. *Rallina tricolor* G. R. Gray, 1858, Aru Islands.
Up to six races have been recognized on basis of size and plumage differences, with *tricolor* of E Indonesia, Australia, New Guinea and outlying islands (including *maxima* of New Guinea, and *robinsoni* of Queensland), *victa* of Tanimbar Is, sometimes including *laeta* of St Matthias I, and *convicta* of New Ireland and New Hanover Is; however, individual variation considerable and geographical variation in size not well understood. Monotypic.
Distribution. New Guinea and offshore islands, Bismarck Archipelago, and N & E Queensland (Australia); also spottily in S Moluccas and E Lesser Sundas, where status unclear.

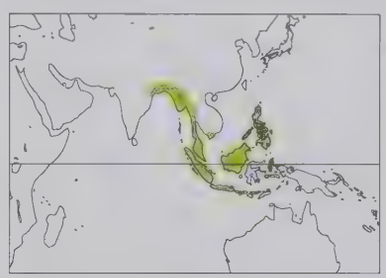
Descriptive notes. 23-30 cm; male 143-231 (164) g, 2 females 194, 200 g, 2 probable migrants 109, 115 g; wingspan 37-45 cm. Distinguished from sympatric forest rails by combination of large size, unmarked dark brown upperparts and tail, green or yellow bill and olive legs; paler fine barring on dark brown underparts varies from indistinct to virtually absent; white bars on remiges usually hidden, except when bird runs to cover with partly spread wings. Sexes alike. Immature not described. Juvenile uniform dark olive brown above and dark brown below. VOICE. Territorial call, given by pairs mostly in evening and during night, a harsh, penetrating note quickly repeated in descending scale with emphasis on first note "nárk-nak-nak..." or "káre-kar-kar..."; also monotonous repeated "tock" note uttered by pairs, sometimes continuously for hours well into night; contact calls low grunts and a repeated soft "plop" note.
Habitat. In Papua New Guinea mostly rain forest and swamp forest; also monsoon forest during rains, sago swamps, gallery forest, secondary growth and once in mangroves; occurs mostly in lowlands, but locally up to 1370 m; normally requires moist habitat, preferably with pools or creeks. In Queensland tropical rain forest, usually with dense understorey; also vine-thicket and monsoon scrub; always near permanent streams or swamps; mostly below 700 m but up to 1250 m; also sometimes in suburban gardens with dense vegetation, and occasionally in *Lantana camara* thickets.
Food and Feeding. Mainly invertebrates, including annelids, oligochaetes, molluscs, crustaceans, terrestrial amphipods, spiders, and adult and larval insects; also frogs and tadpoles; seeds, including beans, also recorded. Mainly crepuscular and nocturnal, but sometimes seen during day. Forages methodically, along shallow stream beds and stream margins, in leaf litter and occasionally along edge of salt water at low tide; rakes through leaf litter with feet and bill; turns over small stones with bill; probes pools, moss and debris.
Breeding. In Queensland lays throughout wet season, Nov-Mar, with Dec-Feb peak; in Papua New Guinea lays early in rains, Nov. Monogamous, with strong pair-bond; some pairs maintain permanent territories; one record of 3 birds attending 2 nests. Nest a shallow cup of dead leaves, twigs and tendrils, diameter 15-20 cm, in dense vegetation or bush or on tree stump 0·6-2 m above ground; or a depression in ground lined with few dead leaves. Usually 5 eggs (3-7), laid at daily intervals; incubation 18-22 days, by both sexes; black downy chicks have black bill and grey to brown (later black) legs and feet; chicks fed by both parents; leave nest soon after hatching but may return to roost for several days; still fed by adults at 5 weeks; leave parents before they can fly; fully-feathered at 4-6 weeks. May form pairs when 4-5 months old.
Movements. Regarded as sedentary over much of range, but partly migratory in NE Australia, where regarded as wet season migrant to Cape York Peninsula from New Guinea, leaving when forest floor dries out in winter. Sedentary further S in Queensland, where rain falls throughout year. Recorded from several islands of Torres Strait, where often heard overhead at night and recorded striking lighthouse. Only record from Ambon (Moluccas) is of 1 coming to a light at night in mid-Jun, possibly migrant from New Guinea. In Port Moresby area, Papua New Guinea, moves away from forest where ground becomes hard and surface water disappears in prolonged dry periods, but remains near permanent water.
Status and Conservation. Not globally threatened. Little information available on status because birds are typically shy and seldom seen. In Papua New Guinea apparently locally common. Australian population declining due to massive and continuing loss of lowland rain forest habitat for agriculture and residential development. Able to occupy dense vegetation in some suburban gardens. Little information on status elsewhere.
Bibliography. Barnard (1911), Beehler *et al.* (1986), Blakers *et al.* (1984), Campbell & Barnard (1917), Coates (1985), Draffan *et al.* (1983), Gill, H. B. (1970), Gill, R. G. (1965), Gregory (1995b), MacGillivray (1914), Magarry (1991), Marchant & Higgins (1993), Mason *et al.* (1981), Mayr (1949), Mees (1965), Ripley (1977), Ripley & Beehler (1985), Serventy (1985), White & Bruce (1986).

22. Andaman Crake

Rallina canningi

French: Râle des Andaman **German**: Andamanenralle **Spanish**: Polluela de Andamán
Other common names: Andaman Banded Crake

Taxonomy. *Euryzona canningi* Blyth, 1863, Port Canning, Andaman Islands.
Monotypic.
Distribution. Andaman Is.
Descriptive notes. 34 cm. Largest *Rallina*; easily distinguished by glossy chestnut plumage, extensive bold barring on underparts, unbarred undertail-coverts and relatively bright apple green bill with narrow whitish tip; barring on wings confined to primaries, outer secondaries and some median and greater coverts; tail noticeably long and fluffy. Sexes alike. Immature duller chestnut; areas barred in



adult are dark grey with chestnut tinge, narrowly banded and streaked with dirty white. Juvenile undescribed. VOICE. A deep croak "kroop"; alarm note a sharp "chick".
Habitat. Marshland in forest; large, open areas of marshland and also recorded in a small marsh on edge of secondary forest.
Food and Feeding. Largely worms, molluscs and insects (including beetles, grasshoppers and caterpillars); possibly also small fish. Large grasshoppers are shaken and battered before being swallowed.
Breeding. Breeds Jun-Aug, during summer. Nest a collection of grass and leaves, placed at foot of large forest tree or under tangled forest undergrowth, not always close to water. Clutch size unknown; incubation by both sexes. Downy chick rich chestnut, slightly greyish under wings, with dusky olive bill.
Movements. Apparently sedentary.
Status and Conservation. VULNERABLE. Precise range not clear: recorded from at least North Andaman and South Andaman Is, and possibly occurs on Great Coco or Little Coco Is (Myanmar). Formerly regarded as common but there appear to be only 2 recent records of single birds. Forest cover remains extensive in Andamans but is suffering slow though continuous loss; introduced predators may also be a threat.
Bibliography. Ali & Ripley (1980), Collar *et al.* (1994), Frith & Frith (1990), Olson (1973b), Pande *et al.* (1991), Ripley (1977, 1982).

23. Red-legged Crake

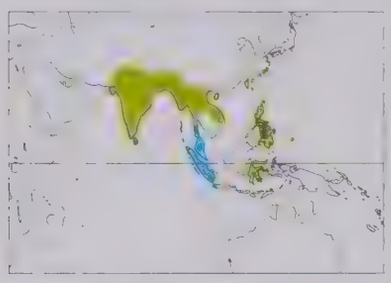
Rallina fasciata

French: Râle barré **German**: Malaienralle **Spanish**: Polluela Patirroja
Other common names: Malaysian (Banded) Crake

Taxonomy. *Rallus fasciatus* Raffles, 1822, Bengkulu, west Sumatra.
Monotypic.
Distribution. Lowlands from NE India (Cachar) and S Myanmar E to Philippines and S to Sumatra and Flores; spottily elsewhere through Greater and Lesser Sundas and Moluccas.

Descriptive notes. 23-25 cm. Sexes similar; female somewhat more cinnamon on head and neck, with narrower black bars on belly and flanks. Easily distinguished from *R. eurizonoides* and *R. tricolor* by boldly barred wings and red legs, and from latter also by white barring on underparts; superficially similar *Porzana paykullii* has white bars on wings confined to some upperwing-coverts (sometimes missing), dark olive brown crown, nape and upperparts, and orange-pink legs; *P. fusca* has unbarred wings, is olive brown from rear crown to tail and has less extensive underpart barring. Immature has poorly defined bars on upperwing-coverts; head, neck and breast brown, and rest of underparts whitish, obscurely barred brown-black; legs and feet brownish. VOICE. Advertising call described as loud "gogogogok" given at night, and during day in rainy weather; also a "girrr" call. Territorial call is loud series of nasal "pek" noises given at dawn and dusk in breeding season; also slow descending trill.
Habitat. Reedy swamps and marshes, rice paddies and taro fields, rivers, water courses, riparian thickets and wet areas in forest and secondary growth. In Philippines, also occurs on open hillsides and in cogon grasslands. Confined to low altitudes up to c. 800 m, except when on migration, when recorded at c. 1400 m.
Food and Feeding. No information.
Breeding. Myanmar, Aug-Sept; Thailand, Aug; Borneo, Apr; Java, Mar; Sumatra, Jan; no date given for Flores. Nest undescribed. Eggs 3-6; both sexes incubate; downy young dark smoky brown. No further information available.
Movements. Movements not properly understood, but species is both resident and migratory in normal range; also probably dispersive; considered predominantly winter visitor in S part of range. Resident Thailand; resident and migrant Malaysia; in Borneo, most of population resident but may be augmented by visitors in winter; probably resident in Philippines. Local resident throughout Greater Sundas, numbers augmented by winter visitors from mainland Asia; normally considered migrant to Wallacea but recorded Apr-Dec, and apparently resident on Flores. Vagrants: Lanyu I (off Taiwan) in Jun; Palau (Micronesia) no date; and Western Australia in Jul.
Status and Conservation. Not globally threatened. Status uncertain, as birds difficult to observe or flush; widely distributed but apparently not particularly common anywhere. Apparently rare in S Vietnam.
Bibliography. Ali & Ripley (1980), Boyd & Alley (1948), Dickinson *et al.* (1991), Harrison & Parker (1967), Hellebrekers & Hoogerwerf (1967), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Marchant & Higgins (1993), van Marle & Voous (1988), Medway & Wells (1976), Ripley (1977, 1982), Schmutz (1977, 1978), Serventy, D.L. (1958), Serventy, V.N. (1985), Smythies (1981, 1986), White & Bruce (1986), Wildash (1968).

24. Slaty-legged Crake



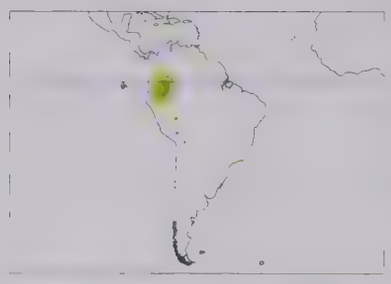
Rallina eurizonoides

French: Râle de forêt **German**: Hinduralle **Spanish**: Polluela de Jungla
Other common names: (Slaty-legged) Banded/Ryukyu/Philippine Crake

Taxonomy. *Gallinula eurizonoïdes* Lafresnaye, 1845, no locality (probably Philippines)
Seven subspecies recognized.

On following pages: 25. Chestnut-headed Crake (*Anurolimnas castaneiceps*); 26. Russet-crowned Crake (*Anurolimnas viridis*); 27. Black-banded Crake (*Anurolimnas fasciatus*); 28. Rufous-sided Crake (*Laterallus melanophaius*); 29. Rusty-flanked Crake (*Laterallus levraudi*); 30. Ruddy Crake (*Laterallus ruber*); 31. White-throated Crake (*Laterallus albigularis*); 32. Grey-breasted Crake (*Laterallus exilis*); 33. Black Rail (*Laterallus jamaicensis*); 34. Galapagos Rail (*Laterallus spilonotus*); 35. Red-and-white Crake (*Laterallus leucopyrrhus*); 36. Rufous-faced Crake (*Laterallus xenopterus*).

Subspecies and Distribution.
R. e. amauroptera (Jerdon, 1864) - Pakistan and India E to E Assam; winters in Sri Lanka and possibly Sumatra.
R. e. telmatophila Hume, 1878 - Myanmar and Thailand E to C Vietnam and SE China (Yunnan and Guangxi); winters in S Thailand and Sumatra, reaching W Java.
R. e. sepiaria (Stejneger, 1887) - Ryukyu Is.
R. e formosana Seebohm, 1894 - Taiwan and Lanyu I.
R. e. eurizonoides (Lafresnaye, 1845) - Philippines and Palau Is.
R. e alvarezi Kennedy & Ross, 1987 - Batan Is (N Philippines).
R e. minahasa Wallace, 1863 - Sulawesi and Sula Is.
Also occurs on Hainan, race undetermined.



Descriptive notes. 21-25 cm; 2 males 118, 128 g, 3 females 99, 105, 180 (with oviduct egg) g, 2 adults 110, 112 g; wingspan 47·5 cm. Sexes alike. Distinguished from *R. fasciata* by darker, browner upperparts, white bars on wings confined to inner webs of remiges (not usually visible) and a few coverts, and greenish grey to black legs and feet. *R. tricolor* lacks white barring on underparts and wing-coverts, and has green or yellow bill. *Porzana fusca* and *P. paykullii* are brown from rear crown to tail and lack white bars on remiges; *P. fusca* has less extensive barring on underparts, and red legs; *P. paykullii* has white bars (sometimes missing) on some upperwing-coverts, and orange-pink legs. Immature has chestnut replaced by dark olive brown, more ashy on side of head and neck; scapulars and wing-coverts have sparse white and black bars; iris brown, legs grey. Juvenile has blackish grey upperparts, and sooty grey underparts with some white flecks on breast and belly; iris dark olive brown; bill and legs black. Races separated on: biometrics, *sepiaria* largest; colour of throat, pale rufous in *minahasa* and *eurizonoides*, purer white in *formosana*; shade of upperparts, *alvarezi* darkest; and width of white bars on underparts, narrower in *amauroptera*, *alvarezi* and *minahasa*. VOICE. Repeated "kek-kek" or nasal "ow-ow", often given persistently during night, even in nocturnal flight; also nasal "kok" to other individuals, a long drumming croak and a hissing, spitting call to intruders at nest.
Habitat. Inhabits forests, well wooded areas and dense scrub, including forest edges, forest floor inside dense patches of remnant original forest vegetation, banks of forest streams, and long grass with dense bushes; also recorded from paddy and taro fields, and from mangroves. Principally lowlands, in well watered habitats up to 1600 m.
Food and Feeding. Takes worms, molluscs, insects, and shoots and seeds of marsh plants. Said to be partly nocturnal.
Breeding. India, Jun-Sept (during SW monsoon); Ryukyu Is, Apr-Jul; Sulawesi, Apr; no date in Palau; juvenile Luzon, Nov. Nests in densest forest as well as more open scrub. Nest an untidy pad of dead leaves, grass and thin twigs, with slight central depression; built on ground in clumps of bamboo or masses of tangled creepers, or on top of tree stumps up to 1 m above ground; not necessarily near water. Eggs 4-8; both sexes incubate eggs and tend young; chick has black down. No further details available.
Movements. Resident and migrant in India, moving at beginning and end of SW monsoon; birds arrive on W coast of Sri Lanka from India in Oct-Nov, spend a few days in lowlands and then move up to winter in hills, leaving Mar-Apr. Migrant Malaysia; winter visitor Sumatra (Nov and Mar-May) and occasionally W Java; resident Ryukyu Is, SE China, Taiwan and Lanyu I; some Palau birds possibly migrant visitors. Moves almost entirely at night, often flying into houses when attracted by lights. Race *telmatophila* straggles to E Himalayas (Nepal, West Bengal, Bhutan) and *eurizonoides* to W Micronesia.
Status and Conservation. Not globally threatened. Apparently races *amauroptera*, *alvarezi* and *telmatophila* are not uncommon over much of their ranges, but the last is uncommon in Sumatra and perhaps only a vagrant to W Java where no recent records. In Ryukyu Is, *sepiaria* decreased in numbers and range on some islands in 1980's, coincident with a rapid increase in numbers of *Amaurornis phoenicurus*, with which it may be in unsuccessful competition for food or nesting sites or both. Status of other races generally unknown, but *eurizonoides* is uncommon in Palau Is.

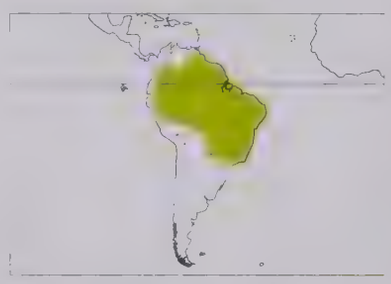
Genus *ANUROLIMNAS* Sharpe, 1893

25. **Chestnut-headed Crake**
Anurolimnas castaneiceps

French: Râle à masque rouge **German**: Rotmaskenralle **Spanish**: Polluela Pituro
Other common names: Chestnut-headed Rail

Taxonomy. *Porzana castaneiceps* P. L. Sclater and Salvin, 1868, Río Napo, eastern Ecuador.
Sometimes placed in *Rallina*, but lacks wing barring and has very short tail. Two subspecies recognized.
Subspecies and Distribution.
A. c. coccineipes Olson 1973 - S Colombia and NE Ecuador.
A. c. castaneiceps (P. L. Sclater & Salvin, 1868) - E Ecuador and N Peru; presumably this race in extreme NW Bolivia (Pando).
Descriptive notes. 19-22 cm; 1 female 126 g. Tail very short. Sexes alike. Distinguished from *A. viridis* by dark brown underparts and entirely rufous face; from *A. fasciatus* by unbarred underparts; from both by unpatterned underwing-coverts and greenish tinge to bill. Very similar *Amaurolimnas concolor* has brown-tinged face, more extensively rufous underparts, and different voice. Immature like adult but duller, with rufous areas largely brown or brownish olive; entire breast and belly dull brown; scattered adult-type chestnut feathers on cheeks, sides of neck and breast; throat light greyish buff. Juvenile not described. Race *coccineipes* has browns of upperparts and underparts tinged more greenish, and has bright red legs and feet. VOICE. Song is a synchronized duet, one bird making loud, high-pitched "ti-too" call and the other answering with "ti-turro" sometimes trilled at end; this antiphonal duet may continue for 3-4 minutes. When disturbed, utters growls and soft "tuk" or "tik" notes.

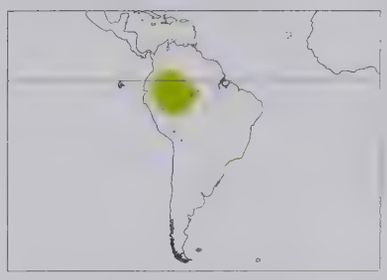


Habitat. Normally said to inhabit humid *terra firme* forest and banks of forest streams, but in NW Bolivia frequents tall secondary growth and overgrown gardens surrounded by forest; in old gardens found in dark, damp thickets with almost impenetrable cover of broad-leaved *Heliconia*-like plants and decaying trunks and branches of trees in areas shaded by stands of trees 4-10 m tall and tall banana plants; similar habitat occupied elsewhere in Amazonia. Occurs E of Andes, from 200 up to 1500 m.
Food and Feeding. Food not recorded, but species presumably feeds on insects and other small invertebrates. Forages on ground inside dense thickets, flicking fallen leaves and probing debris and rotting wood.
Breeding. Bolivia, nearly grown young Jun (egg laid May?); Colombia, breeding condition Jun. Nest, eggs and young undescribed.
Movements. None recorded.
Status and Conservation. Not globally threatened. Regarded as uncommon to rare throughout its range, and possibly of rather local distribution. Status difficult to assess, as birds very wary and difficult to observe.
Bibliography. Blake (1977), Butler (1979), Donahue (1994), Hellmayr & Conover (1942), Hilty & Brown (1986), Meyer de Schauensee (1982), Olson (1973b), Parker & Remsen (1987), Parker *et al.* (1982), Remsen & Traylor (1989), Ripley (1977).

26. **Russet-crowned Crake**
Anurolimnas viridis

French: Râle kiolo **German**: Indioralle **Spanish**: Polluela Coronirrufa
Other common names: Cayenne Crake

Taxonomy. *Rallus viridis* P. L. S. Müller, 1776, Cayenne, French Guiana.
Sometimes placed in *Laterallus*, which it resembles in voice. Two subspecies recognized.
Subspecies and Distribution.
A. v. brunnescens (Todd, 1932) - E Colombia (middle Magdalena Valley).
A. v. viridis (P. L. S. Müller, 1776) - S Venezuela, through the Guianas and Brazil, SW to E Ecuador, E Peru and extreme N Bolivia (Beni).



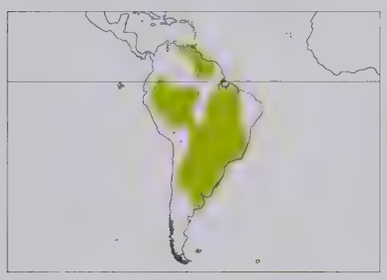
Descriptive notes. 16-18 cm; male 55-63 g, female 69-73 g. Smallest *Anurolimnas*, with relatively long tail. Sexes alike. Distinguished from *A. castaneiceps* and *A. fasciatus* by grey face and entirely rufous underparts; also from *A. castaneiceps* by mottled ashy brown and rufous underwing-coverts, and black bill. Very similar *Amaurolimnas concolor* has brown-tinged face, is more uniform rufous brown above and below, and has yellowish green bill. Immature and juvenile undescribed. Race *brunnescens* browner on upperparts, paler on head and underparts, and slightly larger. VOICE. Loose, churring rattle, similar to calls of *Laterallus melanophaius* and *L. albigularis* but slower and louder; also resembles call of *A. fasciatus*. Most vocal in evening and early morning.
Habitat. Dense thickets of secondary growth saplings at forest edge, thickly overgrown wasteland, damp grassy or bushy pastures, overgrown roadsides, and gardens at edges of towns and villages. Not normally a marsh bird, but in Venezuela recorded from swamps. Mainly terrestrial, but climbs freely in branches of bushes. Occurs up to 1200 m.
Food and Feeding. Very little information available. Insects, including ants, and grass seeds. Forages within cover.
Breeding. Breeds Jan-Jun. Nest a ball of dead grass with a side entrance, sometimes with a ladder-like entrance ramp, hidden c. 1 m up in branches of shrubs, or in coarse herbage, in dense vegetation. Eggs 1-3. No other information.
Movements. None recorded.
Status and Conservation. Not globally threatened. Seldom seen because of skulking habits, but calls frequently; race *viridis* is thought to be common over much of its extensive range; status of *brunnescens* not known but is likely to be similar.
Bibliography. Blake (1977), Haverschmidt (1968), Haverschmidt & Mees (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Olson (1973b), Parker *et al.* (1991), Ripley (1977), Sclater & Salvin (1879), Sick (1985c, 1993), Snyder (1966), Tostain *et al.* (1992).

27. **Black-banded Crake**
Anurolimnas fasciatus

French: Râle fascié **German**: Streifenbauchralle **Spanish**: Polluela Barreada

Taxonomy. *Porzana fasciata* P. L. Sclater & Salvin, 1867, near Caracas, Venezuela.
Sometimes placed in *Laterallus*, which it resembles in voice, but pattern of primary moult differs from that of *Laterallus* and is similar to that of *A. castaneiceps*. Species formerly known as *L. hauxwelli*, as name *fasciatus* erroneously thought to be incompatible with the older species name of *Rallina fasciata*. Monotypic.
Distribution. S & SE Colombia S to E Ecuador and E Peru, and E across W Amazonian Brazil to R Purús.
Descriptive notes. 18-20 cm. Tail short. Sexes alike. Distinguished from *A. castaneiceps* and *A. viridis* by rufous underparts with black bars, and uniform rufous head and neck; also from *A. castaneiceps* by mottled cinnamon and dusky underwing-coverts, and black bill. Immature and juvenile undescribed. VOICE. Song a low churring rattle, similar to that of *A. viridis*, *L. albigularis* and *L. melanophaius*; often given simultaneously by both members of a pair, possibly antiphonal. Often vocal, especially in early morning and late evening.

Habitat. Tall wet grass and marsh vegetation, including that fringing streams and pools. Occurs in lowlands E of Andes, up to 500 m.
Food and Feeding. Nothing recorded.
Breeding. Colombia, Jun. One nest was domed and bulky, of grass with a side entrance, 1·7 m up on a vine-covered fallen limb in a clearing. No other details recorded.
Movements. None recorded.
Status and Conservation. Not globally threatened. Status difficult to assess because of skulking habits in tall wet grass, but species is probably more widespread than the few existing records indicate.
Bibliography. Blake (1977), Butler (1979), Hellmayr & Conover (1942), Hilty & Brown (1986), Meyer de Schauensee (1982), Olson (1973b), Parker *et al.* (1982), Pinto (1964), Ripley (1977), Sick (1985c, 1993), Traylor (1958).



Genus *LATERALLUS* G. R. Gray, 1855

28. **Rufous-sided Crake**

Laterallus melanophaius

French: Râle brunoir **German**: Rothalsralle **Spanish**: Polluela Burrito
Other common names: Rufous-sided Rail

Taxonomy. *Rallus melanophaius* Vieillot, 1819, Paraguay.
Sometimes considered to include *L. albigularis*. Two subspecies recognized.
Subspecies and Distribution.
L. m. oenops (P. L. Sclater & Salvin, 1880) - SE Colombia, E Ecuador, E Peru and W Brazil.
L. m. melanophaius (Vieillot, 1819) - coastal Venezuela E to Surinam and S through C & E Brazil to E Bolivia, Paraguay, Uruguay and N Argentina.

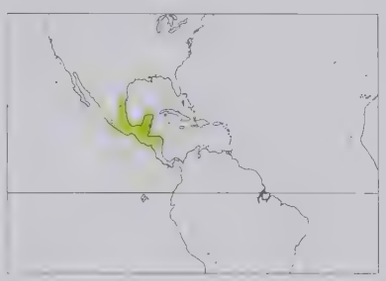
Descriptive notes. 14-18 cm; 1 male 60 g, female 53-54 g; unsexed 46-57 (51) g. Bill relatively long and medium-slender; occasionally shows some narrow white barring on upperwing-coverts and scapulars, and some birds show buffy ochraceous colour from foreneck to breast. Sexes alike. Differs from *L. albigularis* in more extensive white from throat to belly, and plain rufous undertail-coverts. Easily confused with *L. leucopyrrhus* which, however, has rufous tinge to upperparts, sharp demarcation between rufous and white on sides of neck and breast, white lateral undertail-coverts, yellow bill base, and coral red legs and feet. Immature apparently similar to adult but not described; juvenile undescribed. Race *oenops* has lighter, more olivaceous upperparts and paler rufous tinge to forehead and face. Voice. Abrupt, loose churring, very similar to call of *L. albigularis*. Calls frequently.
Habitat. Marshes, especially in dense vegetation along edges; also wet meadows and grassland; often some way from water. In Venezuela also recorded from forest, mudflats, lagoons and dry grassland. In Bolivia, when occurring alongside *L. exilis* in wet pasture, present species apparently more restricted to marsh grasses around patches of open water. Lowlands up to 1000 m.
Food and Feeding. Insects, especially beetles (Curculionidae), spiders, and bugs (Homoptera); captive birds ate mealworms (*Tenebrio* larvae) and blowfly larvae, and occasionally seeds. Forages on the ground and in shallow water.
Breeding. SE Brazil, 2 young Nov. Captive pair built 3 nests, 2 in bushes 0·6 m and over 1 m above ground, and 1 in nestbox on ground. Eggs 2-3; young of first brood fed chicks of second brood; downy chicks black; adult plumage attained at c. 4 months of age.
Movements. None recorded.
Status and Conservation. Not globally threatened. Apparently uncommon in Argentina and in Rio Grande do Sul, SE Brazil; status not recorded elsewhere as birds difficult to observe.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Contreras *et al.* (1990), Gronow (1969), Haverschmidt (1968), Haverschmidt & Mees (1995), Hayes (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), de la Peña (1992), Ripley (1977), Sick (1985c, 1993), Snyder (1966), Storer (1981).

29. **Rusty-flanked Crake**

Laterallus levraudi

French: Râle de Levraud **German**: Venezuelaralle **Spanish**: Polluela Venezolana

Taxonomy. *Porzana levraudi* P. L. Sclater & Salvin, 1868, Caracas, Venezuela.
Monotypic.
Distribution. Venezuela N of R Orinoco. Specimen from NE Brazil (Paraiba) is a subadult *L. exilis*.
Descriptive notes. 14-16·5 cm. Upperwing-coverts variably spotted with rufous in some birds. Sexes alike. Closely resembles the three allopatric *Anurolimnas* crakes, two of which (*A. castaneiceps* and *A. viridis*) normally inhabit forest and thicket; *A. castaneiceps* differs in dark brown belly; *A. viridis* has grey face and very short rufous tail; marsh-dwelling *A. fasciatus* has distinctive blackish barring from lower breast to undertail-coverts. Sympatric *L. melanophaius* has barred underparts, while similar but larger *Amaurolimnas concolor* of dense thickets has rufous-tinged upperwing-coverts, brown belly to undertail-coverts, and yellowish green bill. Immature apparently similar to adult but not described; juvenile undescribed. Voice. Not described.
Habitat. Inhabits swamps, marshes, lakesides, lagoons and flooded pastures in lowlands from 20 up to 600 m.
Food and Feeding. No information available.
Breeding. No information available.
Movements. None recorded.



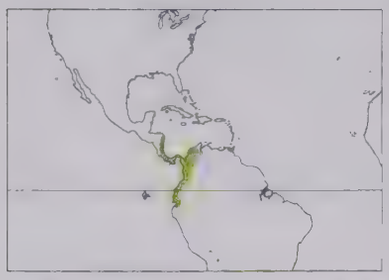
Status and Conservation. VULNERABLE. Confined to Caribbean slope of NW Venezuela, where it has been recorded infrequently from few localities. Recent records are from only 3 areas, at 2 of them in man-made habitats, a pool and a reservoir: in Yacambú National Park (Lara), Morrocoy National Park (Falcón) and Embalse de Taguaiguai (Aragua). In 1940's, species was at least locally common but present status unclear; although considered still locally common in 1980's, population at Yacambú National Park was then small and only 6-12 birds were seen in c. 3-4 ha of habitat at Embalse de Taguaiguai. Numbers are probably declining as a result of the general degradation of wetlands caused by industrial waste, pesticides and the lowering of water levels. Assessment of species' ecological requirements urgently needed, so that conservation strategy may be developed; surveys required in order to determine overall status of species and to assess threats to its survival.
Bibliography. Blake (1977), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Hellmayr & Conover (1942), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Ripley (1977), Storer (1981), Teixeira *et al.* (1989), Wege & Long (1995).

30. **Ruddy Crake**

Laterallus ruber

French: Râle roux **German**: Rubinralle **Spanish**: Polluela Rojiza
Other common names: Red Crake

Taxonomy. *Corethrura rubra* P. L. Sclater and Salvin, 1860, Vera Paz, Guatemala.
In past, up to three races proposed, *ruber*, *ruberrimus* and *tamaulipensis*. Monotypic.
Distribution. S & E Mexico (Guerrero and Tamaulipas) S to Honduras, N Nicaragua and NW Costa Rica (N Guanacaste).



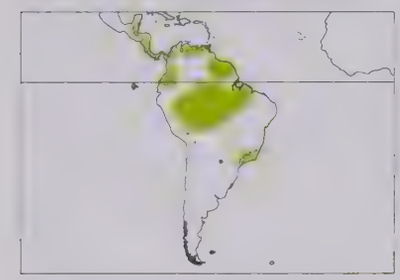
Descriptive notes. 14-16·5 cm; 42-49 (45) g. Sexes alike, but female richer, more chestnut, from lower back to uppertail-coverts; averages slightly smaller, especially in culmen length. Very similar to allopatric *L. levraudi*, but has uniform underparts; within its own range a distinctive small crake. Distinguished from congeners by dark slate top and sides of head, which contrast with chestnut mantle and sides of neck; also unbarred cinnamon to chestnut underparts with paler chin; olive green legs and feet. Immature like adult but paler on belly and with rump to uppertail-coverts like adult male. Juvenile sooty grey; almost black on crown, rump and tail; interscapular region has brownish cast; throat whitish; breast and flanks dark grey; belly pale grey to cream; iris grey-white; bill pinkish to dark horn; legs and feet greenish grey. Voice. Explosive descending trill similar to that of *L. albigularis*, typically preceded by quiet piping notes; calls frequently during breeding season, even until midday. Also a dry, insect-like chatter or churr (a scolding note), sometimes followed by quiet rasps. Calls throughout year.
Habitat. Marshes, including brushy edges; also flooded fields, wet meadows and roadside ditches; pastures with tall grass or weeds; inhabits lowlands up to 1500 m along both slopes of Middle America.
Food and Feeding. No information available.
Breeding. Honduras, Jul-Sept; Nicaragua, Jul. Nest a rather tightly woven ball of dry grass stems, reeds and leaves, lined with finer grass, with a side entrance; one nest with external depth 20 cm and diameter 13 cm, was placed in centre of small tuft of reeds 20 cm above water. Eggs 3-6; black downy chick has pink bill, and grey legs and feet. No other details of breeding recorded.
Movements. Considered resident throughout most of normal range but possibly only a visitor to NW Costa Rica.
Status and Conservation. Not globally threatened. Difficult to observe; current status unclear, but in 1970's species was regarded as fairly common in some areas, possibly the most abundant crake over much of its range in Mexico, where its calls were heard throughout Atlantic coastal lowland marshes in spring. Apparently rare and local at its two known Costa Rican sites, Miravalles and Orosi. No recent information on status in rest of range.
Bibliography. Blake (1977), Dickerman (1968a), Dickey & van Rossem (1938), Edwards (1989), González-García (1993), Hellmayr & Conover (1942), Howell & Webb (1995a), Land (1970), Monroe (1968), Peterson & Chalif (1973), Saab & Petit (1992), Slud (1964), Stiles & Skutch (1989).

31. **White-throated Crake**

Laterallus albigularis

French: Râle à menton blanc **German**: Weißkehlralle **Spanish**: Polluela Carrasqueadora

Taxonomy. *Corethrura albigularis* Lawrence, 1861, Atlantic side of Isthmus of Panama.
Sometimes considered conspecific with *L. melanophaius*, which replaces present species E of Andes; however, may be closer to *L. exilis*. Three subspecies recognized.
Subspecies and Distribution.
L. a. cinereiceps (Lawrence, 1875) - SE Honduras and Caribbean slope of Nicaragua through Costa Rica to NW Panama (W Veraguas).
L. a. albigularis (Lawrence, 1861) - Pacific lowlands of SW Costa Rica (Gulf of Nicoya) through Panama and N & W Colombia to W Ecuador.
L. a. cerdaleus Wetmore, 1958 - E Colombia (Córdoba to Santa Marta region).
Descriptive notes. 14-16 cm; male mean 50 g, female mean 45 g. Occasionally has remiges faintly mottled or barred with white. Sexes alike. Only sympatric *Laterallus* is *L. ruber*, which lacks barring on underparts. Differs from *L. melanophaius* in less extensive white on throat and only onto upper breast; undertail-coverts clearly barred. Immature similar to adult but duller; pale tips to head feathers; sides of head to sides of breast grey, flecked with cinnamon; belly dark brown, very narrowly barred whitish. Juvenile not described. Races separated on plumage: *cinereiceps* has grey face, *cerdaleus* has fairly uniform reddish brown head and throat. Voice. Abrupt, explosive descending trill or churr, similar to that of *L. ruber*; alarm note a sharp "chip".



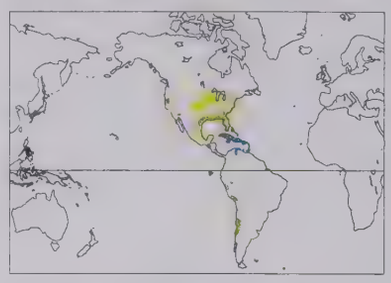
Habitat. Marshes, wet fields and damp grassy pastures, overgrown banks of ditches, canals, ponds and streams, and drying stream beds; also thickets and forest clearings. Does not require standing water; more associated with grass than with marshes in Colombia. Inhabits lowlands up to 1600 m.
Food and Feeding. Takes insects, spiders, seeds of grasses and sedges, and algae. Although normally confined to dense vegetation, ventures into more open spots to feed at dawn and dusk or in dull, rainy weather.
Breeding. Breeds Costa Rica in wet season; Colombia, breeding condition Dec-Aug. Nest a ball, with a side entrance, of woven grass stems and leaves, placed up to 60 cm above ground or water in grass tussock or bush. Eggs 2-5; black downy chick has pale brownish white bill with black band anterior to nostril.
Movements. Resident throughout range, but in wet season may wander to higher ground with low cover.
Status and Conservation. Not globally threatened. Very difficult to see and status unclear; considered common over much of its range in 1970's and 1980's, but in 1960's race *albigularis* was relatively uncommon except in some lowland regions.
Bibliography. Blake (1977), Davis (1972), Hellmayr & Conover (1942), Hilty & Brown (1986), Monroe (1968), Ridgely (1981), Ridgely & Gwynne (1989), Ripley (1977), Sclater & Salvin (1879), Slud (1964), Stiles & Levey (1988), Stiles & Skutch (1989), Storer (1981), Wetmore (1965).

32. Grey-breasted Crake

Laterallus exilis

French: Râle grêle **German**: Amazonasralle **Spanish**: Polluela Pechigrís

Taxonomy. *Rallus exilis* Temminck, 1831, Cayenne, French Guiana.
Monotypic.
Distribution. Guatemala and Belize S through Panama to Colombia and N Ecuador; Venezuela and the Guianas S through Amazonian Brazil and W to E Peru and N Bolivia; extreme SE Brazil; also S Paraguay (Villa Hayes), where status uncertain.



Descriptive notes. 14-15·5 cm; male 26·5-39 (32) g, female 29-43 (36) g. Variable amount of narrow white barring on upperwing-coverts, sometimes absent. Sexes alike. Easily distinguished from congeners with barred flanks by pale grey head to breast, chestnut nape and upper mantle, and olive brown upperparts. Three other superficially similar grey-breasted crakes with barred flanks are sympatric, but all are larger and lack chestnut on nape and mantle: *Neocrex erythrops* has red base to bill and red legs; *Porzana albicollis* and *P. carolina* have patterned upperparts and different head pattern, former has purplish brown legs, latter has white undertail-coverts. Immature has fuscous brown upperparts and medium grey underparts, lacks chestnut on nape and upper mantle, has duller, more restricted barring on underparts, brown iris and largely horn brown bill. Juvenile sooty black with whitish throat and centre of breast; iris and bill as immature. VOICE. Call a series of 2-10 "tink" or "keek" notes; also descending musical rattle and quiet, sharp "check".
Habitat. Marshes, riverbanks, lake edges and wet grassy habitats with dense, short to fairly tall vegetation of 50-100 cm; also flooded rice fields and floating mats of *Paspalum* grass on river. Usually in areas with shallow standing water, 5-15 cm deep; sometimes in dry habitat such as pasture, fields of tall grass in a new housing area, and airfields. Occurs alongside *L. melanophaius* in marshes, and also in habitat similar to that occupied by *L. ruber*. Uses "runways" under grass; Peruvian specimen trapped on runway used by swamp rats (*Holochilus brasiliensis*). Lowlands up to c. 1700 m.
Food and Feeding. Earthworms, spiders, insects (Orthoptera, Homoptera, Coleoptera, Hemiptera, Heteroptera and larval Lepidoptera), and seeds.
Breeding. Surinam, Dec, Feb; Colombia, breeding condition Feb; Panama, possibly Jul; record from Trinidad, Jul, possibly not of this species. Nest spherical with a side entrance, typical of genus; made of woven grass and weed stems. Eggs 3; chick covered with black down.
Movements. Regarded as sedentary, but in Surinam 2 birds were caught at night at lighted houses in Jul and Feb. Not known whether S Paraguay bird, taken in early Aug 1979, was migrant, stray or part of a resident population.
Status and Conservation. Not globally threatened. Fragmented distribution suggests that species may be more widespread than is known, but birds are secretive and very difficult to see. Common in Bolivia and Amazonian Brazil; not uncommon in Surinam and Costa Rica; at Paramaribo, Surinam, many birds recorded in grass fields at new housing project, Dec 1972. Apparently local and uncommon to rare elsewhere, especially in Central America where may be generally less numerous than in South America, a distribution pattern which might be expected in a species retreating from a formerly greater range.
Bibliography. Blake (1977), Contreras & Contreras (1994), Haverschmidt (1968, 1974a), Haverschmidt & Mees (1995), Hayes (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Howell & Webb (1995a), Howell *et al.* (1992), Meyer de Schauensee (1962), Meyer de Schauensee & Phelps (1978), Monroe (1968), Olson (1974a), Parker *et al.* (1991), Pearson (1975), Ridgely (1981), Ridgely & Gwynne (1989), Sick (1985c, 1993), Snyder (1966), Stiles (1988), Stiles & Levey (1988), Stiles & Skutch (1989), Storer (1981), Texeira, Nacinovic & Luigi (1989), Texeira, Nacinovic & Tavares (1986), Tostain *et al.* (1992), Wetmore (1965).

33. Black Rail

Laterallus jamaicensis

French: Râle noir **German**: Schieferralle **Spanish**: Polluela Negruzca

Taxonomy. *Rallus jamaicensis* Gmelin, 1789, Jamaica.
Distinctive race *tuerosi* sometimes treated as separate species. Five subspecies normally recognized.
Subspecies and Distribution.
L. j. coturniculus (Ridgway, 1874) - California and Baja California.
L. j. jamaicensis (Gmelin, 1789) - E USA and E Central America; winters from S USA to Guatemala and Greater Antilles.
L. j. murivagans (Riley, 1916) - coastal Peru.
L. j. tuerosi Fjeldså, 1983 - L Junín, Peru.
L. j. salinasi (Philippi, 1857) - C Chile and extreme W Argentina.
Also 2 presumed Colombian specimens, labelled "Bogotá" and "Nouvelle Grenade".

Descriptive notes. 12-15 cm; *jamaicensis* male 29-43 (35) g, female 29-44 (36) g; *coturniculus* male 21-34 (28) g, female 23-46 (30) g; wingspan 22-28 cm. Sexes similar; female has paler underparts. Very small rail, easily distinguished from congeners and most sympatric rallids by very dark plumage with white spotting and barring (although young of most rallids are black). *Porzana spiloptera* has blackish streaks on dark olive brown upperparts, white spots and bars of upperparts confined to upperwing-coverts and remiges, white barring on belly, flanks and undertail-coverts, and brown legs and feet. Possibly sympatric *Coturnicops notatus* similar in size and colour but has white spotting on head and neck, white chin, white markings on neck and breast, rest of underparts barred, and black legs and feet. Immature similar to adult; iris and legs gradually attain adult colours. Juvenile has dark brown upperparts, more rufous from nape to upper back, with variable small white spots on middle back and wings; face and underparts grey, with white chin, throat and centre of belly; flanks and undertail-coverts browner, barred white; iris brown; legs and feet darker than adult. Races separated on: colour of undertail-coverts, cinnamon or buff in *murivagans* and *tuerosi*; colour of mantle and back, chestnut-brown in *jamaicensis*, more rufous in others, more extensive in *salinasi*; nature of pattern of back to tail and upperwing, boldly barred white in *tuerosi*, variably spotted in others; white barring on flanks, broader in *salinasi*; and size, *coturniculus* smallest. VOICE. Male gives "kic-kic-kerr" call ending in a downward slur; female gives low "croo-croo-croo". Also growls and barking notes.
Habitat. Marshes, both fresh and saline, and wet meadows and savanna. In North America occupies sites with shallower water (under 3 cm in Arizona) than other rallids; most breeding areas have fine-stemmed emergent plants, and substrate of ideal habitat usually moist soil with scattered small pools. In dense vegetation probably uses runways of mice. Birds in salt-marsh habitats require surrounding higher vegetation for escape during extreme high tides. Structure apparently more important than plant species composition in determining suitability of habitat. Race *tuerosi* inhabits wide rushy (*Juncus*) zones with open spaces of partly flooded moss or short matted grass in marshes fringing L Junín at 4080 m in C Peruvian Andes. Race *salinasi* occurs in salt-marsh and inundated fields. Sometimes in hay fields during migration.
Food and Feeding. Takes mainly small (under 1 cm) aquatic and terrestrial invertebrates, including snails, Amphipoda, Isopoda, spiders, ants, aphids, grasshoppers, beetles, bugs, earwigs and flies; also seeds of *Typha* and *Scirpus*; eats more seeds in winter. Foraging poorly known; active throughout day and probably forages on or near substrate at edges of stands of emergent vegetation.
Breeding. USA, May-Aug; Panama, Jul; Peru, end of dry season through rainy season; Chile, Nov-Dec. Monogamous; territorial when breeding. Nest a bowl of dominant local grasses, rushes etc., with woven canopy of dead or living vegetation and ramp of dead vegetation from substrate to entrance; external diameter 11-15 cm, height 8-10 cm; internal diameter 7-8 cm; depth of cup 3-7 cm; built in thick marsh vegetation having both dead and living plant components; usually placed low down in centre of vegetation clump over moist substrate or very shallow water; sometimes in depression in ground; may build nest up in response to high tides. Eggs 4-13 (7·6) in *jamaicensis*, 3-8 (6) in *coturniculus*, 3-7 (4·9) in *salinasi*, 2 in *tuerosi*; incubation 17-20 days, by both sexes; black downy chick has sepia bill; chicks semi-precocial, brooded for first few days; both parents, sometimes only female, care for chicks; juvenile plumage attained by 6 weeks; immature plumage acquired in autumn or early winter. Age of first breeding probably 1 year. May lay replacement and second clutches. Nest success high in Arizona; adult survival apparently high in stable habitats, despite predation by herons and other birds during extreme high tides, a major source of mortality for populations in tidal marshes.
Movements. E USA populations winter in coastal E USA (S through Florida and rarely N to New Jersey) and also S to Cuba, Jamaica and Guatemala. Recorded only in breeding season in S Mexico, Belize and Panama; only in winter in Guatemala and Jamaica; most Cuban records are of winter residents; transient in Bahamas; may winter more widely than is known in West Indies and in Central American breeding range; may breed very locally in Greater Antilles; present all year in Costa Rica. USA spring migration mid-Mar to early May; autumn migration early Sept to early Nov, mostly mid-Sept to mid-Oct; migrates at night along broad front; sometimes strikes towers and buildings. Accidental Canada (Ontario, Quebec), Maine, Rhode I, and Bermuda. Adults of Californian race (*coturniculus*) sedentary but juveniles may disperse erratically. South American races apparently sedentary.
Status and Conservation. Not globally threatened. Race *tuerosi*, sometimes treated as full species, considered Endangered; known only from L Junín, where recorded from 2 sites on SW shore (near Ondores and Pari) but likely to occur through large portions of the 15,000 ha of marshland surrounding the lake; nearby lakes do not have suitable habitat. This form at risk from pollution and water level changes which have affected the lake since at least 1955; in particular, strong desiccation of reedmarshes caused by drought and unsustainable water management by Electro Peru, and also occasional flooding with very acid water from Cerro de Pasco mines; however, *tuerosi* still survived in Jan 1995. All other races are locally distributed, often rare or infrequently recorded. Both races occurring in USA regarded as threatened in most states; in USA, breeding range has contracted seriously this century, both of *jamaicensis* at inland sites, where no confirmed nesting recorded since 1932, and of both races at coastal sites, where populations must have declined drastically before 1970's when laws protecting coastal wetlands were enacted. More susceptible than other marsh rallids to disturbance from grazing and agriculture because habitat is at edge of marshes. Race *coturniculus* threatened by marsh subsidence caused by groundwater removal, dyking of salt-marshes, water level fluctuation, and wildfires. Continued massive degradation and loss of shallow wetland habitats gives cause for greater concern in future. In South America *salinasi* is rare, and was not recorded from Chile for 25 years until a dead bird was found in Oct 1994. Race *jamaicensis* no longer occurs on Puerto Rico.

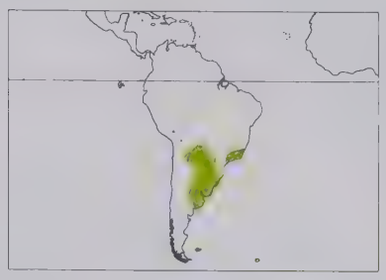
34. Galapagos Rail

Laterallus spilonotus

French: Râle des Galapagos **German**: Galapagosralle **Spanish**: Polluela de Galápagos

Taxonomy. *Zapornia spilonota* Gould, 1841, Santiago (James) Island, Galapagos.
Sometimes considered a race of *L. jamaicensis*, of which it is an insular derivative. Monotypic.
Distribution. Galapagos Is, occurring on Pinta, Fernandina, Isabela, Santiago, Santa Cruz, Floreana and San Cristóbal.



Descriptive notes. 15·5 cm; 35-45 g (no precise data). Sexes similar but female sometimes has paler throat. Very similar in plumage to *L. jamaicensis*, with blackish face, dark chocolate brown upperparts with small white spots on wings and from mantle to uppertail-coverts, dark slate grey neck and breast, chocolate brown flanks and belly with small white spots, and blackish undertail-coverts with white bars; lacks bold barring on flanks of *L. jamaicensis*, and white markings on upperparts far less distinct. Non-breeding adult has white spots on upperparts reduced or absent. Juvenile has blackish grey upperparts, greyer on face and throat; sooty brown underparts with no white spots. Change from juvenile to adult-type plumage gradual, with no distinctive immature plumage; involves mantle and back becoming increasingly brown, white spotting increasing, iris colour changing from black through brown and orange to crimson, and bill gradually darkening to black. Voice. Vocal repertoire extensive, including cackles, clucks, warbles, trills and hisses. Territorial advertising call of adults, frequently heard, is a rapid "chi-chi-chi-chirroo", the "rroo" being a falling slur; similar in form to advertising call of *L. jamaicensis*.
Habitat. Historically recorded from 2 habitat types: coastal mangroves, from which no longer known, and in grass and forest of highland moist regions, where occurs in deep thickets and in dense ground cover. Recorded from *Psychotria* thickets on Santiago; from *Scalesia* forest, shrubby *Miconia robinsoniana* belt, patches of bracken (*Pteridium aquilinum*), open sedge-fern meadows and moist farming regions on Santa Cruz; and from highland fern belt on Pinta. Generally tolerant of man-modified habitats, e.g. agricultural land, but does not venture into overgrazed short-grass pasture. Precise altitudinal limits not known: occurs on all islands higher than 500 m; may ascend to 1700 m on Isabela.
Food and Feeding. Primarily invertebrates: snails, Isopoda, Amphipoda, spiders, dragonflies, moths, Hemiptera, ants and caterpillars; also some seeds. Feeds throughout day; normally forages on ground, walking with depressed tail, darting head from side to side, jabbing bill rapidly into litter, picking up and tossing or moving aside leaves and twigs. Also takes prey from stems and overhanging leaves; frequently probes into moss and other epiphytes on *Miconia* trunks; sometimes climbs 0·5 m up into vegetation to forage. Also forages at pools, streams and *Sphagnum* bog patches; wades breast-deep and takes small prey from water surface.
Breeding. Breeds Sept-Apr, from middle of cool season to end of hot season. Monogamous and territorial. Nest a deep, semi-domed cup with side entrance; made of herbaceous stems; built on ground and covered by dense, low vegetation. Eggs 3-6; incubation 23-25 days, by both parents, with changeovers every c. 50 minutes; newly hatched downy chicks black, with black iris and white bill with black tip, weigh 8-9 g; chicks leave nest soon after hatching, and cared for and fed by both parents; juveniles feed themselves but stay with parents until almost fully grown; adult-type plumage fully attained by 80-85 days. May raise two broods per season. Age of first breeding 1 year.
Movements. None.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Now known only from islands high enough to have an extensive moist region. In late 1970's species was considered still common in highland habitats, especially on Santiago and Santa Cruz, and population on Santa Cruz appeared stable, but no recent assessment of status has been made. Birds fly weakly and possibly vulnerable to introduced predators, e.g. dogs, cats and pigs; black rats (*Rattus rattus*) appear not to be significant nest predators, probably as a result of incubating adult's aggressive behaviour towards intruders. Short-eared Owl (*Asio flammeus*) may be natural predator. Introduced animals are threat to habitat: on Pinta no rails found after goats destroyed dense ground vegetation in 1968-1970 but, after introduction of hunting in 1971 to reduce goat population, vegetation regenerated and rails were again common in 1973. Most of archipelago is under national park protection and programme to eradicate introduced predators exists. Reasons for abandonment of mangrove habitat not known: unlikely to be simply a result of introduced predators or competitors because rails have also disappeared from mangroves on Fernandina, where no introductions have occurred. Much of habitat protected within Galapagos National Park but all islands where species occurs, except Fernandina, have introduced mammals; rail populations should be surveyed regularly to monitor status.
Bibliography. Collar *et al.* (1994), Franklin *et al.* (1979), Gifford (1913), Harris (1973, 1982), Ortiz & Carrión (1991), Ripley (1977), Ripley & Beehler (1985), Rosenberg (1990), Salvin (1876), Storer (1981).

35. Red-and-white Crake

Laterallus leucopyrrhus

French: Râle blanc et roux **German**: Weißbrustralle **Spanish**: Polluela Rojiblanca

Taxonomy. *Rallus leucopyrrhus* Vieillot, 1819, Paraguay.
Monotypic.
Distribution. SE Brazil, Paraguay and Uruguay to NE Argentina (S to Buenos Aires).
Descriptive notes. 14-16 cm; 1 female 46·5 g, 10 unsexed 34-52 (45) g. Distinctively patterned crake: pure white throat and centre of breast sharply demarcated from adjacent bright rufous areas; flanks boldly barred black and white; undertail-covert pattern unique in genus, black in centre and white laterally; bill has broad yellow base and lower mandible, rest blackish; legs and feet bright coral red.

Some birds have diffuse rufous barring on upperwing-coverts, while a few have more prominent white barring, sometimes bordered with black. Sexes alike. *L. melanophaius* lacks sharp demarcation between rufous and white at sides of neck and breast, and has rufous undertail-coverts, all-dark bill and olive brown legs; *L. xenopterus* has buffy ochraceous breast, strong black and white barring on wings, black tail and undertail-coverts, rather heavy blue-grey bill and blue-grey legs. Immature similar to adult; juvenile has dark brown upperparts, grey underparts, blackish bill and black legs. Voice. Utters a prolonged throaty chatter; contact call is a low squeak or whistle.
Habitat. Open marshy areas in lowlands. Inhabits dense tussocky or matted grasses (sometimes heavily grazed) 30-50 cm tall, on moist ground or in water 2-4 cm deep; also coarse grass, 1·5-2+ m tall, with scattered tree-ferns on moist or flooded ground. Uses runways on ground beneath dense matted vegetation; in captivity, also climbs freely in bushes.
Food and Feeding. Forages by searching ground and occasionally prodding dead leaves or twigs. Captive birds ate earthworms, insects and millet seed.
Breeding. Argentina, Oct. Monogamous. Nest spherical with side entrance, made of grasses; one aviary nest was large pile of wet leaves, 18 cm deep and 23 cm across, placed 2 m up in dense honeysuckle (*Lonicera*). All following information from captive birds: eggs 2-3; incubation 23-24 days, by both sexes; black downy chicks have black bare parts, and one weighed 7·8 g; chicks leave nest soon after hatching and can feed themselves immediately, but adults normally feed and care for them; young of first brood, aged c. 8 weeks, also fed young of second brood; independent at c. 4 weeks; fully grown and feathered at 6 weeks, when eye and legs show red tinge; rufous feathers appear from 5-7 weeks of age.
Movements. None recorded.
Status and Conservation. Not globally threatened. No recent information. Formerly regarded as locally common in Argentina and Paraguay but rare in Rio Grande do Sul, Brazil. Kept in captivity relatively frequently and, at least in 1970's, was more available through the bird trade than many other small rails, suggesting that it may have been fairly common.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Contreras *et al.* (1990), Essenberg (1984), Everitt (1962), Forrester (1993), Gibson, L. (1979), Hayes (1995), Hellmayr & Conover (1942), Kleefisch (1984), Klimaitis & Moschione (1987), Levi (1966), Meise (1934), Meyer de Schauensee (1982), Narosky & Yzurieta (1987), Olrog (1984), de la Peña (1992), Pereyra (1931), van Praet (1980), Rutgers & Norris (1970), Sick (1985c, 1993), Storer (1981).

36. Rufous-faced Crake

Laterallus xenopterus

French: Râle de Conover **German**: Rotgesichtralle **Spanish**: Polluela Guaraní
Other common names: Horqueta Crake

Taxonomy. *Laterallus xenopterus* Conover, 1934, Horqueta, Paraguay.
Monotypic.
Distribution. SC Brazil (Federal District) and C Paraguay.

Descriptive notes. 14 cm; 3 unsexed 51-53 g. Tail relatively long, bill stout and tarsus short. Sexes alike. Distinguished from other *Laterallus* by buffy ochraceous foreneck to breast, normally rather duller than in *L. melanophaius*; from sympatric *L. melanophaius* and *L. leucopyrrhus* by boldly barred inner secondaries, upperwing-coverts and scapulars, black tail and undertail-coverts, heavy blue-grey bill and blue-grey legs and feet; some individuals of both of the above species have diffuse or narrow rufous or white barring on upperwing-coverts and scapulars, but never as extensive or as prominent. Voice. Not described.
Habitat. Inhabits coarse, tussocky or matted grass on moist to shallowly flooded substrates in marshes. Reported from tussocky grass 30-50 cm tall growing on moist ground or in 3-4 cm of water; also in coarse grass 1·5-2 m tall in 2-3 cm of water; such marshes (wet *campos*) commonly form in low areas of E Paraguay and adjacent parts of Brazil. Occurs alongside *L. leucopyrrhus* in these habitats.
Food and Feeding. Nothing recorded. Specimens captured in traps baited with peanut butter, rolled oats, cracked maize and banana.
Breeding. No information available.
Movements. None recorded.
Status and Conservation. VULNERABLE. Reliably known from only 3 areas. In C Paraguay the type was collected at Horqueta in 1933 and 4 birds were collected in Curuguaty area in 1976-1979. Over 1200 km to NE there were several sight records, and one specimen, from Brasília area during period 1978-1989. Species presumably occurs in wetlands between these two centres. Population not known but doubtless more widespread and numerous than existing records suggest, because areas of occurrence poorly studied and birds difficult to locate; judged relatively frequent around Brasília. No known threats in Paraguay. In Brazil, wholesale loss of wet *campo* habitats from drainage and adjacent *Eucalyptus* plantations may have serious effects on hitherto undiscovered populations; fire is also a potential threat. Work is needed to rediscover populations in Paraguay; voice should be recorded, enabling use of taped playback to ascertain range and status of species.

37. **Woodford's Rail**

Nesoclopeus woodfordi

French: Râle de Woodford **German**: Salomonenralle **Spanish**: Rascón de las Salomón
Other common names: Solomons Rail

Taxonomy. *Rallina Woodfordi* Ogilvie-Grant, 1889, Aola, Guadalcanal, Solomon Islands.
Sometimes placed in *Rallina* or even *Rallus*, but *Nesoclopeus* differs in structural characters, and may provide link between *Rallina* and *Gallirallus*. Forms superspecies with *N. poecilopterus*, with which may be conspecific. Three subspecies recognized.
Subspecies and Distribution.
N. w. tertius Mayr, 1949 - Bougainville I.
N. w. immaculatus Mayr, 1949 - Santa Isabel I.
N. w. woodfordi (Ogilvie-Grant, 1889) - Guadalcanal I.
Also reported from Malaita and Choiseul (Solomon Is); sightings from New Georgia and Kolombangara may be referable to *Gallirallus rovianae*.

Descriptive notes. 30 cm. Fairly large, very dark rail with long, powerful bill; probably flightless. Sexes alike. Much darker than *N. poecilopterus* with less marked facial pattern; lacks tawny bars on remiges. Immature similar to adult but has white on chin, and browner underparts with pale edges to breast feathers. Juvenile undescribed. Race *tertius* smallest, *immaculatus* largest; *woodfordi* has white spots on primaries, and obscure ventral barring; *immaculatus* blacker overall, and lacks white on remiges and wing-coverts; *tertius* has belly and flanks faintly mottled buff, undertail-coverts vaguely barred white, and white barring on primaries; nominate has black bill, grey legs and red eye, *immaculatus* has greyish bill, dark greenish yellow legs and orange-red eye, and *tertius* has pale yellowish horn bill and grey legs. Voice. Unmusical series of metallic shrieks of unvarying pitch, generally delivered in threes.
Habitat. Lowland forest, secondary growth and swamp forest, occasionally up to 1000 m; on Santa Isabel apparently prefers riparian habitats, including abandoned gardens, up to 300 m.
Food and Feeding. Worms, snails, insects, frogs, lizards and small snakes; also young shoots of taro plants. Occasionally digs in gardens.
Breeding. Bougainville, Aug. Eggs 2-4. A nest, purported to be of this species, from Santa Isabel in Jul 1988 was situated under small bush in lowland forest near stream; made of rootlets, leaves and other plant matter, measured c. 25 cm across and had shallow depression c. 15 cm across in which were 6 eggs almost identical to known eggs of this species. No further information available.
Movements. None.
Status and Conservation. ENDANGERED. May be close to extinction. Nominate race from Guadalcanal is known only from the type specimen and may be extinct, having fallen victim to introduced predators: cats have wiped out most terrestrial mammals on Guadalcanal. There were three observation of *immaculatus* from Santa Isabel in 1987 and 1988, where this bird occasionally forms part of the local human diet when caught by dogs or in traps set for the Pacific Black Duck (*Anas superciliosa*). No records of *tertius* from Bougainville between 1936 and 1985, when one bird was seen in forest which has since been logged.
Bibliography. Blaber (1990), Coates (1985), Collar & Andrew (1988), Collar *et al.* (1994), Diamond (1987, 1991), Finch (1985), Hadden (1981), Harrison & Parker (1967), Kaestner (1987), Olson (1973b), Ripley (1977), Sibley (1951), Webb (1992).

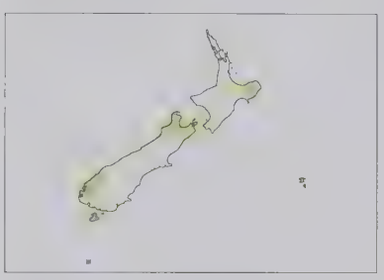
38. **Bar-winged Rail**

Nesoclopeus poecilopterus

French: Râle des Fidji **German**: Fidschiralle **Spanish**: Rascón de las Fiji
Other common names: Fiji Rail

Taxonomy. *Rallina pœciloptera* Hartlaub, 1866, Viti Levu, Fiji Islands.
Sometimes placed in *Rallina* or even *Rallus*. Forms superspecies with *N. woodfordi*, with which may be conspecific. Monotypic.
Distribution. Viti Levu and Ovalau, S Fiji. Almost certainly extinct on Taveuni, N Fiji.

Descriptive notes. 33 cm. Probably flightless. Sexes alike; female possibly slightly larger. Very similar to *N. woodfordi*, but differs in having brown upperparts, medium dark slate grey underparts with faint pale barring from flanks to undertail-coverts, somewhat more marked facial pattern, tawny bars on remiges, white bars on all underwing-coverts, brown eye, yellow or orange-yellow bill and yellow legs. Immature and juvenile undescribed. Voice. Not described.
Habitat. Remote forested areas, secondary forest, old taro fields and possibly swamps.
Food and Feeding. No information available.
Breeding. Recorded nesting Oct-Dec and possibly Mar. One nest, "of sedges", contained 6 eggs; on another occasion a male and 4 eggs were obtained by local people. No other information.
Movements. None.
Status and Conservation. Almost certainly EXTINCT. An unconfirmed record from N of Waisa, near Vunidawa, Viti Levu, in 1973, the first record since 1890; however, species is thought unlikely to have survived there because a number of other ground-dwelling species, including two non-endemic volant rails (*Gallirallus phillipensis* and *Porphyrio porphyrio*), have disappeared as a result of predation by introduced mongooses and feral cats. Almost certainly extinct on Taveuni, where it was probably rare even before the introduction of mongooses and was regularly hunted by dogs. Known from 12 specimens collected on Viti Levu and Ovalau in 19th century; no estimate ever made of its abundance because it was shy and seldom seen.
Bibliography. Collar & Andrew (1988), Collar *et al.* (1994), Diamond (1991), Fullagar *et al.* (1982), Greenway (1967), Hay (1986), Holyoak (1979), King (1978/79), Layard (1875, 1876), Mayr (1945), Olson (1973b), Pratt *et al.* (1987), Ripley (1977), Watling (1982).



Genus *GALLIRALLUS* Lafresnaye, 1841

39. **Weka**

Gallirallus australis

French: Râle wéka **German**: Wekaralle **Spanish**: Rascón Weka

Taxonomy. *Rallus australis* Sparrman, 1786, Dusky Sound, South Island, New Zealand.
Includes *G. troglodytes*, now regarded as a black morph of present species. Considerable geographical variation, with up to eight races accepted in past; situation complicated by extensive individual variation. Four subspecies currently recognized.
Subspecies and Distribution.
G. a. greyi (Buller, 1888) - North I.
G. a. australis (Sparrman, 1786) - N & W South I.
G. a. hectori (Hutton, 1874) - formerly E coast and interior of South I but now confined to Chatham Is, where introduced.
G. a. scotti (Ogilvie-Grant, 1905) - Stewart I.
Introduced to many islands: *greyi* to Kapiti, Rakitu, Mokoia and Kawau, and to Bay of Islands; nominate to Kapiti, Chatham and Macquarie (now extinct on last); *hectori* to Chatham; and *scotti* to Solander and other outlying islands off Stewart I, and also to Kapiti and Macquarie (now extinct on latter).

Descriptive notes. Male 50-60 cm, 532-1605 (1049) g, wingspan 50-60 cm; female 46-50 cm, 350-1035 (737) g. Unmistakable: large, hefty, thickset, flightless species with stout bill, legs and feet; tail remarkably long for a flightless rail. Sexes similar but female smaller and may have narrower dark pink base and creamier tip to bill. Nominate and race *scotti* very variable, and commonly grouped into chestnut, grey and black morphs, although degree of individual variation has led some authors to group chestnut and grey birds together into single morph: typical chestnut morph bird has mottled red-brown underparts; grey morph has predominantly greyish underparts below brown breast band; and black morph extensively black with dark red-brown streaking on upperparts. Immature similar to adult. Juvenile similar to adult of same morph, but generally darker, though paler in *hectori*; upperparts appear less streaked because dark feather centres less distinct, almost lacking in some *greyi*; underparts may be more uniform and breast band indistinct; flanks often blotched, not barred; dark forms often have brown spots in plumage; bill grey-black; iris brown; legs grey-brown. Race *greyi* very dark, with extensive dark grey belly, reduced breast band, little barring on flanks, and dark legs; *hectori* more yellowish buff-brown; *scotti* smaller than nominate. Voice. Adult "spacing call" a repeated shrill whistle "coo-eet", rising in pitch; most often heard at dawn and dusk and in early evening; often given by pair in duet; heard throughout year. Resonating boom call "doon-doon-doon" given during territorial or aggressive encounters.
Habitat. Frequently inhabits forest, sometimes edges only; also woodland, scrub and grassland, including subalpine tussock grassland. Occurs on beaches, particularly those with rotting seaweed, and at tidal creeks and bays; found at margins of estuarine and freshwater wetlands. Also occupies modified habitats such as lawns, rough pasture, cultivated land and plantations. Inhabits hills, mountains, cliffs, moraine, sandy and rocky shores, sand dunes and urban environments. Prefers low vegetation which gives cover but does not hinder movement; avoids forest with no suitable dense understorey. Occurs from sea-level up to c. 1500 m; may prefer low altitudes in some areas.
Food and Feeding. Omnivorous and opportunistic, taking mainly native fruit and invertebrates, sometimes vertebrates; eats more vegetable matter in winter. Takes foliage, roots, fruit and seeds of many vascular plants; also fungi and seaweed. Invertebrate prey includes earthworms, molluscs, wide variety of crustaceans, myriapods, arachnids and insects; marine animals. Vertebrate prey includes frogs, lizards, and eggs and young of other birds; may kill chickens and young ducks; also eats rats, mice and young rabbits, and scavenges carcasses. Diurnal and nocturnal; feeds mainly on ground. Scratches in litter with bill to depth of 8 cm, covering up to 50 m²/day; lifts dead *Rhopalostylis* palm leaves to search below them; searches seaweed and debris on beaches; searches in tree hollows; takes petrels from burrows; follows wild pigs, searching where they have rooted; climbs in trees; scavenges at camp-sites. Spears eggs with bill and runs off with them. Hammers large objects with bill to kill or break up; holds down objects in feet.
Breeding. Season highly variable, depending on climate, food and size of population; start recorded Aug-Nov, end recorded Nov-Mar, but when population expanding may breed throughout year. Monogamous; often permanently territorial; pair-bonds often permanent; non-monogamous associations (two females with one male) recorded twice. Nest on dry ground; situated in or under tussocks, in burrows, under logs, stumps or rocks, in tree-hollows, also concealed in outbuildings; up to 7 sites per territory, used for many years; nest of sedges, grasses, lilies, twigs and moss, lined with finer grasses and sometimes feathers, wool, hair or leaves; built by both sexes (captivity) or by male only. Usually

On following pages: 40. New Caledonian Rail (*Gallirallus lafresnayanus*); 41. Lord Howe Rail (*Gallirallus sylvestris*); 42. Okinawa Rail (*Gallirallus okinawae*); 43. Barred Rail (*Gallirallus torquatus*); 44. New Britain Rail (*Gallirallus insignis*); 45. Buff-banded Rail (*Gallirallus philippensis*); 46. Guam Rail (*Gallirallus owstoni*); 47. Roviana Rail (*Gallirallus rovianae*); 48. Slaty-breasted Rail (*Gallirallus striatus*).

2-4 eggs (1-6), laid 2+ days apart; incubation 26-28 days, usually by female during day, male at night; hatching asynchronous; downy chicks brown-black with black bill, brown iris and dark purple to pink-grey legs; chicks leave the nest after 2-3 days; feathered at 4 weeks; fed and cared for by parents for 40-108 days. Co-operative breeding occasional, chicks being fed either by extra adult or (captivity) by young of previous broods. Age of first breeding 1 year but can breed in first year. May rear up to 4 broods per year.

Movements. Although sedentary and flightless, can move for significant distances. Normally confined to territory all year; may walk up to 1 km away to good feeding areas. Most subadults disperse up to 6 months after independence, set up their own core areas and either stay at one site, or move between core areas, until they establish territory or die; dispersal distance may exceed 9 km; subadults can walk 4+ km/day and on islands may swim or wade at low tide. Greatest natural movements 9 km (subadult) and 35 km (adult male), both involving crossing major rivers or lakes. Mass migrations, associated with disappearance of many populations in North I, reported from 1890 to 1930's; reasons for these movements unknown. Rapid increases in populations recorded, one in South I due to movement associated with plagues of mice; others also possibly due to short-term changes in food supply. Seasonal altitudinal movement, and movement from forest to open ground in summer, also recorded. Sudden disappearances may be due to disease. Homing ability well documented; longest returns include 130 km, and 72 km in 6 weeks.

Status and Conservation. Not globally threatened. Currently considered near-threatened. Race *hectori* CITES II. Formerly occurred throughout North I and much of South I, D'Urville I and Stewart I, and some inshore islands. Current range greatly reduced and fragmented, but in some areas species is recolonizing previous range. Introduced to many offshore and outlying islands, sometimes unsuccessfully. Locally rare to common; population sizes can also fluctuate markedly, possibly due to variations in climate and food availability. Local irruptions occur and birds readily recolonize areas, but some attempts to re-establish species have been unsuccessful. Sometimes adversely affects native fauna (e.g. lizards and petrels) and flora on offshore islands to which it has been introduced, e.g. since 1960's has affected native vegetation and fauna, especially Fiordland Penguins (*Eudyptes pachyrhynchus*), on Taumaka I, where introduced early this century. In some places eradication has been undertaken, though need for this on some islands is disputed. Formerly hunted extensively for food but currently protected in most places; sometimes considered a pest because birds pull up seedling crops, kill poultry and eat eggs, but they also eat pest insects. Poisoned bait for mammals has reduced populations locally, while recolonization may be hindered by predators. Many killed on roads when populations are high.

Beauchamp (1986, 1987a, 1987b, 1988), Beauchamp *et al.* (1993), Blackburn (1968), Brothers & Skira (1984), Bull *et al.* (1985), Carroll (1963a, 1963b, 1963c), Chambers (1989), Coleman *et al.* (1983), Cooper & Morrison (1984), Cooper *et al.* (1986), Fullagar *et al.* (1982), Guthrie-Smith (1910, 1914), Lever (1987), Lindsay *et al.* (1959), Macmillan (1990), Marchant & Higgins (1993), Miskelly (1981, 1987), Moncrieff (1928), Pracy (1969), Robertson (1976), St. Clair & St. Clair (1992), Turbott (1967), Wilkinson (1927), Williams (1979).

40. New Caledonian Rail

Gallirallus lafresnayanus

French: Râle de Lafresnaye **German**: Pelzralle **Spanish**: Rascón de Nueva Caledonia
Other common names: New Caledonian Wood-rail

Taxonomy. *Gallirallus Lafresnayanus* J. Verreaux and Des Murs, 1860, New Caledonia.
Sometimes placed in genus *Tricholimnas*, or in *Rallus*. Monotypic.
Distribution. New Caledonia.

Descriptive notes. 45-48 cm. Although flightless, has fairly longish tail. Sexes alike but female somewhat smaller. Lacks rufous and dark barring on remiges which is noticeable character of the possibly closely allied *G. sylvestris*, and also of *G. australis*. Immature largely black, washed chocolate brown on upperparts apart from head, and slightly richer chocolate at sides of neck and breast. Juvenile undescribed. References to fluffy and decomposed plumage may refer to first-year birds which have retained some juvenile feathers. Voice. Unknown.
Habitat. Dense humid forest, now probably only in relatively inaccessible areas, but formerly also in forested river valleys near coast.
Food and Feeding. Captive birds ate raw meat and vegetable matter, and caught rats. Diet thought to be similar to that of *G. sylvestris*, i.e. almost any invertebrate, and suggested to include worms and snails. Foraging methods possibly also similar to those of *G. sylvestris*. Said to be nocturnal (captivity) but possibly largely diurnal and crepuscular.
Breeding. No information available.
Movements. None.
Status and Conservation. CRITICALLY ENDANGERED. Until recently, thought to be extinct because had not been recorded by ornithologists during present century, last having been collected in 1890. However, occasional local reports this century suggest that species may still survive in relatively inaccessible areas of forest, albeit in very small numbers. Not found during a search of 3 areas of the island in 1976, but there was an unsubstantiated sighting from N New Caledonia in 1984. Species likely to be threatened by introduced species such as dogs, cats, rats, deer and especially pigs. Its habit of crouching when chased makes it vulnerable to dogs.

Bibliography. Collar & Andrew (1988), Collar *et al.* (1994), Delacour (1966), Fullagar *et al.* (1982), Greenway (1967), Hannecart (1988), Hannecart & Létocart (1983), Layard & Layard (1882), Olson (1973b), Ripley (1977), Stokes (1979), Vuilleumier & Gochfeld (1976), Warner (1947).

41. Lord Howe Rail

Gallirallus sylvestris

French: Râle sylvestre **German**: Waldralle **Spanish**: Rascón de la Lord Howe
Other common names: Woodhen

Taxonomy. *Ocydromus sylvestris* P. L. Sclater, 1869, Lord Howe Island.
Sometimes placed in *Tricholimnas* or *Rallus*. Includes *G. (Tricholimnas) conditicius*, known from one specimen and sometimes thought to be specifically distinct, but now generally regarded as an immature of present species (see page 111). Monotypic.
Distribution. Lord Howe I.

Descriptive notes. Male 34-42 cm, 410-780 (536) g, wingspan 49-52 cm; female 32-37 cm, 330-615 (456) g, wingspan 47-49 cm. Flightless, with short tail and rather long, downcurved bill. Sexes alike, female smaller. Predominantly plain olive brown bird, oldest individuals developing white cheeks and occasionally white nape; rufous and dark brown barring on remiges, a character shared by *G. australis* and *G. philippensis*, but lacking in *G. lafresnayanus*. Immature like adult, but pointed juvenile remiges retained; iris orange. Juvenile very similar to adult but upperparts slightly more reddish brown and underparts browner; bill initially shorter, grey-black becoming browner; remiges pointed; iris dark grey; legs and feet duller. Voice. Advertising call a loud, repeated piercing whistle "coo-eet", often given in duet by pair, and often answered by neighbours; calls during day and occasionally at night. Alarm call a loud explosive "brr-deep". Contact call of adults and young deep drumming "booomp" notes, audible at close range.
Habitat. Subtropical forest. Before human settlement, probably occurred over most of island at low to high altitudes, but subsequently restricted to highest parts of mountains, up to 825 m, in gnarled moss-forest (not a preferred habitat) dominated by *Bubbia*, *Dracophyllum*, *Negria*, *Leptospermum* and palms, with understorey of tree-ferns (*Cyathea*) and litter-covered floor. Now re-established in some lowland forest areas, where inhabits closed megaphyllous broad sclerophyll forests, particularly stands of palm *Howea forsteriana* on igneous soils, and also *Ficus*, *Drypetes* and *Cryptocarya*. Occurs in forest bordering pasture and gardens, and such open areas may be included in territories. Rarely occurs in rain forest, the most widespread vegetation on the island, possibly because less food available near soil surface. Occurs on boulder-covered slopes, steep scree, in valleys, on plateaux, often near cliffs and sometimes near coast.
Food and Feeding. Mainly worms, crustaceans and insect larvae; also molluscs, myriapods, spiders and Hemiptera. Takes eggs and chicks of shearwaters, petrels and domestic fowl. Also eats lichens, fungi, pteridophytes, and flowers and fruits of vascular plants. Will eat meat, stew, butter, porridge, biscuits, bread, chocolate and rat poison. Forages on forest floor among leaf litter, palm leaves, rotten logs, moss and lichens, raking litter aside with bill but not using feet. Chisels wood; enlarges holes in soil with bill and probes to 10 cm deep; pulls aside large fallen palm leaves to glean underneath; probes rotten logs and moss. Also frequents areas inhabited or regularly visited by people. Obtains water from streams, pools and droplets on moss.
Breeding. Normally lays Aug-Jan; one lowland pair laid 11 times in 18 months, Jan 1982 to Jun 1983. Monogamous and permanently territorial; pair-bond normally permanent. Nest a shallow depression in ground, lined with dry grass, ferns, moss, palm fronds and leaves; 10-25 cm across and 7·5 cm deep; cavity depth 2·5 cm; nest well hidden in thick vegetation, under tree roots or log, or in petrel burrow; built by both sexes. Eggs 1-4 in captivity, laid at intervals of 24-36 hours; incubation 20-23 days, by both sexes; downy chick sooty black, with dark legs and iris; chicks fed and cared for by both parents; move from nest to nursery (brood nest) within 2 days of hatching; fully feathered at 28 days; almost fully grown at 65 days, when in heavy post-juvenile moult. Young of previous brood often feed and defend young of next brood and assist in territorial defence. Can pair and breed when 9 months old. Breeding success greater in lowlands than on Mt Gower, and greatest in Settlement area, where birds receive food and water from islanders.
Movements. Largely sedentary, but birds move from mountains to lower areas, such movements taking place at night, when most roadkills occur. Juveniles disperse from natal territories in Jun-Jul, when 3-5 months old, and then inhabit occupied or marginal territories, usually disappearing before next breeding season.
Status and Conservation. ENDANGERED. CITES I. When island first discovered in 1788, species was apparently widespread and common, particularly in lowlands, but in 1853, only 19 years after settlement, was restricted to mountainous regions and by 1930 occurred only in the summit regions of Mt Lidgbird and Mt Gower, where c. 30 birds (at most 10 breeding pairs) survived in 1980. Reason for virtual extinction was combination of habitat degradation by introduced pigs and goats, and predation by introduced cats, dogs, pigs and possibly people. Land clearance occurred over only small part of island, so unlikely to have had major effect. In 1980, 3 pairs were removed for captive breeding and over the next 4 years 85 captive-bred birds were released into the wild, where they have become re-established in some lowland areas; effective predator control measures were also introduced. Recent estimates suggest population of 170-200 birds, with 40-50 breeding pairs. Major current threat to population is predation by Masked Owl (*Tyto novaehollandiae castanops*), introduced in 1920's to control rats; efforts are being made to eliminate owls from the island. Rats not considered a problem, and rails sometimes kill them. Rail population small, vulnerable, largely derived from limited genetic pool, and may be limited by suitable habitat, so constant monitoring recommended. It is intended to set up a captive breeding colony to provide reservoir of birds to augment wild population if necessary.

Bibliography. 42. Okinawa Rail

Gallirallus okinawae

French: Râle d'Okinawa **German**: Okinawaralle **Spanish**: Rascón de Okinawa

Taxonomy. *Rallus okinawae* Yamashina and Mano, 1981, near Mt Fuenchiji, Kunigami-Gun, north Okinawa.
Forms superspecies with *G. torquatus* and *G. insignis*. Monotypic.
Distribution. N Okinawa, Ryukyu Is.
Descriptive notes. 30 cm; 1 adult 433 g, 1 fully grown 435 g; wingspan 50 cm. Almost flightless; tail very short and decomposed; legs long and strong. Scarcely visible chestnut feathers are present on side of breast; some white barring on primaries. Most similar to races *sulcirostris* and *limarius* of larger, volant *G. torquatus*, but differs in having reduced white facial stripe, and reddish bill and legs. Flightless *G. insignis* larger, has different head pattern, black undertail-coverts, black bill and pink legs and feet. Immature like adult but has darker bill tip and culmen. Juvenile has paler, olive-tinged upperparts and head, mottled rather than barred underparts, brownish bill, brown iris and fleshy yellow-ochre legs and feet. Voice. Highly vocal. Calls include "kwi kwi kwi ki-kwee ki-kwee", "ki-ki-ki", "kyip kyip kyip kyip", a rolling "kikirr krarr" followed by "kweee" notes on rising scale and

becoming almost pig-like squeals, a call rather reminiscent of neighing of horse, and deep bubbling. Normally calls only in early morning, late afternoon and evening, when voice carries further in calm conditions.

Habitat. Subtropical broadleaf evergreen forest with dense undergrowth and some water; occurs in primary and secondary forest, along forest edges and in small forest patches; also in scrub and around cultivated areas close to forest, where ground is damp or streams, pools or reservoirs occur. Found from sea-level up to highest hilltops at 498 m in mountainous areas. Requires standing water for bathing; roosts in trees.

Food and Feeding. Insects, particularly locusts, and lizards, taken on forest floor; possibly also takes some food from shallow water when visiting pools to bathe and drink.

Breeding. Lays May-Jul. Monogamous and territorial; pair-bond apparently permanent. Nest placed on ground. Eggs 2-3; incubation period unknown; downy chick black, bill white with blackish base and tip, iris black, legs and feet yellowish.

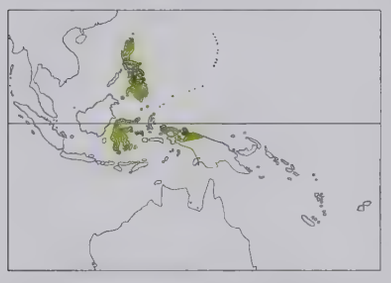
Movements. Sedentary, but in winter some may wander to reach areas just S of main distribution; ages of birds involved in these movements unknown.

Status and Conservation. ENDANGERED. Confined to largely uninhabited forests of N quarter (Yambaru) of Okinawa I, N from the Shioya to Higashi-son line; S Okinawa is highly developed and overcrowded. Species apparently reasonably common in its very small range, population estimated at c. 1800 birds; widespread wherever suitable habitat remains. Threatened by continuing deforestation: in recent years pace of development has increased in N, with building of golf courses, dams and public roads in hitherto continuous pristine forests, and its S distributional boundary is gradually moving N into the Itaji forest. Predators probably include domestic cats, dogs and indigenous snakes; cats are often observed along forest roads. Potential introduced predators include weasel (*Mustela itatsi*) and mongoose (*Herpestes edwardsi*), which are spreading into the rail's original habitat. Roosting in trees is probably adaptive in avoiding snake predation, but arboreal, nocturnal brown tree snake (*Boiga irregularis*), which has extirpated tree-roosting *G. owstoni* from Guam, has been observed on Okinawa and may have potential to establish itself.

Bibliography. Brazil (1984, 1985, 1991), Collar & Andrew (1988), Collar *et al.* (1994), Harato & Ozaki (1993), Ikenaga (1983), Ikenaga & Gima (1993), Kuroda (1993), Kuroda *et al.* (1984), Miyagi (1989), Ripley & Beehler (1985), Sonobe (1982), Thiede (1982), Vuilleumier *et al.* (1992), Yamashina & Mano (1981), Yanagisawa *et al.* (1994).

43. Barred Rail

Gallirallus torquatus



French: Râle à collier **German**: Zebraralle **Spanish**: Rascón Acollarado

Taxonomy. *Rallus torquatus* Linnaeus, 1766, Philippines.

Sometimes placed in *Rallus* or *Hypotaenidia*. Forms superspecies with *G. okinawae* and *G. insignis*. Five subspecies recognized.

Subspecies and Distribution.

G. t. torquatus (Linnaeus, 1766) - Philippines.
G. t. celebensis (Quoy & Gaimard, 1830) - Sulawesi and adjacent islands.
G. t. sulcirostris (Wallace, 1863) - Peleng (Banggai) and Sula Is, off EC Sulawesi.
G. t. kuehni (Rothschild, 1902) - Tukangbesi Is, SE of Sulawesi.
G. t. limarius (J. L. Peters, 1934) - Salawati I and N Irian Jaya.

Descriptive notes. 33-35 cm; 1 female 241 g. Sexes alike; some white barring on inner webs of outer primaries. Easily separable from sympatric rallids on plumage. *G. insignis* and *G. okinawae* are almost flightless and differ in head pattern; *G. okinawae* has reddish bill and legs, and *G. insignis* black undertail-coverts and pink legs. Immature duller than adult; often washed buffy on underparts; throat whitish; in nominate race, breast band olive-brown and undertail-coverts reddish brown bordered with white. Juvenile not described. Races separated on plumage and size: *celebensis* lacks rufous breast band, and has variable proportions of black and barring on throat and upper breast; *sulcirostris* has deep rufous brown upperparts and an intensely black throat; *kuehni* largest, with dark upperparts; *limarius* has long bill. VOICE. Loud, very discordant, harsh croaking, often lasting several seconds.

Habitat. Occurs in open grassland, rice and maize fields, dry second growth and coastal swamps, and at edges of marshes. Often prefers areas where grassland, marshy spots and small groves of trees intermingle. Found in elephant grass; avoids closed forest and extensive crop fields; not restricted to sites with water but favours moist or wet areas. Occurs from sea-level up to 1000 m.

Food and Feeding. Food not recorded. Sometimes forages along roadsides.

Breeding. Luzon, Apr, Nov; Sulawesi, Dec. Nest not described; built on ground. Usually 3 eggs, sometimes 4; female known to incubate. No other information.

Movements. None recorded.

Status and Conservation. Not globally threatened. Very shy and retiring; no information on current status. Nominate race formerly common on Philippines; *celebensis* reported as common in N Sulawesi in 1980's; *limarius* formerly regarded as quite rare.

Bibliography. Andrew, P. (1992), Baltzer (1990), Beehler *et al.* (1986), Diamond (1991), Dickinson *et al.* (1991), DuPont (1971), Eck (1976a), Olson (1973b), Parkes (1971), Perennou *et al.* (1994), Rand & Gilliard (1967), Rand & Rabor (1960), Ripley & Beehler (1985), Rozendaal & Dekker (1989), Stresemann (1941), Watling (1983), White & Bruce (1986).

44. New Britain Rail

Gallirallus insignis

French: Râle de Nouvelle-Bretagne **German**: Bartralle **Spanish**: Rascón de Nueva Bretaña
Other common names: Bismarck/Pink-legged/Sclater's Rail

Taxonomy. *Rallus insignis* P. L. Sclater, 1880, Kahabadai, New Britain.

Sometimes placed in *Rallus*, or in monospecific *Habropteryx*, although affinities are clearly with *G. torquatus*. Forms superspecies with *G. okinawae* and *G. torquatus*. Monotypic.

Distribution. New Britain.

Descriptive notes. 33 cm. Probably almost flightless, although some reports that it may fly well; tail very short and decomposed; some white barring on inner webs of primaries. Sexes alike. *G. torquatus* and *G. okinawae* differ in having distinctive head pattern and barred undertail-coverts; *G. torquatus* is volant and has longer tail and brown legs; *G. okinawae* has reddish bill and legs. Immature and juvenile not described. VOICE. Loud, short calls, suggestive of dog or pig, uttered by day and night. Duetting birds call alternately to each other for several minutes. Groups reported to follow a leader, which regularly utters loud screams, often from elevated calling site, when followers utter low, nasal gulping notes.

Habitat. Heavy damp forests and mountain valleys; also swampy cane grass; wanders into gardens when foraging. Occurs from sea-level to at least 1130 m.

Food and Feeding. Snails, insects (including beetles) and vegetable matter.

Breeding. Social organization not known; commonly occurs in parties. Nests on the ground. No further information available.

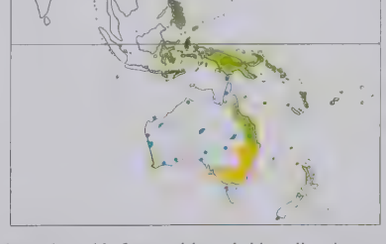
Movements. None recorded.

Status and Conservation. Not globally threatened. No recent assessment of status but regarded as locally common in 1980's. Snared and eaten by local people. Extensive research required on ecology, biology and status.

Bibliography. Bishop (1983), Coates (1985), Diamond (1972a), Gilliard & LeCroy (1967), Mayr (1949), Meyer (1936), Schönwetter (1935).

45. Buff-banded Rail

Gallirallus philippensis



French: Râle tiklin **German**: Bindenralle **Spanish**: Rascón Filipino
Other common names: Banded/Land Rail, Banded Land-rail

Taxonomy. *Rallus philippensis* Linnaeus, 1766, Philippines.

Sometimes placed in *Rallus*. Forms superspecies with *G. owstoni*, and perhaps with *G. rovianae*; probably also with extinct *G. wakensis*, *G. pacificus*, *G. dieffenbachii* and *G. modestus*. Great geographical variation, with up to 26 subspecies recognized; validity of some racial distinctions, e.g. *tounelierie*, questionable in view of individual plumage variation, minor sexual size differences, and changes due to age and wear; possible race *wahgiensis* included in *reductus*; *randi*, *norfolkensis*, *australis* and some *yorki* in *mellori*; other *yorki* in *tounelierie*. Extinct form *dieffenbachii* sometimes included as race, but now generally considered specifically distinct. Race *macquariensis* of Macquarie I recently extinct. Twenty extant races currently recognized.

Subspecies and Distribution.

G. p. andrewsi (Mathews, 1911) - Cocos (Keeling) Is.
G. p. philippensis (Linnaeus, 1766) - Philippines; Sulawesi E to Buru; Sumba (race?), Alor, Sawu, Roti and Timor.
G. p. pelewensis (Mayr, 1933) - Palau Is.
G. p. xerophilus (van Bemmel & Hoogerwerf, 1941) - Gunungapi (Lesser Sundas).
G. p. wilkinsoni (Mathews, 1911) - Flores.
G. p. lacustris (Mayr, 1938) - N New Guinea.
G. p. reductus (Mayr, 1938) - C highlands and NE coastal New Guinea, including Long I.
G. p. anachoretae (Mayr, 1949) - Kaniet (Anchorite) Is, NW of Ninigo Is.
G. p. admiralitatis (Stresemann, 1929) - Admiralty Is.
G. p. praedo (Mayr, 1949) - Skoki (Admiralty Is).
G. p. lesouefi (Mathews, 1911) - New Hanover, Tabar and Tanga Is, and possibly New Ireland (Bismarck Archipelago).
G. p. meyeri (Hartert, 1930) - New Britain and Witu Is (Bismarck Archipelago).
G. p. christophori (Mayr, 1938) - Solomon Is.
G. p. mellori (Mathews, 1912) - S & SW New Guinea, Australia and Norfolk I.
G. p. assimilis (G. R. Gray, 1843) - New Zealand.
G. p. tounelierie Schodde & de Naurois, 1982 - Coral Sea islets, from SE New Guinea archipelagos and Great Barrier Reef E to Surprise group (off N New Caledonia).
G. p. swindellsi (Mathews, 1911) - New Caledonia and Loyalty Is.
G. p. sethsmithi (Mathews, 1911) - Vanuatu and Fiji.
G. p. ecaudatus (J. F. Miller, 1783) - Tonga.
G. p. goodsoni (Mathews, 1911) - Samoa and Niue I.

Descriptive notes. 25-33 cm; male 126-234 (185) g, female 115-265 (172) g, unsexed 130-303 (189) g; wingspan 40-52 cm. Tail relatively long; distinguished from congeners by combination of head pattern, variably spotted and barred upperparts and upperwing-coverts, rufous and blackish bars on all remiges except outer 2 which are barred black and white; white chin, grey throat, buff breast band (most races); barred underparts, including undertail-coverts; pink bill and pinkish grey legs. Sexes similar; female may be slightly smaller. Immature like adult but retains worn juvenile remiges; also has narrow or obscured nuchal collar but some adults may perhaps show this feature; iris probably yellow-brown. Juvenile duller than adult; head pattern less distinct and with little chestnut; throat mottled; smaller spots, usually olive-buff, on upperparts; breast band, if present, less distinct; underparts barred grey, not grey-black; bill grey-black; iris brown. Races separated on plumage pattern, including: extent of breast band, variable even within races; darkness of upperparts; extent of spotting on upperparts; pattern of uppertail-coverts, spotted, barred or plain; and pattern and extent of barring on underparts; also differ in lengths of wing, culmen and tarsus. VOICE. Repeated, squeaky, harsh "kreek" note, mostly heard in morning and evening, especially in breeding season; probably territorial. Also low-pitched growl, quiet repeated grunts (probably contact notes), and explosive hisses with deep growls when chicks threatened.

Habitat. Many types of wetland, including marshes, swamps, lakes, pans, rivers, streams, temporary inundations, estuaries, coastal lagoons, mangrove swamps, salt-marsh and tidal mudflats; also sewage ponds, farm dams and drainage channels. Occurs on beaches, reef flats, sandbanks and coral cays. Also found in wet to dry grass, bushed grassland, heathland, scrub, woodland, forest, and rocky and grassy uplands; in crops, pasture, gardens and parks, and on golf courses and airstrips. Favours dense, rank vegetation such as tall grass, rushes, reeds, etc.; also inhabits islands with little cover and no surface water, and may be flushed from petrel burrows. From sea-level up to 3600 m.
Food and Feeding. Worms, molluscs, crustaceans (including crabs), insects, spiders, small fish, frogs and tadpoles, eggs of birds and turtles, young of Sooty Tern (*Sterna fuscata*), fruits, seeds, young plants and other vegetable matter; also carrion from roadkills, chicken feed, bread and grain. Feeds at all times of day and night, but mostly crepuscular. Forages on ground; feeds at edges of reedbeds and other dense cover, among bushes and mangroves, and in pastures; scavenges along strandline; forages at rubbish dumps. Probes and pecks in mud and shallow water; captures prey by stabbing with slightly open bill; pecks at animals encrusting mangrove trunks; takes seeds from plants or ground. Pecks large snail shells until broken; spears eggs with bill. Once recorded hoarding food.
Breeding. Cocos (Keeling), Jan, May, Jun; Philippines, May, Nov; Lesser Sundas, Apr, Aug, but all year on Flores; Moluccas, Jul/Aug; New Guinea, mainly in rains but also in dry season; Australia, mainly Aug-Mar, but eggs and chicks recorded all months in tropics (N Queensland); Norfolk I, Dec; New Zealand, Sept-Dec, Mar; Vanuatu, mainly Oct-Mar; Samoa, chicks Jan, Mar-Apr, Jul-Sept, but breeds all year on Apia; Niue I, Jul; Tonga, Feb, Jul. Monogamous and territorial. Nest a cup of dry grass and stems, sometimes with interwoven dead rooted stems; or roughly woven platform of grass and rushes with depression on top; sometimes with flimsy canopy of growing vegetation; external diameter 10-23 cm; platform height 17 cm; internal cavity depth 2·5-6·5 cm. Placed on or above ground (sometimes above water) in long grass, marsh vegetation or crops (oats, lucerne); also in sheltered position under bush, tree, banana leaf, or in hollow; sometimes in tree or shrub, or on sand. Usually 4-8 eggs (2-8), with larger clutches (up to 12) probably from 2 females laying in same nest; eggs laid at daily intervals; incubation 18-19 days, by both parents; if nest disturbed, adult may carry eggs in bill to hastily constructed nest nearby; chicks leave nest soon after hatching; fed and cared for by both parents, possibly largely by female; black downy chicks have grey eyestripe or cheek patch, black legs and bill, and brown iris; feathers begin to appear at 5 days; attain adult weight at 3 weeks; evicted by parents when 5-9 weeks old; fly at 2 months, when post-juvenile moult begins. Age of first breeding probably 1 year. In Western Samoa, chick mortality high from feral cat predation. May breed up to 3 times (Australia) or 5 times (Western Samoa) per year.
Movements. Regarded as sedentary throughout much of range but is widely dispersive and possibly also migratory. No autumn or winter records in much of S Australia, but present all year in N with reduced reporting rate in winter. Some evidence for migration or dispersal on Cape York and across Torres Strait; movements also suggested between islands in Coral Sea. Recorded New Zealand all months except Jul, mostly in summer. May move in response to availability of water, e.g. from dry areas to areas of high rainfall. Flies at night; sometimes hits telegraph wires, street lights and lighthouses. Vagrant to Tasmania; ephemeral populations on Lord Howe I probably derived from vagrants; vagrant to Mauritius (no details).
Status and Conservation. Not globally threatened. Race *andrewsi* of Cocos (Keeling) Is regarded as Endangered, and now confined to North Keeling and West Is, with total population of c. 100 birds; extirpated elsewhere by cats, rats, habitat destruction and hunting. Locally common in Philippines and (less so than previously) Palau Is; locally common to abundant in New Guinea. Race *anachoretae* considered very scarce in 1970's, due to trapping by foreign labourers; current status unknown. Common to uncommon in Australia and New Zealand, but has declined markedly in New Zealand this century as a result of habitat destruction and predation; habitat loss caused by wetland drainage, and stock grazing and trampling, but may be offset locally to some extent by the birds' use of artificial wetlands and other man-created habitats. On some islands, populations reduced or eliminated (e.g. Macquarie and probably Solander) by introduced cats, rats and *G. australis*; these may prevent colonization on others. In Fiji, race *sethsmithi* probably extirpated from Vanua Levu and Viti Levu by introduced mongooses, but thriving on Taveuni I. Locally common in Western Samoa; very common on Niue I and in some Tonga islands.

46. **Guam Rail**

Gallirallus owstoni

French: Râle de Guam **German**: Guamralle **Spanish**: Rascón de Guam

Taxonomy. *Hypotaenidia owstoni* Rothschild, 1895, Guam.
Sometimes placed in *Hypotaenidia* or *Rallus*. Forms superspecies with *G. philippensis*, and perhaps with *G. rovianae*; probably also with extinct *G. wakensis*, *G. pacificus*, *G. dieffenbachii* and *G. modestus*. Monotypic.
Distribution. Guam (extinct in wild).
Recently introduced to nearby Rota I.

Descriptive notes. 28 cm; male 174-303 (241) g, female 170-274 (220) g. Virtually flightless; can fly for only 1-3 m; tail very short and decomposed; toes very short. In fresh plumage, has indistinct, dull olive-buff breast band which becomes abraded to leave breast clear grey; some individuals have pronounced reddish tinge on nape. Sexes alike but female smaller. Darker than *G. philippensis* and lacks chestnut on face, breast and usually nape; black and white barring on more remiges, decreasing from extensive, bold barring on outer primaries to narrow barring on secondaries as brown of feather centres becomes broader; uniform brown upperparts with no spots or bars; black bill with grey base. Duller underparts than *G. rovianae* and has different facial pattern and more extensive white wing markings. Juvenile similar to adult but with less extensive areas of grey on neck, breast and supercilium. Voice. During breeding season makes loud penetrating screeches "keee-yu"; also a series of short "kip" notes.
Habitat. Formerly occurred in most habitats on Guam, including forest, secondary grassland, mown grass, e.g. along roads and under telephone lines; scrub, mixed woodland and scrub, and fern thickets. Absent from interior of mature forest and wetland habitats.
Food and Feeding. Snails, slugs, insects (Orthoptera, Dermaptera and Lepidoptera), geckos and some vegetable matter; also fish, tomatoes, melon, palm leaves, and carrion, e.g. amphibians crushed by cars. Introduced giant African snail (*Achatina fulica*) became an important food when it expanded its range into most of the island's habitats. Takes food items from ground surface; chases low-flying insects, especially butterflies; takes seeds and flowers from low grasses and shrubs, stretching up to reach items 40 cm above ground. Often forages along field edges and roadsides, but seldom far from cover. Most active at dawn and dusk; also forages at night.
Breeding. Breeds throughout year, but possibly with peak period during rains, Jul-Nov. Monogamous and territorial. Nest located on dry ground in dense grass; a shallow cup of interwoven loose and rooted grass; built by both sexes. Eggs 3-4; incubation 19 days, by both sexes; hatching asynchronous; black downy chick has black bare parts; chicks leave nest within 24 hours of hatching; fed and cared for by both parents; chick begins to attain juvenile feathers during 4th week; reaches adult weight at 7 weeks; post-juvenile moult apparently complete at 16 weeks, when birds become sexually mature. Number of broods per year unknown.
Movements. None recorded.
Status and Conservation. EXTINCT IN THE WILD. In past, widely distributed and abundant, although taken by local people with dogs and snares, and despite presence of introduced predators such as feral pigs and cats. Before 1960's population was estimated as 10,000's; declined rapidly during 1970's, along with most other indigenous birds, as a result of the spread throughout the island of the introduced brown tree snake (*Boiga irregularis*); by 1981 population reduced to c. 2000 birds, by 1983 to less than 100, and species became extinct in the wild by 1987. In 1983 a captive breeding programme was set up, and c. 180 breeding birds are now located on Guam and in 16 zoos in USA. Captive breeding has been very successful, the founding birds showed surprisingly good genetic diversity, and efforts are being made to establish a self-sustaining experimental population on the snake-free island of Rota in S Northern Mariana Is; action also being taken to extirpate brown tree snake from Guam, so as to permit reintroduction there; birds released on Rota recently bred for first time (reported 1996), and further introductions planned in order to bolster population on Rota.
Bibliography. Aguon (1983), Baker (1951), Beck (1988), Beck & Savidge (1990), Carpenter & Stafford (1970), Collar & Andrew (1988), Collar *et al.* (1994), Derrickson (1996), Diamond (1991), Engrbring & Pratt (1985), Haig *et al.* (1990, 1993), Hay (1986), Jenkins (1979, 1983), King (1978 79), Lint (1968), Pérez (1968), Pratt *et al.* (1979, 1987), Savidge (1987), Strophlet (1946), Witteman & Beck (1991), Witteman *et al.* (1991).

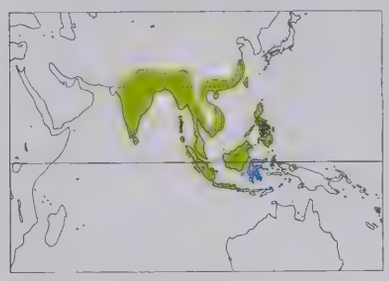
47. **Roviana Rail**

Gallirallus rovianae

French: Râle roviana **German**: Rovianaralle **Spanish**: Rascón de Roviana

Taxonomy. *Gallirallus rovianae* Diamond, 1991, near Munda, New Georgia, Solomon Islands. May form part of *G. philippensis* superspecies. Birds from Kolombangara recently suggested to be subspecifically distinct. Monotypic.
Distribution. C Solomon Is, on New Georgia, Kolombangara, Wana Wana, Kohinggo and Rendova.

Descriptive notes. 30 cm. Known only from the holotype, sex and age unknown, but apparently fully grown. Medium-sized rail, flightless or nearly so, but with long tail; unmarked upperparts almost uniform dark chestnut brown, showing slightly richer colour on nape which continues into richer, more reddish chestnut mask through eye; wing barring restricted to small white spots on primary coverts; colours of bare parts in life not known (for purposes of plate, predicted from closest relatives). Closest in plumage to *G. philippensis* and *G. owstoni*, but appears less boldly patterned than former and has longer tarsus; underpart barring brown, not black; also has reduced barring on wings. Birds recently observed on Kolombangara reported to be generally darker and to lack breast band. Voice. Call said to be rapidly repeated high-pitched note, which has given rise to its Roviana name "Kitikete".
Habitat. Described as occurring in forest, especially second growth, where young trees grow on abandoned garden sites; also recorded in open ground on grassy airstrip.
Food and Feeding. Said to be omnivorous, taking worms, small crabs, seeds, coconut shoots, and potatoes and taro from gardens.
Breeding. Reported to breed in dry season, Jun, when rainwater is not a problem on forest floor. Nest said to be depression in the ground, lined with debris. Reported 2-3 eggs. No further information available.
Movements. None.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Listed distribution mainly based on reports by local people on the islands concerned; in 1994 sighted on Kolombangara, where reported to be common. May also occur on nearby islands of Vangunu and Tetipari, where it has not yet been sought. Apparently does not occur on the other major islands near New Georgia (Vella Lavella, Ranongga, Simbo, Gizo and Nggatokai), as local inhabitants do not know it. Seems to be widespread on New Georgia; current status elsewhere not known, but its extremely restricted distribution gives cause for concern.
Bibliography. Collar *et al.* (1994), Diamond (1991), Gibbs (1996).



48. **Slaty-breasted Rail**

Gallirallus striatus

French: Râle strié **German**: Graubrustralle **Spanish**: Rascón Rufigris
Other common names: Blue-breasted Banded Rail

Taxonomy. *Rallus striatus* Linnaeus, 1766, Manila, Philippines.
Sometimes placed in *Rallus* or *Hypotaenidia*. Seven subspecies recognized.
Subspecies and Distribution.
G. s. albiventer (Swainson, 1838) - India and Sri Lanka to SC China (SE Yunnan) and Thailand; some may winter in S Thailand and Malaysia.
G. s. obscurior (Hume, 1874) - Andaman and Nicobar Is.
G. s. jouyi (Stejneger, 1886) - SE China and Hainan.

G. s. taiwanus (Yamashina, 1932) - Taiwan.
G. s. gularis (Horsfield, 1821) - Vietnam and Cambodia through Malaysia to Sumatra, Java and S Borneo.
G. s. striatus (Linnaeus, 1766) - Philippines, Sulu Is, N Borneo and also Sulawesi, where may not be resident.
G. s. paratermus (Oberholser, 1924) - Samar I, EC Philippines.

Descriptive notes. 25-30 cm; adult 100-142 g. Flight often described as weak. Distinctive medium-sized rail, easily distinguished from sympatric rallids by combination of chestnut crown and nape, blue-grey breast, narrow white bars and spots on upperparts and wings, white-barred underparts, and fairly long, reddish bill. Female duller on upperparts, and more whitish on belly. Immature like adult but white barring less distinct; upperparts, including crown and hindneck, indistinctly streaked darker; breast more brownish; underparts paler. Juvenile imperfectly described: probably less patterned than immature, with white bars on upperparts largely absent. Races separated on: size, *jouyi* largest; and overall colour, with nominate *obscurior* and *paratermus* darkest, *gularis* and *taiwanus* palest. VOICE. Said to call infrequently. Has sharp whistle, repeated sharp "kerrek", and noisy "ka-ka-ka". Race *obscurior* utters deep croak, apparently reminiscent of sympatric *Rallina canningi*.
Habitat. Wetlands of many types, including marshy meadows, reedmarsh, paddy fields, and mangroves. Also occurs in *Imperator* grassland and dry rice fields, in gardens and damp areas near villages, drainage ditches; dry scrub and bush near country roads (Sumatra), and forest (Andamans). Recorded most commonly up to 1000 m, but also up to 1500 m and rarely (Sri Lanka) to 1850 m.
Food and Feeding. Worms, molluscs, crustaceans, insects (including ants) and their larvae, spiders, and the seeds and shoots of marsh plants. Takes much food from surface of ground, but also takes seeds and insects from vegetation by jumping up, or by perching on plants. Probes soft soil with bill for earthworms and insect larvae; picks up and sweeps aside fallen leaves and grasses; does not scratch with feet. Observed feeding along edges of tidal water and paddy fields, in the latter instance apparently taking aquatic insects. Swims and dives well.
Breeding. India and Sri Lanka, Jun-Oct; Sumatra, Jun, Dec; Java, Jan-Jul and Sept-Nov, but most in Mar-May; Philippines, Aug-Sept. Monogamous. Nest well concealed in thick vegetation at marsh edge, or in forest (Andamans); a pad of matted weeds, reed stems and grass, c. 25 cm in diameter, built on the ground or on dead reed debris; both sexes build, predominantly the male. Eggs 5-9, in captivity laid at daily or more frequent intervals; incubation 19-22 days, by both sexes, predominantly by female; black downy chicks have blackish bill, grey iris and dark brown legs and feet; leave nest soon after hatching; fed and cared for by both parents.
Movements. Normally regarded as resident and no regular movements recorded, but it is speculated that some winter birds in S Thailand and Peninsular Malaysia may be migrant *albiventer*; species may be merely migrant to Sulawesi. In India moves locally under stress of drought or flood; in Philippines considerable post-breeding dispersal occurs. Records from Bali, Sawu and Timor may refer to vagrants.
Status and Conservation. Not globally threatened. Little recent information available: *striatus* apparently uncommon, but very secretive, in Philippines. Formerly, *albiventer* widespread and quite common in India and Sri Lanka; *obscurior* probably common in Andamans and Nicobars; *gularis* uncommon in South Vietnam, but common in Peninsular Malaysia, Sumatra, Java and Borneo; *taiwanus* apparently fairly common; *paratermus* known only from type locality on Samar; no information available for race *jouyi*.

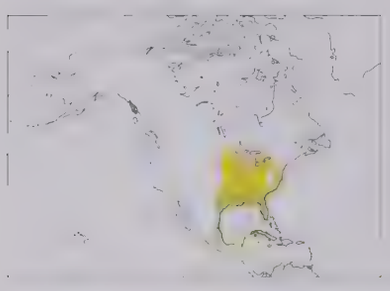
49. Clapper Rail
Rallus longirostris

French: Râle gris **German**: Klapperralle **Spanish**: Rascón Piquilargo

Taxonomy. *Rallus longirostris* Boddaert, 1783, Cayenne, French Guiana.
This largely saltwater and brackish water species is often considered conspecific with the largely freshwater-marsh *R. elegans*; provisionally treated as forming superspecies. Californian races *levipes*, *obsoletus* and *yumanensis* sometimes placed in *R. elegans*; race *tenuirostris* of *R. elegans* sometimes transferred to present species. Hybridization with *R. elegans* occurs occasionally in areas of sympatry, and mitochondrial DNA studies of the two species have yielded inconclusive results. Twenty-one subspecies currently recognized.
Subspecies and Distribution.
R. l. obsoletus Ridgway, 1874 - C California, mainly in San Francisco Bay.
R. l. levipes Bangs, 1899 - coastal C California to N Baja California.
R. l. yumanensis Dickey, 1923 - SE California, S Arizona and NW Mexico.
R. l. beldingi Ridgway, 1882 - S Baja California.
R. l. crepitans Gmelin, 1789 - coastal Connecticut S to NE North Carolina.
R. l. waynei Brewster, 1899 - coastal SE North Carolina to E Florida.
R. l. saturatus Ridgway, 1880 - Gulf coast from SW Alabama to extreme NE Mexico (Tamaulipas).
R. l. pallidus Nelson, 1905 - coastal Yucatán (SE Mexico).
R. l. grossi Paynter, 1950 - Quintana Roo (SE Mexico).
R. l. belizensis Oberholser, 1937 - Ycacos Lagoon, Belize.
R. l. scotti Sennett, 1888 - coastal Florida.
R. l. insularum W. S. Brooks, 1920 - Florida Keys.
R. l. coryi Maynard, 1887 - Bahamas.
R. l. leucophaeus Todd, 1913 - I of Pines (Cuba).
R. l. caribaeus Ridgway, 1880 - Cuba to Puerto Rico and Lesser Antilles E to Antigua, also Guadeloupe.
R. l. cypereti Taczanowski, 1877 - coasts from extreme SW Colombia (Nariño) through Ecuador to extreme NW Peru (Tumbes).
R. l. phelpsi Wetmore, 1941 - extreme NE Colombia and extreme NW Venezuela.
R. l. margaritae Zimmer & Phelps, 1944 - Margarita I (Venezuela).
R. l. pelodramus Oberholser, 1937 - Trinidad.
R. l. longirostris Boddaert, 1783 - coasts of Guyana, Surinam and French Guiana.
R. l. crassirostris Lawrence, 1871 - coastal Brazil from Amazon estuary to Santa Catarina.



Descriptive notes. 31-40 cm; male 300-350 (322) g, female 248-301 (268) g. Large rail with long, slender, slightly decurved bill. Normally divided into two groups: *longirostris* group, comprising 4 races of W North and Central America, which resemble *R. elegans* in large size and brightness of feather fringes on upperparts; and *obsoletus* group containing all other races. Races *obsoletus*, *levipes* and *scotti* have two colour morphs: brown, in which upperpart feathers have dark brown to brown-black centres and buff-brown fringes; and olive, in which upperpart feathers have darker, blacker centres and duller, more olive, fringes. Race *ramsdeni* has at least two colour morphs, in which upperpart feathers margined with variety of olive-greys and browns. It is not clear to what extent these colour variations may be explained by age-related plumage differences. Sexes alike, but female smaller. Races sympatric with *R. elegans* differ from that species in having more grey on face, variably duller fringes to upperpart feathers, and duller neck, breast, upperwing-coverts and flank barring. Possibility of hybrids is potential complication. Markedly larger than sympatric *R. limicola*, which is darker overall with brighter rufous upperwing-coverts. Immature similar to adult but with duller bare parts. Juvenile darker (blackish in some races) on upperparts, with brownish feather edges; underparts duller cinnamon, mottled grey, belly more white and flank bars absent or indistinct; eye brown. Races separated on size, and on plumage, e.g. extent of grey on face, and general tone of upperpart and underpart colours. VOICE. Very similar to that of *R. elegans*. Advertising call of both sexes ("clapper" call) a series of loud, rapid "kak" notes. Courtship call of male a series of harsh "kek" notes. Also has grunting call and very low "hoo" note; during breeding season female gives series of 1-5 "kek" notes followed by "burr".
Habitat. Salt and brackish marshes, particularly those with tidal sloughs; in California favours marshes with tall, dense cordgrass (*Spartina foliosa*) and *Salicornia*; mangrove swamps; also locally, mostly in lower Colorado River Valley (race *yumanensis*) in tropical and subtropical freshwater marshes with *Typha* and *Scirpus*.
Food and Feeding. Molluscs, leeches, crustaceans (including crayfish and many crabs), aquatic insects (especially dytiscid beetles), grasshoppers, spiders, small fish, frogs and tadpoles, and mice; also seeds (including rice), berries, green plant material and tubers of woody plants; water snake and adult Savanna Sparrow (*Passerculus sandwichensis*) recorded once. Feeds opportunistically on most readily available foods; eats more vegetable matter in winter. Apparently hunts by sight; probes exposed and shallowly flooded mud and sand; takes crabs from burrows by probing, sometimes inserting head and neck into burrow; gleans items from substrate; throws aside surface litter with bill and seizes small invertebrates hiding under it; catches fish while wading, swimming and sometimes diving; scavenges dead fish and forages at grassy edges of mangroves. Mostly forages on substrates adjacent to cover; most active at low tide, and during morning and early evening.
Breeding. USA, Mar-Jul, mostly Apr-Jun; Mexico, Mar; Trinidad, Apr-Dec, mostly May-Jun; Venezuela, Apr. Monogamous; pair-bond maintained only during breeding season, when birds territorial. Nest a platform or cup of rushes, sedges and marsh grass; or of sticks and dead leaves; built on ground in clump of vegetation, often in *Spartina* or *Juncus*, 60-120 cm tall; race *yumanensis* nests in *Typha* and *Scirpus*; situated on dry hummock, under low shrubs, or among mangrove roots; sometimes with base in water; often with canopy of dead or growing material; rim up to 45 cm above substrate; many have ramp from ground to rim. External diameter 18-35 cm; cavity diameter 12-15 cm, depth 1-6 cm; thickness 7-15 cm; height of nest mass up to 30 cm. Male most active in nest-building. Up to six brood nests (with no canopy) constructed near breeding nest; built of dead vegetation, these may float with rising tide. Eggs 3-14, laid daily; second broods smaller; replacement clutches may be only 4-6 eggs; incubation 18-29 days, by both sexes; hatching asynchronous; chicks semi-precocial; downy chicks jet black with greenish gloss on upperparts, dark brown eyes, grey legs, and white or pink bill with black base; leave nest as soon as hatched but use brood nests for first few days; feathers growing at 4 weeks; fed and cared for by both parents for 5-6 weeks; independent thereafter; fully feathered at 7-8 weeks; fly at 10 weeks, when wings fully grown; at 10+ weeks resemble adults except for dull bare parts. Nesting success 40-90% (usually high); egg success also high; initial losses usually followed by persistent renesting attempts; most failures due to flooding by extreme high tides, but on high ground predation is problem; Californian birds suffer heavy predation by rats (*Rattus norvegicus*). Normally 1 brood, but 2 recorded in most USA races.
Movements. In North America primarily resident, but northernmost populations partially migratory and some evidence from ringing and observation that birds in SE make movements, sometimes over long distances, which probably involve migration as well as dispersal and wandering. Movements appear to be overland as well as coastal. In North Carolina, in autumn large numbers have been forced down by heavy fog, and have been found dead under telephone wires. In winter, race *crepitans* ranges S to Florida, where occurs alongside at least 3 other races. W coast race *yumanensis* formerly thought to be migratory but radio telemetry studies indicate most birds resident, although some possibly winter on W coast of Mexico from Sonora to Nayarit. Casual wandering by birds of *obsoletus* group recorded on Pacific coast to Farallon Is, N to N California and S to S Baja California; by *longirostris* group on Atlantic coast N to New Brunswick, Prince Edward Island, Nova Scotia and Newfoundland, and inland to C Nebraska, C New York, Vermont, W Pennsylvania, West Virginia and C Virginia. South American populations sedentary.
Status and Conservation. Not globally threatened. In USA, 3 races considered Endangered. Race *levipes* has declined mainly because of habitat loss; less than 25% of its original habitats remain in USA, where population estimated at 190 pairs in 1990, with c. 240 pairs left in Mexico; severe threats posed by habitat destruction and modification, and by predators. About 85% of habitat of *obsoletus* has been dyked or destroyed; urban development poses continuing threat, together with pollution and introduced predators. Most of remaining population (c. 400 birds in 1991) occurs in San Francisco Bay, where development pressure greatest. Race *yumanensis* has experienced recent contractions and expansions of its freshwater and brackish water marsh habitats, and in 1992 population S to Colorado Delta estimated at c. 2000 birds; it is threatened by wetland loss and high water flows, being susceptible to effects of development projects along Colorado R. Recovery plans for these races include acquisition of habitat, habitat improvements, restoration of normal tidal flows, eliminating pollution, establishment of refuges, and captive breeding. All North American races vulnerable to habitat destruction and the effects of pesticides and contaminants, although species shows high tolerance to DDT and DDD. Species also hunted extensively in E and Gulf coastal states, where effects largely unknown; hunting pressure low in W coast areas where threatened races occur. Probably more widespread in Colombia than the few known localities suggest. Race *coryi* regarded as locally common in Bahamas (Cat I), as is nominate in French Guiana; current status of other races not known, but some were formerly considered locally common.

50. King Rail
Rallus elegans

French: Râle élégant **German**: Königsralle **Spanish**: Rascón Elegante

Taxonomy. *Rallus elegans* Audubon, 1834, Charleston, South Carolina.
This largely freshwater-marsh bird is often considered conspecific with the largely saltwater-inhabiting *R. longirostris*; provisionally treated as forming superspecies. Race *tenuirostris* of C Mexico sometimes considered specifically distinct, or transferred to *R. longirostris*; Californian races of *R. longirostris* (*levipes*, *obsoletus*, *yumanensis*) sometimes placed in present species. Hybridization with *R. longirostris* occurs occasionally in areas of sympatry, and mitochondrial DNA studies of the two species have yielded inconclusive results. Three subspecies currently recognized.
Subspecies and Distribution.
R. e. elegans Audubon, 1834 - E Canada and NE USA; winters S to E Mexico.
R. e. tenuirostris Ridgway, 1874 - C Mexico.
R. e. ramsdeni Riley, 1913 - Cuba and I of Pines.
Descriptive notes. Race *elegans* 38-48 cm, male 340-490 (416) g, female 253-325 (306) g; *tenuirostris* 33-42 cm, male 271-331 g, female 220-268 g. Large rail with long, slender bill, slightly decurved near tip and usually orangish at base. Sexes alike, but female smaller. Polymorphic in nominate race: pale morph has upperpart feathers edged buff; dark morph with tawny olive feather edges. Much larger than *R. limicola*, which is blue-grey on side of head and duller overall, with brighter rufous upperwing-coverts. Differs from sympatric races of *R. longirostris* in having brighter fringes to upperpart feathers (not so evident in comparison with W & S USA populations of *R. longirostris*); little or no grey on face; richer and more chestnut upperwing-coverts; brighter cinnamon neck and breast; and bolder flank barring. Possibility of hybrids is potential complication. Immature similar to adult but duller, with light brown to yellowish bill. Juvenile duller and darker, largely fuscous-black on upperparts, with brown feather edges; pale cinnamon to buff or white on underparts with indistinct barring on sides and flanks; has yellow tongue and mouth lining (orange-red in adult). Races separated on size, nominate largest; also on plumage, *ramsdeni* resembling pale morph nominate, and *tenuirostris* less boldly

Water Rail (*Rallus aquaticus*); 56. African Rail (*Rallus caerulescens*); 57. Madagascar Rail (*Rallus madagascariensis*); 58. Brown-banded Rail (*Lewinia mirificus*); 59. Lewin's Rail (*Lewinia pectoralis*); 60. Auckland Rail (*Lewinia muelleri*).

marked on upperparts and paler on underparts. VOICE. Very similar to that of *R. longirostris*. Breeding-season advertising call of both sexes a series of "cheup" or "chac" notes, slower and more regular than advertising call of *R. longirostris*. Courtship call, heard both day and night, is loud, harsh series of "kik" or "kuk" notes. Also has a soft, rapid "tuk" call, a deep boom (male only), a purring call (female) and a "rak-k-k" or "chur-ur-ur" distress call.

Habitat. Freshwater and locally brackish marshes; successional stages of marsh-shrub swamp, rice fields, flooded farmland, river margins, and upland fields near marshes. Occasionally in salt-marsh during migration. Preferred vegetation types include grasses (Poaceae), sedges (Cyperaceae), rushes (Juncaceae) and *Typha*; in coastal plain marshes, where present species most abundant, *Scirpus*, *Spartina*, *Zizaniopsis*, *Panicum*, *Cladium*, *Echinochloa* and *Polygonum* predominate. Occurs up to 2500 m in Mexico, where uses seasonal, as well as permanent, freshwater wetlands.

Food and Feeding. Principally crustaceans, especially crayfish and crabs; also molluscs, aquatic and terrestrial insects, spiders, fish, frogs, and seeds of aquatic plants. Mainly diurnal; forages within or close to cover; usually in aquatic habitats with shallow water, immersing part or all of bill; also, especially on autumn migration, forages in deep water, immersing head, neck and sometimes body; probes in mud; also feeds on dry land, picking food items from substrate.

Breeding. Lays Florida early Feb to mid-Jul; elsewhere in North America Mar/Apr to Jun/Aug; Mexico, May-Aug, possibly Apr-Sept. Monogamous and territorial. Nest-site usually over shallow water in marsh; also in roadside ditches, rice fields, swamps and upland fields. Nest a platform or cup of dead, dry grasses, sedges or rushes; at wet sites on base of wet decaying vegetation or flattened stems; usually with canopy of grass and entrance ramp. Outside diameter 20-28 cm, inside depth of cup 1·5 cm. Nest placed in grass clump or between tussocks, on ground or up to 45 cm (usually up to 30 cm) above highest water mark; may be raised as water rises after heavy rain. Male may be most active in building. Several brood nests constructed near breeding nest. Usually 10-12 eggs (3-15), laid at daily intervals; late clutches contain fewer eggs; incubation 21-24 days, by both sexes; chicks precocial; black down of chicks has faint greenish sheen, bill grey-black on basal half, white around nostrils and flesh-coloured on distal half; leave nest soon after hatching; fed and cared for by both parents; juvenile plumage evident at 4 weeks; young fly at 9-10 weeks, when post-juvenile moult is under way; independent at 6-10 weeks; post-juvenile moult apparently complete by Nov. Nest success usually high. Age of first breeding 1 year. May rear 2 broods per season in S USA.

Movements. Winters primarily from S Georgia, Florida and S Texas to Mexico and Cuba; occurs casually in winter throughout most of breeding range; temperature important in determining winter distribution, and species avoids areas where marshes freeze. Spring arrivals noted Apr-May. Migrates alone and at night; strikes buildings, telephone lines, etc., and appears in cities during migration. In Mexico, occupation of seasonal wetlands indicative of local movements and dispersal. Casual or accidental Newfoundland, Prince Edward Island, Maine, E Colorado and Dry Tortugas Is (Florida).

Status and Conservation. Not globally threatened. Listed as vulnerable in Canada (1985); in USA listed as endangered in 6 states, and threatened or of special concern in 6 others. Severe declines evident in N part of range since 1940's, mainly as result of loss, modification and degradation of wetland habitats, and pesticide use. Populations in S USA appear more stable. Birds often killed in muskrat (*Ondatra zibethicus*) traps, and are frequent road casualties when forced to move during floods in breeding season. Best chance for long-term survival in North America is considered to be offered by wildlife refuges, where a complex of habitats should be encouraged, including tussocky, shallowly flooded, densely vegetated sites for cover and nesting, and drying patches for brood foraging. Race *tenuirostris* has limited range, confined to freshwater marshes of C Mexico; its habitats are under threat from increasing agricultural, industrial and urban development. Current status of race *ramsdeni* not clear.

(1975), Howell & Webb (1995a), Meanley (1953, 1956, 1957, 1965b, 1969, 1992), Meanley & Meanley (1958), Meanley & Wetherbee (1962), Regan (1994), Reid (1989), Reid *et al.* (1994), Risen (1992), Root (1988), Speight (1981), Warner & Dickerman (1959).

51. Plain-flanked Rail

Rallus wetmorei

French: Râle de Wetmore **German**: Wetmoreralle **Spanish**: Rascón de Wetmore
Other common names: Wetmore's Rail

Taxonomy. *Rallus wetmorei* Zimmer and Phelps, 1944, La Ciénaga, Aragua, Venezuela.
Suggested to be conspecific with *R. longirostris*, but ranges overlap. Monotypic.
Distribution. Coastal N Venezuela.

Descriptive notes. 24-27 cm. Possibly flies poorly: remiges and rectrices appear soft. Sexes alike. Similar to sympatric *R. longirostris phelpsi*, but smaller; lacks grey on side of head and has plain brown underparts, lacking all barring; bill brown, iris reddish brown. These features also serve to distinguish it from allopatric *R. limicola*, which also differs in being smaller and having rufous upperwing-coverts, dusky and red bill, and red iris. Immature and juvenile undescribed. VOICE. Undescribed.

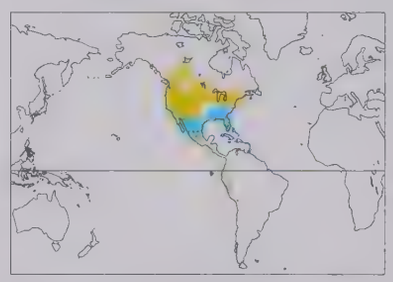
Habitat. Coastal mangroves, "mangrove swamp", and shallow saltwater or brackish lagoons and marshes with emergent vegetation.

Food and Feeding. Nothing recorded; presumably similar to *R. longirostris*.

Breeding. Breeding condition: female, Apr; male, May. A Sept specimen is apparently a juvenile. Nothing else known.

Movements. Apparently sedentary.

Status and Conservation. ENDANGERED. Extremely rare and very poorly known. Restricted to coast of N Venezuela, where known from at most 8 localities in 3 states: near Chichiriviche (unconfirmed sighting), Cuare Wildlife Refuge and Tucacas in E Falcón; Puerto Cabello, Borburata and Patanemo in N Carabobo; and La Ciénaga and Playa de Cata in Aragua. Not recorded in Carabobo State since 1945, and only recent records are from Playa de Cata in Apr 1991, and from Chichiriviche and Cuare Wildlife Refuge (both possibly referring to same bird) in 1980's. Probably at least locally common when discovered, 11 specimens being collected at Tucacas in May 1951, and 9 at Puerto Cabello in Sept 1945. Since these localities are easily accessible, it is likely that the paucity of subsequent records indicates a considerable population decline. Its mangrove habitats are being destroyed by housing development and by expanding oil exploration. Cuare Wildlife Refuge threatened by squatters, hotels, tourist pressure, illegal hunting, pollution and restriction of water flow from the sea; Playa de Cata lagoon has been closed off from the sea by a dyke.



Bibliography. Blake (1977), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Hellmayr & Conover (1942), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Mountfort (1988), Ripley (1977), Scott & Carbonell (1986), Wege & Long (1995), Zimmer & Phelps (1944).

52. Virginia Rail

Rallus limicola

French: Râle de Virginie **German**: Virginiaralle **Spanish**: Rascón de Virginia

Taxonomy. *Rallus limicola* Vieillot, 1819, Pennsylvania.
Forms superspecies with *R. semiplumbeus* and *R. antarcticus*; latter sometimes considered a race of present species. Three subspecies recognized.
Subspecies and Distribution.
R. l. limicola Vieillot, 1819 - S Canada and W, C & NE USA; winters from SW Canada and E Great Lakes through S USA and Mexico to Guatemala.
R. l. friedmanni Dickermann, 1966 - volcanic belt of CS Mexico to extreme S Mexico to Guatemala.
R. l. aequatorialis Sharpe, 1894 - extreme SW Colombia, and Andes of Ecuador.
Birds from coastal Peru (Trujillo S to Pisco) are of an unnamed race.

Descriptive notes. 20-25 cm; male 64-124 (94) g, female 67-80 (74) g. Sexes alike, female smaller. Much smaller than *R. longirostris* and *R. elegans*, with slightly decurved bill, extensive blue-grey on side of head, and duller upperparts with brighter rufous upperwing-coverts. Immature very similar to adult, but darker. Juvenile has sooty black upperparts with olive-brown feather edges; dull sepia-tinged upperwing-coverts; grey face, pale chin and throat, blackish underparts with white mottling, poorly defined flank barring and whitish centre to breast and belly; cinnamon-tipped undertail-coverts; grey-brown iris, blackish upper and brownish lower mandibles; dusky brown legs and feet; juvenile *aequatorialis* has much less white mottling on underparts. Races separated on: overall appearance and size, *aequatorialis* duller and smaller; colour of upperparts, darkest in *limicola*; and underparts, palest in *friedmanni*. Peruvian birds smaller and more brightly coloured. VOICE. Territorial advertising call of male a series of loud, rapid "kid kid kidic kidic" sequences. Other calls include loud series of "kik" notes followed by "queeah", and a descending series of pig-like grunts.

Habitat. Freshwater marshes with stands of robust emergent vegetation, e.g. rushes, sedges, *Typha* and tall grasses; wet meadows and irrigated hay fields; also brackish marshes and occasionally coastal salt-marshes; *páramo* bog in Andes. Prefers moist to shallowly flooded (under 15 cm) habitats with muddy, unstable foraging substrates. On migration uses areas of flooded annual grasses or forbs. In winter also found in moist coastal grasslands and brackish or saltwater marshes. Occurs in subtropical and temperate zones, from sea-level to 3660 m. In winter normally frequents regions warm enough to prevent marshes from freezing; presence in colder areas of USA in winter possibly results from use of wetlands artificially warmed by hot-water discharge from electricity-generating plants. Often occurs alongside *Porzana carolina* but prefers less deeply flooded to saturated sites.

Food and Feeding. Earthworms, molluscs, crayfish, amphipods, many insects (including Hymenoptera) and their larvae, small fish, frogs and small snakes; also variety of aquatic plants, including seeds of many marsh plants; more plant material eaten in autumn and winter. Feeds mainly by probing in mud and shallow water; also probes under matted or floating vegetation; will climb in pursuit of food. Forages primarily at dawn and dusk; usually remains in or next to cover but may feed in open at dusk.

Breeding. North America, Apr-Jul; Ecuador, chick/juvenile Aug. Monogamous; pair-bond maintained only during breeding season, when territorial. Female probably selects nest-site. Nest almost always in freshwater marsh or in rank vegetation near fresh water; platform or cup of coarse grass, reeds and *Typha*, well concealed in sedge tussocks, at base of *Typha* clumps or on piles of broken reeds or driftwood; sometimes over water; loose canopy of growing vegetation often constructed. Placed up to 60 cm above substrate, sometimes with entrance runway, or built up from substrate to height of 20 cm; external diameter 14-20 cm, height 7-8 cm; internal diameter 10-13 cm; depth of cup 1-6 cm. Both sexes build. Male builds 1-5 brood nests near breeding nest. Eggs 4-13 (mean 8·5), laid daily; incubation 18-20 days, by both sexes; all eggs hatch within 48 hours; chicks precocial; leave nest within 3-4 days of hatching; black downy chick has greenish gloss on back, black iris, brownish black legs and feet, and pink or buff bill with black band across middle; cared for by both parents; fed until 2-3 weeks old; feathers grow from 2nd week; independent at 3-4 weeks, flying at 4 weeks; full juvenile plumage attained at 6 weeks; post-juvenile moult begins at 12-14 weeks. Overall nesting success (North America) 53%; chick mortality probably high; predators of eggs and young include fish, frogs, snakes, birds and mammals; many nests lost to flooding in some areas. Both sexes can breed in first year. In USA may produce 2 broods per season, especially in S.

Movements. Most North American populations migratory. Migrants arrive on breeding grounds in USA Mar-May, most in Apr; arrivals possibly influenced by weather and vegetation development; males arrive first on breeding grounds. Departs Aug-Nov, timing possibly influenced by weather conditions; birds congregate at larger marshes prior to autumn migration. Wintering birds present in Mexico late Aug to Apr. Migrates at night, at low altitudes; sometimes strikes towers, telephone lines or wire fences. Casual or accidental to Bermuda, Cuba and Greenland; one sight record Puerto Rico.

Status and Conservation. Not globally threatened. In USA still locally common but has suffered considerable habitat reduction as wetlands have been lost to agriculture and to urban, industrial and reservoir development; palustrine and riverine wetlands are currently among the most threatened habitats in USA. In North America, populations declined 2·2% annually from 1982 to 1991, during a period when natural droughts also reduced availability of wetlands; total population now considered relatively stable. Winter habitat inland is possibly increased by hot-water discharge from power plants, and occurrence of species in other inland areas may be influenced by presence of wildlife refuges, some of which hold the densest winter populations. Legally hunted in 37 states and in Ontario, Canada, with liberal bag limits which may not be tenable, as causes of population declines not understood; current annual harvest probably within sustainable levels but harvest surveys needed. Preservation, restoration and proper management of inland freshwater wetlands are major priorities to safeguard

habitats. Fairly common to uncommon but local in Mexico. Status in Colombia unclear. In Ecuador rare, local and probably declining; agriculture and siltation may have resulted in little habitat remaining in Andes. One of rarest sedentary waterbirds in Peru, where occurs in only a few of the remaining coastal marshes; these are under serious threat from drainage for agriculture and urban development, and from pollution and reed-cutting.

Bibliography. Andrews (1973), Baird (1974), Bang (1968), Bent (1926), Berger (1951), Billard (1948), Binford (1973), Blake (1977), Conway (1990, 1995), Conway & Eddleman (1994), Conway *et al.* (1994), Dickerman (1971), Eddleman *et al.* (1988), Fjeldså (1990), Fjeldså & Krabbe (1990), Glahn (1974), Godfrey (1986), Griese *et al.* (1980), Harrison (1978), Hellmayr & Conover (1942), Hilty & Brown (1986), Horak (1970), Howell & Webb (1995a), Irish (1974), Johnson & Dinsmore (1985, 1986a, 1986b), Kaufmann (1971, 1977, 1983, 1987b, 1988c, 1989), Loery (1993), Mousley (1937, 1940), Pospichal & Marshall (1954), Reynard (1974), Root (1988), Rundle & Fredrickson (1981), Sayre & Rundle (1984), Tanner & Hendrickson (1954), Walkinshaw (1937), Wiens (1966), Zimmerman (1984).

53. **Bogota Rail**

Rallus semiplumbeus

French: Râle de Bogota **German**: Bogotáralle **Spanish**: Rascón de Bogotá
Other common names: Peruvian Rail (*peruvianus*)

Taxonomy. *Rallus semiplumbeus* P. L. Sclater, 1856, Bogotá, Colombia.
Forms superspecies with *R. limicola* and *R. antarcticus*; sometimes considered conspecific with latter. Race *peruvianus*, known only from type specimen, might merit specific status. Two subspecies normally recognized.
Subspecies and Distribution.
R. s. semiplumbeus P. L. Sclater, 1856 - E Andes of Colombia.
R. s. peruvianus Taczanowski, 1886 - locality unknown: Peru?
Unconfirmed record from Ecuador (Laguna Kingora, Sigsig).

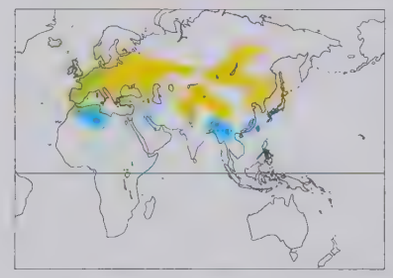
Descriptive notes. 25-30 cm. Sexes alike. Plumbeous grey head, breast and upper belly separate from structurally similar *R. limicola*; irregular white barring on flanks tinged brownish towards rear flanks; dull red bill and legs. Differs from much smaller *R. antarcticus* in olive brown feather edges to dorsal plumage and less regularly spaced and narrower white barring on flanks. Immature not described. Juvenile like adult but with slightly sooty feather tips on breast, and whitish throat. Race *peruvianus* probably less uniform; darker chestnut on upperwing-coverts; more extensive pale throat. VOICE. Variety of squeaks, grunts, and whistling and piping notes, usually starting low, growing in intensity, then wavering and trailing off rather abruptly. Also brief, rapid "tititititirr" when disturbed. Does not call at night.
Habitat. Restricted to the savanna and *páramo* marshes of temperate zone of E Andes of Colombia, characteristically occurring in dense, tall fringing reeds and rushes (e.g. *Scirpus*, *Typha*, *Juncus*, some *Cortadera*) and vegetation-rich shallows with *Elodea*, *Myriophyllum* and *Potamogeton*. Found in rushy fields, reedbeds, often with open, regenerating burned areas; reed-filled ditches and fens fringed with dwarf bamboo (*Swallenochloa*). May also tolerate modified habitats where floating mats of *Azolla*, *Ludwigia* and *Limnobium* replace emergent vegetation; avoids *Eichhornia crassies*. Once seen at a small roadside pool. Altitudinal range 2100-4000 m.
Food and Feeding. Primarily aquatic invertebrates and insect larvae, but also worms, molluscs, dead fish, frogs, tadpoles and plant material. Active from dawn to dusk; forages in areas with thin carpet of floating plants, at edges of reedbeds, on marshy shoreline, in flooded grass and marsh, and on patches of dead waterlogged vegetation.
Breeding. Dependent juveniles Jul-Aug; these and other observations suggest breeding Jul-Sept; also empty nest Oct. Apparently monogamous and territorial. No details of nest or eggs available; black downy chick has white upper mandible with central black bar, and black lower mandible; young cared for by both parents.
Movements. None recorded.
Status and Conservation. ENDANGERED. Uncommon to locally fairly common; restricted to departments of Cundinamarca and Boyaca in E Andes of Colombia, where healthy populations remain in a few areas, notably Laguna de Tota with c. 400 birds, Laguna de la Herrera with c. 50 territories, and Parque La Florida with 54 pairs. All major savanna wetland localities are seriously threatened, mainly from drainage but also from encroachment, agrochemicals and other pollution, tourism, hunting, burning, cattle trampling, cultivation, fluctuating water levels and water loss to irrigation. Throughout its range species has suffered enormous habitat loss caused by drainage, and few suitable characteristically vegetated marshes (with high plant productivity) remain because of pollution and siltation. Apparently able to survive in small patches of remaining habitat; breeding territories are 0·2-0·45 ha in area.
Bibliography. Blake (1959, 1977), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Fjeldså (1990), Fjeldsa & Krabbe (1990), Hellmayr & Conover (1942), Hilty (1985), Hilty & Brown (1986), King (1978/79), Lozano (1993), Meyer de Schauensee (1982), Ripley (1977), Varty *et al.* (1986), Wege & Long (1995).

54. **Austral Rail**

Rallus antarcticus

French: Râle austral **German**: Magellanralle **Spanish**: Rascón Pidén

Taxonomy. *Rallus Antarcticus* King, 1828, Straits of Magellan.
Sometimes regarded as conspecific with *R. limicola* or *R. semiplumbeus*, with both of which forms superspecies. Monotypic.
Distribution. C Chile and N Argentina patchily S to Tierra del Fuego.
Descriptive notes. 20 cm. In fresh plumage, breast and sides washed olive brown. Sexes alike. Similar to *R. semiplumbeus* but smaller, with sandy buff (not brown) edges to dorsal plumage, and broad, regularly spaced, black and white bars on flanks. Immature undescribed; juvenile like adult but with white throat and sooty grey feather tips on breast. VOICE. Undescribed.
Habitat. Wet fields, rushy parts of meadows, rushy lake shores and reedbeds, mostly adjacent to coast. In Chile, some birds spent winter months in garden of house, where they appeared very tame, before returning to adjacent dense reedbeds.
Food and Feeding. One stomach contained caddisflies (*Limnophilus meridionalis*, Trichoptera). Birds wintering in a garden fed on grubs found underneath decomposing leaves, and even ate left-over dog food. Diet probably similar to that of *R. limicola*.



Breeding. Chile, Oct, possibly Nov; Argentina, possibly Nov; probably breeds throughout its range, but data lacking. Only definite nest was recorded from "C Chile", but locality not given. Possible nest of this species was placed on ground under thick bramble (*Rubus*) bordering irrigation canal; eggs were in depression scantily lined with grass stems and rushes; two other possible nests were in grass tussocks 20 cm above water in lagoon. Eggs 8, possibly also 4 and 6; possible chick of this species had whitish bill with distal half of upper mandible black, and black streak on lower mandible.
Movements. Northward post-breeding migration may occur, at least in southernmost populations, Mar-Apr.
Status and Conservation. CRITICALLY ENDANGERED. Known from up to 19 localities, with additional records from unspecified sites, but seems to have disappeared in course of last 100 years: only two specimens have been collected since 1901, and there have been no certain records since 1959 (when the last was collected) despite species occurring in a region where ornithological activity has not been insignificant. Possibly already rare at start of this century. Reasons for decline unclear, although overgrazing and disappearance of practically all the tall grass habitat in Patagonia has been suggested. Reported to be seen occasionally near El Bolsón, Río Negro (SC Argentina); when its calls become known, species may possibly be found with more certainty and regularity; immediate priority is to locate remaining populations.
Bibliography. Blake (1977), Canevari *et al.* (1991), Chebez (1994), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Fjeldså (1990), Fjeldså & Krabbe (1990), Hartert & Venturi (1909), Hellmayr & Conover (1942), Humphrey *et al.* (1970), Johnson (1965b), Meyer de Schauensee (1982), Narosky & Yzurieta (1987), Navas (1962), Oates (1901), Olrog (1984), de la Peña (1992), Wege & Long (1995).

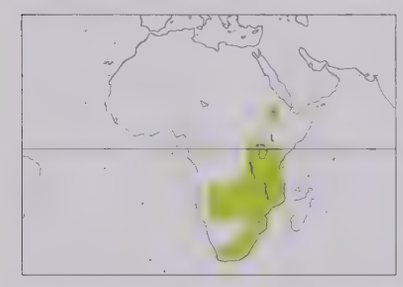
55. **Water Rail**

Rallus aquaticus

French: Râle d'eau **German**: Wasserralle **Spanish**: Rascón Europeo

Taxonomy. *Rallus aquaticus* Linnaeus, 1758, Great Britain.
Forms superspecies with *R. caerulescens* and *R. madagascariensis*. Four subspecies recognized.
Subspecies and Distribution.
R. a. hibernans Salomonsen, 1931 - Iceland.
R. a. aquaticus Linnaeus, 1758 - Europe, N Africa and W Asia to upper basin of R Ob'; winters S to N Africa and Turkmenistan.
R. a. korejewi Zarudny, 1905 - Aral Sea and L Balkhash S to Iran, Kashmir and WC China; winters patchily from Iraq to coastal E China.
R. a. indicus Blyth, 1849 - N Mongolia and E Siberia (upper R Yenisey and middle R Lena) to Manchuria, Korea, Sakhalin and N Japan; winters from E Bengal and Assam, Myanmar, N Thailand and N Laos E to SE China and Hainan, Taiwan and S Japan.

Descriptive notes. 25-28 cm; male 88-190 (128) g, female 74-138 (102) g; wingspan 38-45 cm. Female smaller, with shorter bill. In c. 60% of nominate birds, variable number of greater and median upperwing-coverts have white bars, black-bordered or on black feathers; white markings may also occur on alula, primary coverts and even remiges, while some have white speckles on mantle, back or rump; undertail-coverts usually appear white but may have variable amounts of buff, and sometimes show black barring; pattern has been used for individual recognition. Differs from all American congeners, except *R. wetmorei*, in lacking contrasting rufous or chestnut on upperwing-coverts. *R. caerulescens* of sub-Saharan Africa is larger, with unstreaked, deep vinous brown upperparts and brighter red legs and feet. Immature very like adult but duller, with whiter chin, small pale supraloral streak, olive brown patch on ear-coverts, olive brown tinge on breast, and duller legs and feet. Juvenile may have duller upperparts; grey of head and underparts replaced by buff or white with brown to black bars and feather tips; flanks buff with dark brown to black bars; undertail-coverts often appear entirely buff; bare parts dull. Races separated on plumage: *hibernans* and *korejewi* paler on underparts, and *korejewi* also on upperparts; *indicus* has brown streak through eye, whiter chin, brown tinge to breast and sides and more extensive wing barring. VOICE. Announcement call ("sharming") comprises grunting notes rising in middle of call to high-pitched, trilling whistles, likened to piglets squealing; pair members often call antiphonally in duet, male giving lower notes. Courtship-song rendered "tyick-tyick-tyick", often ending with trill "tyüirr"; also gives series of ticks followed by wheezy scream, and various groans, grunts, purrs and whistles. Calls usually given from cover; vocal by day throughout year; may call all night early in breeding season.
Habitat. Occupies almost any type of dense riparian and aquatic vegetation at still or slow-moving water; usually requires muddy ground for foraging; suitable habitat may form small pockets or narrow strips in other habitat types. Breeding habitat includes reedbeds and other emergent vegetation of swamps, marshes and fens, and at fringes of open water; also occurs on floating islands, rice paddies and lotus ponds; on Japanese offshore islands found amongst grasses and dwarf bamboo stands. Occurs at both fresh and saline lakes and marshes. On migration and in winter exploits wider range of habitats, such as farm sewage outfalls, island bracken, flooded thickets of blackberry (*Rubus*), gravel pits and other very small wetland patches; even, when displaced by frost, drainpipes, rubbish dumps, open ditches and gardens. In Iceland in winter largely dependent on marshy areas with warm water from volcanic springs. Vulnerable to extreme conditions, e.g. ice or severe floods. Mainly lowland, but resident up to 2000 m.
Food and Feeding. Worms, leeches, molluscs, shrimps, crayfish, spiders, many terrestrial and aquatic insects and their larvae (including Dermaptera, Odonata, Trichoptera, Hemiptera, Coleoptera, Diptera, Lepidoptera, Orthoptera), and small vertebrates (killed or as carrion) including amphibians, fish, birds and mammals. Plant foods include shoots, roots, seeds, berries and fruits; eats more plant material in autumn and winter. Forages on dry ground or mud near water; also wades in shallow water, taking items on and below surface, and from emergent vegetation; sometimes feeds while swimming, rarely by diving. Leaps up to take insects from vegetation; climbs in vegetation to take berries; flies into apple trees to remove fruit.



Breeding. W & C Europe, late Mar to Aug; Morocco and Algeria, May-Jun; Tunisia, Jun; Egypt, Apr-Jun; former USSR, May; Kashmir, Jun-Aug. Monogamous; highly territorial when breeding. Nest a substantial cup of dead leaves and plant stems; usually in thick vegetation of reeds or rushes on ground near or in water, rarely on tree stump or in open; surrounding vegetation often pulled down into loose canopy. External diameter 13-16 cm; height c. 7 cm; may be built up if water level rises. Both sexes build. Usually 6-11 eggs (5-16), laid at daily intervals; incubation 19-22 days, by both sexes; chicks precocial; black downy chick has visible patch of red skin on hind crown, white bill with black base and tip, grey to brown-black iris and grey-brown to blackish legs and feet; fed and cared for by both parents, apparently only until 20-30 days old; initially brooded and fed mainly in nest; begin to feed themselves at c. 5 days; fully independent and capable of flight at 7-8 weeks; post-juvenile moult starts soon after fledging (c. 10 weeks) and is usually finished by Jul-Oct. Age of first breeding 1 year. 2 broods normal; replacements laid after egg loss.
Movements. Nominate race both sedentary and migratory, birds from N of range moving S & SW to winter in Mediterranean basin, N Africa (extending far into Sahara, in Algeria and Libya) and E to S Caspian area. In Europe and Russia autumn migration begins Aug, peaks Sept-Oct, ends Dec; spring migration begins Feb, peaks Mar to mid-Apr and ends by May. Passes through Morocco Sept, Algeria Sept-Oct, Egypt Sept-Nov; occurs coastal Libya Oct-Apr and at Saharan sites Dec-Apr. Passage recorded Azerbaijan Sept-Nov and Mar-May. Scarce passage migrant in Oman, occasionally overwintering; occurs Aug-May. Has bred in Cyprus and wanders to Spitsbergen, Madeira, Canary Is and Azores. Race *hibernans* probably migrates to Faeroes in winter, occurs on passage at Scottish islands and in winter in Ireland, and wanders to Greenland and Jan Mayen. Race *korejewi* partly migratory and wanders to Sind and NW India, and to E Arabia. Race *indicus* largely migratory, occurring in winter S to Borneo (3 records, Brunei and Sarawak); occurs N Japan May-Oct and winters S Japan to Yaeyama Is Oct-Mar/Apr. Migrates at night, on broad fronts, and even crosses mountain systems such as Alps.
Status and Conservation. Not globally threatened. No evidence of significant changes in status of nominate race, which is regarded as locally common over much of range, including N Africa and Azerbaijan, although wetland habitat loss must have affected its numbers. Has benefited locally in UK from increased habitat provided by gravel pits and disused canals. Race *hibernans* is most numerous in S of Iceland; current status not clear but probably scarce in some areas. Current status of races *korejewi* and *indicus* unclear in many areas but formerly regarded as at least locally common; however *indicus* is uncommon throughout Japan. Range in Asia probably more extensive than is known.

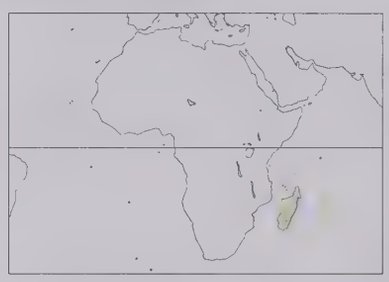
56. **African Rail**

Rallus caerulescens

French: Râle bleuâtre **German**: Kapralle **Spanish**: Rascón Cafre
Other common names: African Water/Cape/Kaffir Rail

Taxonomy. *Rallus cærulescens* Gmelin, 1789, Cape of Good Hope.
Forms superspecies with *R. aquaticus* and *R. madagascariensis*. Monotypic.
Distribution. Sub-Saharan Africa, principally from Ethiopia to E Zaire and Kenya and S to Cape of Good Hope. Status uncertain in W Africa; occurrence in NE Central African Republic and coastal Kenya requires confirmation.



Descriptive notes. 27-28 cm; male 146-205 (180) g, female 120-170 (146) g. Unpatterned, deep vinous brown upperparts are unique character within genus. Sexes similar but female smaller; face to breast may be greyer, less slaty blue, with some pale markings; may have a little brown on sides of neck and breast and less regular barring on flanks. Larger than *R. aquaticus*, which has streaked upperparts; similar-sized *Rougetius rougetii* of Ethiopia has cinnamon-rufous underparts. Immature similar to adult but duller; chin and throat white; sides of neck and breast brown; flanks brownish black barred rufous buff to white; outer undertail-coverts tipped rufous buff; eye, bill, legs and feet brown, becoming redder with age. Juvenile has darker upperparts; face, sides of neck and breast dark brown; breast brown, mottled pale; flanks to undertail-coverts blackish brown, barred rufous; centre of breast and belly buff; eye brown; bill, legs and feet dark brown. Voice. Common territorial call, given by both sexes, often in duet or chorus, is loud high trill winding down into spaced single notes and falling in pitch and volume. Also wheezy "kreee" during territorial and aggressive encounters, shrill "ri-ri-ri" when fighting, loud rattle, deep "krock", and various growls, squeaks, short trills and clunking notes.
Habitat. Reedbeds and dense rank growth in permanent and temporary swamps and marshes, and beside lakes, pools, rivers and streams; sometimes on mature pans; tolerates brackish conditions; in breeding season moves out into seasonally inundated dense hygrophilous grassland and sedge meadow adjoining permanent cover, and occupies seasonally wet sugar cane adjacent to marshes. In W Africa also in paddy fields; in Sudan in thick secondary growth along rivers. Prefers shallowly flooded areas with mud and/or floating vegetation for foraging. Recorded from sea-level to 3000 m, but occurrence at low altitude and in coastal areas mainly confined to regions S of 20° S.
Food and Feeding. Worms, crabs, spiders, aquatic and terrestrial insects and their larvae, small fish and small frogs; also some vegetable matter, including seeds; occasionally carrion (crayfish, crabs, small mammals). Forages mainly on moist to shallowly flooded ground, sometimes on dry ground; probes mud, clumps of wet grass and mats of floating vegetation; while wading takes food from water surface and also by immersing head and neck; takes prey from low vegetation. Climbs readily in tall reedbed vegetation, sometimes probably to forage. Feeds both within and outside cover; most active in early morning and late afternoon.
Breeding. Ethiopia, Aug; SW Zaire, "dry season"; Kenya, May-Jun; Malawi, Feb-Mar; Zambia, Jan, breeding condition May; Zimbabwe, Jan-May; Mozambique, Jan; South Africa, Jul-Mar, in suitable habitat winter breeding possibly occurring more frequently than is known. Monogamous; strongly territorial when breeding. Nest is a shallow cup of aquatic plants (reeds, sedges, rushes); well concealed in aquatic vegetation, usually over water; external diameter 15-20 cm; depth of cup 2-5 cm; nest rim 10-40 cm above water. Both sexes build, and also construct brood platforms 20-50 cm above water. Eggs 2-6; incubation c. 20 days, by both sexes; chicks leave nest soon after hatching; black downy chicks have greyish eyes, slate legs and feet, and pink bill with black distal half; fed and cared for by both parents until 6-8 weeks old; body feathers appear at 2-3 weeks, remiges at 4-5 weeks; well feathered by 6-7 weeks; remiges fully grown at 8-9 weeks. Post-juvenile moult begins at 6-7 months; complete at 8-9 months. Age of first breeding 1 year. Not known to be multiple-brooded; will relay if clutch fails.
Movements. No evidence for regular migrations. Most seasonal variations in numbers explained by dispersal of immatures or by local movements to and from habitat rendered temporarily unsuitable by burning, drying out or reduction of cover. Possibly some seasonal movements in N Namibia and N Botswana. Known occurrence in W Africa is erratic: W Sierra Leone, May-Oct; Cameroon, Jan, Feb, Oct; NE Gabon, Oct-Nov; Congo, Feb. One came to lights at night, Tsavo West, SE Kenya, Dec 1985. Vagrant to São Tomé I (undated skin).
Status and Conservation. Not globally threatened. Regarded as widespread and locally common over much of main range, though undoubtedly under-recorded in many areas. Rare and erratic in W Africa; uncommon to rare in Ethiopian highlands and in S Sudan, where known only from Imatong Mts. Although its wetland habitats are continually being reduced, in South Africa species is under no immediate threat and is able to colonize relatively small, artificially created, wetland patches.

57. **Madagascar Rail**

Rallus madagascariensis

French: Râle de Madagascar **German**: Madagaskarralle **Spanish**: Rascón Malgache

Taxonomy. *Rallus Madagascariensis* J. Verreaux, 1833, Madagascar.
Forms superspecies with *R. aquaticus* and *R. caerulescens*. Monotypic.
Distribution. E Madagascar.

Descriptive notes. 25 cm; 1 male 148 g. Sexes alike. Distinguished from other medium-sized Madagascar rails by long, slender, decurved bill, lack of white on throat, unbarred flanks, and olive brown upperparts flecked with black; from *Canirallus kioloides* also by white undertail-coverts. Immature duller than adult, with brownish bill and brown eyes. Voice. Sharp "tsi-ka" when flushed; also "kik-kik". Calls frequently during day, from dense cover.
Habitat. Small to large marshes with dense long grass, reeds and sedges; river margins; grassland at forest edges; dense herbaceous vegetation of wet woodland and forest. Occurs from sea-level to 1800 m, more frequently at high altitudes.
Food and Feeding. Only invertebrates recorded. Moves about slowly in dense aquatic vegetation, searching for food and probing mud with long bill.
Breeding. Very poorly known. Lays Aug-Oct. Nest not described; built on ground in aquatic vegetation. No data on clutch size or downy young.
Movements. Suggested to be possibly migratory, but no evidence found.
Status and Conservation. Not globally threatened. Becoming rare throughout range as result of pressure on natural habitats in E half of Madagascar, to which species is confined and where it was formerly (1929-1931) common, especially at high altitudes. Direct destruction of wetland habitats continues, especially to create rice paddies for feeding Madagascar's rapidly growing population, and no Madagascan wetland has full legal protection; in view of the need to expand rice cultivation, it is unlikely that wetlands will be included in new protected areas. Another threat is habitat alteration through effects of deforestation, such as variations in quantity, quality and frequency of water available from wetland catchments, and siltation as result of extensive soil erosion; fertilizers and pesticides from rice paddies are also affecting wetlands and their invertebrate communities. Has been listed in 2 Special Reserves and may occur in others, but is easily overlooked because of its shyness. Still relatively common in some pristine wetlands, e.g. Torotofotsy marsh, near Périnet; but only small populations exist in the few areas which are protected. Long-term survival depends on implementation of a wetland protection programme and creation of additional protected areas.
Bibliography. Benson *et al.* (1976-1977), Dee (1986), Delacour (1932), Dowsett & Forbes-Watson (1993), Langrand (1990), Milon *et al.* (1973), Olson (1973b), Rand (1936), Ripley (1977), Salvan (1972a), Snow (1978).

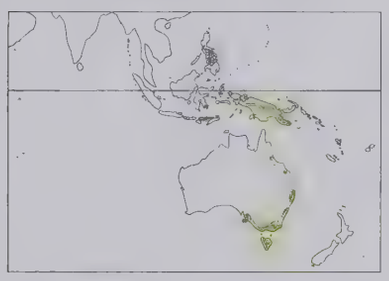
Genus *LEWINIA* G. R. Gray, 1855

58. **Brown-banded Rail**

Lewinia mirificus

French: Râle de Luçon **German**: Luzonralle **Spanish**: Rascón de Luzón
Other common names: Luzon Rail

Taxonomy. *Rallus mirificus* Parkes and Amadon, 1959, Aritao, Luzon, Philippines.
Sometimes placed in genus *Dryolimnas*. Forms superspecies with *L. pectoralis* and *L. muelleri*; on occasion regarded as distinctive race of *L. pectoralis*. Monotypic.
Distribution. Luzon, N Philippines.
Descriptive notes. 20 cm. Sexes alike. Differs from *L. pectoralis* in absence of black streaks on less brightly coloured head and hindneck, whiter throat and lack of prominent barring on upperwings. Distinguished from sympatric *Gallirallus* species by smaller size, and by relative extent of pale markings on upperparts and barring on underparts; from sympatric *Porzana* species by longer bill, rufous crown and nape, and pattern of upperparts. Immature duller than adult: dark greyish brown on crown



and hindneck, and greyer on cheeks and upper breast; bill darker than that of adult. Juvenile undescribed. VOICE. Not described.
Habitat. Precise habitat unknown, but species recorded from wet grassy areas; unlike congeners, may have strict ecological requirements. All records to date are from mountain foothills, migrating birds being recorded at altitude of c. 1000 m.
Food and Feeding. Unknown; food and feeding habits presumably similar to those of *L. pectoralis*.
Breeding. Unknown; probably breeds during rainy season.
Movements. In 1965-1970, total of 191 birds trapped at Dalton Pass in May-Jun and Oct-Dec, apparently while undertaking post-breeding dispersal or intra-island migration, the latter possibly between Cagayan Valley and Central Plain or between Sierra Madre and Cordillera Central. Also recorded elsewhere in mountain foothills in Dec-Jan.
Status and Conservation. ENDANGERED. Uncommon and secretive; recorded only from Luzon, where known from records of migrating birds at Dalton Pass in Sierra Madre Mts, and from six other localities in Nueva Écija, Nueva Vizcaya, Camarines Norte, Benguet and Mountain Provinces. Paucity of known localities, and lack of records since 1979, suggest that species is probably becoming increasingly rare.
Bibliography. Amadon & DuPont (1970), Collar & Andrew (1988), Collar *et al.* (1994), Danielsen *et al.* (1994), Dickinson *et al.* (1991), DuPont (1971), Hornbuckle (1994), McClure & Leelavit (1972), Parkes & Amadon (1959), Paynter (1963), Poulsen (1995), Ripley (1977).

59. **Lewin's Rail**

Lewinia pectoralis

French: Râle à poitrine grise **German**: Krickralle **Spanish**: Rascón Pectoral
Other common names: Slate-breasted Rail, Lewin's Water Rail

Taxonomy. *Rallus pectoralis* Temminck, 1831, New South Wales.
Sometimes placed in *Dryolimnas* or *Rallus*. Forms superspecies with *L. mirificus* and *L. muelleri*, both of which are on occasion considered races of present species. Eight subspecies recognized.
Subspecies and Distribution.
L. p. exsul (Hartert, 1898) - Flores (Lesser Sundas).
L. p. mayri (Hartert, 1930) - Arfak Mts, W New Guinea.
L. p. captus (Mayr & Gilliard, 1951) - C New Guinea.
L. p. insulsus (Greenway, 1935) - Herzog Mts, E New Guinea.
L. p. alberti (Rothschild & Hartert, 1907) - mountains of SE New Guinea.
L. p. clelandi (Mathews, 1911) - SW Australia (probably extinct).
L. p. pectoralis (Temminck, 1831) - E & SE Australia.
L. p. brachipus (Swainson, 1838) - Tasmania.

Descriptive notes. 18-27 cm; male 65-112 (88) g, female 63-111 (82) g, juvenile 42-78 (66) g; wingspan 31-35 cm. Female slightly smaller and has duller rufous head and hindneck with heavier black streaking. Differs in plumage from *L. mirificus* and *L. muelleri* in having noticeable streaks on head and hindneck, prominently dark-streaked upperparts and prominently barred upperwings. Distinguished from sympatric *Gallirallus* species by smaller size, and by pattern of upperparts, upperwings and underparts; from sympatric *Porzana* species by longer bill, rufous crown and nape, and pattern of upperparts and upperwings. Immature as adult. Juvenile has similar pattern to adult but much darker overall; lacks rufous on head and hindneck; barring on underparts less distinct and extends to upper breast; bill grey-black. Races separated on prominence of crown streaks, colour of crown, upperparts and breast, extent of white on throat, and on biometrics. VOICE. Commonest calls an accelerating series of loud notes likened to two coins being tapped together, and loud "crek"; also pig-like grunts.
Habitat. In Australia most often occurs at freshwater to saline wetlands, either permanent or ephemeral and usually with standing water: swamps, marshes, inundations, creeks, lakes, pools, farm dams, marshy streams, salt-marshes and estuaries. Requires dense fringing or emergent cover of long or tussocky grass, reeds, rushes, sedges or bracken; occasionally in thickets of wetland shrubs; sometimes uses wetlands in rain forest, woodland, riverine forest or wet heathland. Occasionally occurs away from water in parks, gardens, pasture, hay fields, lucerne, tangles of bramble or *Lantana*, and even in dry grass and ferns under canopy of scrub. In New Guinea occurs in medium-height, dense, dry upland grassland at 1040-2600 m, as well as in thick cover near water.
Food and Feeding. Largely earthworms, molluscs and arthropods, especially insects and crustaceans; occasionally frogs and eggs of birds; takes some vegetable matter; captive birds also ate meat. Crepuscular and diurnal; forages on dry ground, dry peat, soft soil and mud, and often in shallow water (less than 5 cm deep) at wetland edges, small pools and channels; usually forages within, or close to, dense vegetation, emerging from cover only briefly. Occasionally feeds on garden lawns and in short pasture. Pecks and probes; often immerses head in water; probe rate 1 per second; drills vigorously with long bill; foraging bouts interrupted by sudden dashes into cover, especially with large prey items.
Breeding. Season in Australia usually Aug-Jan; in New Guinea breeds Sept-Mar, and possibly also Jun-Aug, during both rainy and dry seasons. All following information from Australian populations. Probably monogamous and territorial. Nest a shallow cup or saucer-shaped structure, well hidden in clumps of grass or sedge at edge of marsh or other flooded area; usually above water but also on dry ground near water; sometimes solid platform in denser cover; often has approach runway or ladder. Nests often at high density along drainage areas and river flats. Average height above ground 64 cm; external diameter 18 cm and depth 8 cm; cavity diameter 12-13 cm and depth 4 cm. Woven from rushes or dead grass stems; lined with fine green stems; often with canopy woven from overhanging vegetation; construction takes 4 days to over 1 week. Eggs 3-8; colour differences and largest clutch size suggest occasional laying by 2 females; eggs laid at daily intervals; incubation 19-20 days, probably by female only; black downy chicks have black bill and iris, and grey legs; chicks remain in nest for up to 24 hours; young fed by both parents. May raise two broods per season; last brood may remain with parents during following autumn. Hatching success of 18 eggs 72%; eggs taken by water rat (*Hydromys chrysogaster*); young and adults taken by cats, dogs, Variable Goshawks (*Accipiter novaehollandiae*) and Kelp Gulls (*Larus dominicanus*).
Movements. Virtually unknown, as sightings rare and observation difficult; seldom seen to fly. In Australia present at some sites all year but in S the lack of records and lower reporting rates in winter may reflect some seasonal absence; may move to coastal and sub-coastal New South Wales to breed; no records S South Australia Jun-Aug. In Tasmania birds may move locally in response to changing conditions. Movements appear to be nocturnal and one bird struck window at night; birds probably fly c. 12 km to and fro between Maatsuyker I and mainland Tasmania. No movements recorded in New Guinea or Flores.
Status and Conservation. Not globally threatened. Race *exsul* known only from a few specimens from S & W Flores and last recorded in 1959. Race *clelandi* of SW Australia known from four specimens collected at 2-3 localities; has not been seen since 1932, despite being regarded as reasonably common at that time; it is probably extinct as result of draining, burning, grazing and trampling of its wetland habitats. Races *pectoralis* and *brachipus* widespread and uncommon to common throughout their ranges, with no recent declines noted; birds are able to occupy disturbed and artificially created habitats, and to occur close to human habitation and even in industrial areas. In New Guinea, race *captus* may be fairly common but other races may be uncommon to rare.
Bibliography. Beehler *et al.* (1986), Blakers *et al.* (1984), Coates (1985), Czechura (1983), Fletcher (1913), Garnett (1993), Gilbert (1936), Gilliard & LeCroy (1961), Harrison, C.J.O. (1975), Jaensch *et al.* (1988), Leicester (1960), Marchant & Higgins (1993), Milledge (1972), Olson (1973b), Rand & Gilliard (1967), Serventy (1985), Skemp (1955), Watson (1955), White & Bruce (1986).

60. **Auckland Rail**

Lewinia muelleri

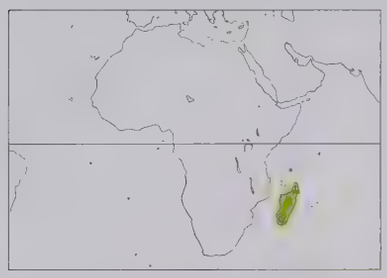
French: Râle d'Auckland **German**: Aucklandralle **Spanish**: Rascón de las Auckland

Taxonomy. *Rallus muelleri* Rothschild, 1893, Auckland Island.
Sometimes placed in genus *Dryolimnas*. Forms superspecies with *L. mirificus* and *L. pectoralis*; on occasion regarded as race of *L. pectoralis*. Monotypic.
Distribution. Aucklands Is of Adams and Disappointment.

Descriptive notes. 17-18 cm; 1 female 63 g, 4 adults 89-100 (93) g, 1 juvenile 63 g. Sexes similar, but may differ in extent of rufous on head and neck, with female possibly duller, as in *L. pectoralis*. Differs from *L. pectoralis* in much smaller size, slightly straighter bill, and somewhat softer, denser plumage with little streaking on head and none on hindneck, olive brown upperparts with sparse, narrow dark streaks, restricted sparse barring on upperwing-coverts and reduced spots on primaries. Immature undescribed; juvenile apparently similar to that of *L. pectoralis* but with darker lores and ear-coverts, and with pale streaking occupying 30% of crown and 60% of upperparts. VOICE. Commonest calls a loud descending "crek" repeated at 1 per second, and a loud, sharp, whistle-like call at 4 per second; also makes grunts and clicks.
Habitat. Frequents herbaceous vegetation on damp to wet, flat to steeply sloping ground with clear areas at ground level and dense canopy c. 1 m above. Occurs in herb fields with megaherbs and sedges, and grasslands with sedges, ferns, low woody shrubs and tussocks; also ventures into scrubby forest with 2·5 m high canopy and 1 m sub-canopy over dense patches of grass and sedge. Occurs from sea-level to 500 m.
Food and Feeding. Little information, but food and foraging methods probably very similar to those of *L. pectoralis*. Once seen foraging at a rubbish dump. Active from just before sunrise to just after sunset; possibly also for some time after darkness falls.
Breeding. Season probably Oct-Dec. Probably monogamous and territorial. Two nests described: both in wetlands, in tussocks of *Carex appressa* and *Chionochloa antarctica*, sheltered by overhanging or interlaced vegetation and with well defined entrance runway. Nest a shallow cup of grasses and/or sedges; external diameter 14-23 cm and depth 7-16 cm; internal diameter 7 cm and depth 2-7 cm; cup 13-15 cm above ground. One clutch of 2 eggs recorded; incubation period probably similar to that of *L. pectoralis*; downy young not described.
Movements. Probably none, but observations difficult. Can fly but apparently does so only infrequently.
Status and Conservation. VULNERABLE. Probably eliminated on Auckland I by feral cats and/or pigs in 1860's, and thought to be extinct on other islands until a population of several hundred was discovered on Adams I (10,000 ha) in 1989, and one of c. 500 on Disappointment I (400 ha) in 1993. These islands are part of the Auckland Islands Nature Reserve and access is strictly controlled; survival of species depends on the continued exclusion of mammalian predators, especially rats, cats and pigs. Adams I has no introduced mammals but has New Zealand Falcons (*Falco novaeseelandiae*) and Brown Skuas (*Catharacta antarctica*), possible predators of present species.
Bibliography. Collar *et al.* (1994), Elliott *et al.* (1991), Falla (1967), Falla *et al.* (1981), Greenway (1967), Johnstone (1985), King (1978/79), Marchant & Higgins (1993), Robertson (1985), Soper (1976).

PLATE 14

inches 7
cm 18



Genus *DRYOLIMNAS* Sharpe, 1893

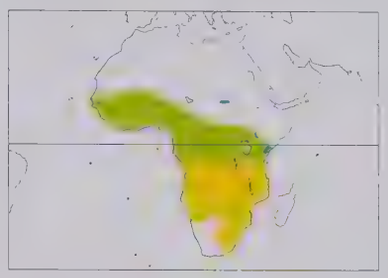
61. White-throated Rail

Dryolimnas cuvieri

French: Râle de Cuvier **German**: Cuvierralle **Spanish**: Rascón de Cuvier
Other common names: Cuvier's Rail

Taxonomy. *Rallus Cuvieri* Pucheran, 1845, Mauritius.
Sometimes included in the genus *Canirallus*, but skeletally very close to *Lewinia pectoralis* with which sometimes considered congeneric. Race *abbotti*, of Assumption I, recently extinct. Two extant subspecies recognized.
Subspecies and Distribution.
D. c. cuvieri (Pucheran, 1845) - Madagascar; formerly also Mauritius.
D. c. aldabranus (Günther, 1879) - Aldabra Is, Indian Ocean.

Descriptive notes. 30-33 cm; volant race *cuvieri*, male 276 g, female 258 g; flightless race *aldabranus*, male 145-218 (189) g, female 138-223 (176) g. Fairly large rail with striking, well defined plumage pattern. Distinguished from other rails on Madagascar by larger size, dusky abdomen and thighs with narrow white barring; white on throat and undertail-coverts; and straight, bill of medium length with reddish at base sometimes extending well towards tip and covering much of bill. Sexes alike, but female *aldabranus* has bright pink base to upper mandible, male dull or dark red base. Immature duller than adult, with brownish bill and brown eyes; juvenile *aldabranus* duller than adult. Race *aldabranus* smaller and paler, with dusky streaks on upperparts faint or absent, but very variable and can be much more similar to nominate; extinct *abbotti* also smaller and paler, with more extensive white on throat. Voice. Rather vocal. Contact call a muffled staccato grunt "mp", often followed by "yeah"; when agitated, utters grunt followed by click; also gives loud click of warning, sometimes followed by whistle, and a squeal of distress. Song, usually uttered towards evening, sometimes during night, begins with "mp yeah" notes and develops into a series of loud, piercing whistles, rising in pitch and intensity and developing frequency changes; often duets.
Habitat. Inhabits a wide variety of diverse habitats on Madagascar: forest with luxuriant herbaceous ground cover; woodland water courses; stream edges with tall, dense herbaceous growth; wetlands, including marshes with long grass, reeds and sedges, and rice paddies; mangroves and coral islet beaches; ranges from sea-level to 1800 m, but less numerous above 1100 m. On Aldabra, occurs mainly on extremely rough, heavily dissected coral limestone covered with very dense scrub dominated by *Pemphis acidula*; also in less dense vegetation and mangroves; presence of feral cats appears to eliminate species from otherwise suitable habitat.
Food and Feeding. Diet consists chiefly of invertebrates, including small molluscs, ghost crabs and many types of insect, including flies, beetles, termites and the eggs and larvae of ants; birds sometimes scavenge dead crabs. Takes tortoise droppings, possibly to extract insects; gleans parasites from carapaces of tortoises; takes insects and their eggs from decaying tortoise carcasses; eats eggs and hatchlings of green turtle (*Chelonia mydas*) at nests on beach, extracting buried hatchlings with bill after probing. Forages in leaf litter, including *Casuarina* needles on Aldabra, where also feeds at litter disturbed by passing tortoises, in mud among mangroves, and on rocky or sandy shores. When feeding in water, submerges head and rakes vigorously into mud with bill. In coastal areas species is known to drink salt water.
Breeding. In Madagascar, possibly breeds mostly during rains, laying Oct, Feb, Mar, and breeding condition Nov, Jan; on Aldabra lays Dec. Monogamous and permanently territorial, forming permanent pair-bond; unmated females also hold territories. Female normally selects nest-site, to which male is led. Nest flimsy, few twigs and leaves placed in depression among rocks, or more substantial deep bowl of interwoven leaves and grass placed on ground in dense vegetation. Usually 3-4 eggs (3-6); downy chick black with olive tinge, bare parts black, iris olive green; both parents tend young, which are fed until they become independent at 12-15 weeks, after which parents become aggressive to them, but immatures may stay near parents until onset of next breeding season. In *aldabranus* typically only 1 young per brood survives, probably due to predation. Age of first breeding 9 months or more; longevity at least 5-6 years.
Movements. On Aldabra populations may be transient to some degree, and large numbers of birds may be attracted to long-term campsites, dispersing when people leave; not attracted to temporary camps. No evidence of any significant movements occurring in Madagascar.
Status and Conservation. Not globally threatened. Race *aldabranus* has been considered Rare. Abundant over much of range in Madagascar but generally appears to be rarer on central plateaux, probably as result of hunting; obviously very adaptable, occupying wide range of habitat types. On Aldabra, race *aldabranus* occurs on 2 major and several smaller islands, having apparently been wiped out on other islands shortly after introduction of cats in c. 1890; current population c. 8000 individuals but distribution continues to contract; territory size 1-2 ha; no known significant predators of adults, although birds are occasionally eaten by humans; population probably stable; threat posed by feral cats currently not serious but colonization by cats may constitute major long-term threat, so establishment of captive breeding populations has been recommended; can apparently tolerate large populations of rats (*Rattus rattus*) but these may take eggs and chicks as do land crabs (*Cardisoma carnifex*). Race *abbotti* exterminated on Assumption I before 1937, probably after introduction of cats.
Bibliography. Albignac (1970), Benson (1967), Benson *et al.* (1976-1977), Collar (1994), Dee (1986), Dowsett & Forbes-Watson (1993), Frith (1977), Hambler *et al.* (1993), Huxley & Wilkinson (1977, 1979), King (1978/79), Langrand (1990), Milon *et al.* (1973), Penny (1974), Penny & Diamond (1971), Rand (1936), Salvan (1972b), van Someren (1947), Stoddart (1971), Wilkinson & Huxley (1978).



Genus *CREX* Bechstein, 1803

62. African Crake

Crex egregia

French: Râle des prés **German**: Steppensumpfhuhn **Spanish**: Guión Africano

Taxonomy. *Ortygometra (Crex) egregia* W. K. H. Peters, 1854, Tete, Zambezi.
Sometimes placed in genus *Porzana* on the basis of a superficial resemblance to *P. albicollis*, but plumage and skeletal differences make the relationship untenable. Sometimes placed in monospecific genus *Crecopsis* but probably more appropriately included in *Crex* on basis of similarities to *C. crex*. Monotypic.
Distribution. Sub-Saharan Africa from Senegal E to Kenya and S to Cape Province, South Africa, except arid areas of SW & S Africa, where W limits correlate with 300-mm summer rainfall isohyet.

Descriptive notes. 20-23 cm; 3 males 121-141 (133) g, 16 unsexed 92-137 (117·5) g; wingspan 40-42 cm. Sexes similar but female normally looks slightly smaller, with less contrasting head pattern, duller grey face to breast, less regular underpart barring with narrower black bars, and almost unbarred centre belly. Easily separable from *C. crex* by smaller size, darker upperparts, lack of rufous on wing-coverts, entirely grey face, foreneck and breast, and black and white bars from flanks to undertail-coverts. Other sympatric crakes (*Porzana*, *Aenigmatolimnas*) smaller, with white markings on upperparts, different underpart pattern and short bill; *Rallus caerulescens* has dark, unpatterned upperparts, long red bill and red legs and feet. Immature similar to adult but duller; grey breast has brownish wash; underpart barring brown-black and off-white; iris hazel; orbital ring yellow-brown; bill, legs and feet grey. Juvenile has duller, darker upperparts; dark grey-brown face, foreneck and entire underparts, with no barring; whitish belly; blackish to dark brown bill; grey iris, legs and feet. Voice. Advertising call of male a series of rapid, grating "krrr" notes. Both sexes give sharp, loud "kip" call, often repeated and sometimes modified to descending double note "kiu", with aggressive, territorial and alarm functions, and also given in flight by nocturnal migrants. Also a wheezy "kraaa" when mating.
Habitat. Predominantly occurs in grasslands, from those (often seasonally moist or inundated) at edges of freshwater swamps, marshes and open waters to dry grassland in lightly wooded country; also in rice, maize and cotton fields, neglected cultivation, rank herbage, moist sugar cane adjacent to marshy areas, and on airfields; may occur close to human habitation. At Ndola, Zambia, occupied tussocky damp grassland 0·3-1 m tall. Grassland territories often include thickets, or large termite mounds with dense vegetation, apparently used as refuges. Recorded from sea-level up to at least 2000 m, but rare in high altitude grasslands. Grassland habitat frequently burnt in dry season, forcing emigration of birds.
Food and Feeding. Feeds on earthworms, molluscs, insects and their larvae (especially termites, ants, beetles and grasshoppers), and small frogs; also consumes seeds (especially grass seeds) and vegetable matter (grass blades, green shoots and leaves). Forages within cover, and in open on roads and tracks; picks up insects and seeds from ground; turns over dead grass and litter; probes bases of grass tussocks; digs in moist or dry ground with bill; makes rapid runs to catch fast-moving prey; stretches up to take prey from low-growing plants. Generally most active early and late in day, after rain and during light rain.
Breeding. Breeds during rains; Senegal Jul; Sierra Leone, Jun-Aug; Ivory Coast, chicks Apr, May, Oct; Ghana, Apr; Nigeria, Jul-Sept in N, Jun-Sept in C, Apr-Nov in S; Zaire, Jan; C & W Kenya, May-Jun, breeding condition Jul; N Tanzania, Jun; S Tanzania Jan-Mar; Angola, Apr; Malawi, Jan-Mar; Zambia and Zimbabwe, Dec-Mar; Botswana, Jan; South Africa, Oct-Mar. Possibly largely monogamous, but association of 1 male and 2 females recorded; pair formation may occur before leaving wintering area; territorial on both breeding and wintering grounds. Nest a shallow cup of grass blades, placed in scrape or depression on dry to moist ground, hidden under grass tussock or small bush; sometimes 2-15 cm above dry ground or standing water in dense grass or other plants; occasionally floating; loose canopy of grass blades often present; external diameter 21-23 cm, depth 4-9 cm; cup diameter 11-12 cm, depth 2-5 cm; building continues during egg-laying. Eggs 3-9, laid daily; incubation variously estimated 14-24 days, by both sexes; hatching asynchronous; black downy chicks have blackish brown bare parts; chicks leave nest soon after hatching; fed and cared for by one or both parents; fledging 4-5 weeks; young can fly when two-thirds grown.
Movements. Seasonality of occurrence too complex and poorly documented to be mapped accurately (map largely hypothetical). Moves away from equator, both N & S, to breed during rains, being primarily wet-season breeding visitor S of c. 5° S. Main periods of occurrence: S Tanzania, Dec-Apr; Zambia, Zimbabwe and Botswana, Nov-May; Malawi, Dec-Apr; Mozambique, Oct-Mar; Namibia and South Africa, Nov-May; scattered dry-season records from SE Tanzania, Zambia, Zimbabwe, Namibia and South Africa show that some birds remain after breeding when suitable habitat persists. Stragglers to Namib Desert and Namibian W coast attributed to effect of prolonged E winds. In E Africa, occurs in W & C Kenya mostly Apr-Dec; occurs W Sudan only in rains (probably breeds). Apparently resident throughout year in some W African countries, but shows marked N-S seasonal movements in Nigeria, where many move N in rains to breed, and most records from S are in dry season; similar movements noted Senegal, Gambia, Ivory Coast and Cameroon; May-Jul passage noted in SW Central African Republic; local movements noted Sierra Leone. Seasonally occurring non-breeding populations located coastal Kenya, May-Dec, and NE Gabon, Oct-Mar (not mapped). Migrates at night, when hits lighted windows and is found in city centres; caught at lights in mist, S Tanzania and SE Kenya, May and Nov. Vagrant to São Tomé and Bioko I.
Status and Conservation. Not globally threatened. Widespread and locally common throughout most of range except in rain forest and arid regions; distribution and status relatively well documented, as species is less secretive than other crakes. Overgrazing, cultivation and wetland destruction must have

Bald-faced Rail (*Gymnocrex rosenbergii*); 76. Bare-eyed Rail (*Gymnocrex plumbeiventris*).

reduced habitats in many areas: e.g. early this century, not uncommon around Durban (Natal) in marshes which have since been drained. Despite this, and despite the fact that numbers are killed for food in some regions, species appears to be under no immediate threat. As for *C. crex*, some of grassland habitats may have increased locally in recent years.

63. **Corncrake**

Crex crex

French: Râle des genêts **German**: Wachtelkönig **Spanish**: Guión de Codornices

Taxonomy. *Rallus Crex* Linnaeus, 1758, Sweden.
Great variation in colour within all populations renders impractical recognition of race *similis* of Kazakhstan. Monotypic.

Distribution. W & NW Europe (from British Is) E to NW China and C Siberia. Winters mainly from E Zaire and S Tanzania S to E South Africa.

Descriptive notes. 27-30 cm; male 129-210 (165·5) g, female 138-158 (145) g; wingspan 42-53 cm. Sexes similar, but female has slightly warmer buff upperparts, narrower and duller grey streak over eye, and sometimes less grey on cheeks, neck and breast. Non-breeding plumage similar to breeding, but upperparts more rufous brown, less grey; male has less grey on side of head, and little or none on neck and breast; female has faint grey tinge in streak over eye, and often none on cheeks, neck and breast. Separable from *C. egregia*, which is sympatric in wintering areas, by larger size, paler upperparts, chestnut upperwing-coverts, less grey on face, neck and breast, and underparts barred with red-brown and white; easily distinguishable on plumage from other sympatric crakes in breeding and wintering ranges. Immature very like adult but probably with limited barring on upperwing-coverts. Juvenile like adult but has narrower, more buff-yellow-tinged, brown feather fringes on upperparts; less barring on upperwing-coverts; grey of sides of head, foreneck and breast replaced with buff-brown, sometimes with white dots on breast; less contrastingly barred flanks; duller iris; dark grey legs and feet. VOICE. Advertising call of male a monotonous, rasping double call "krek-krek"; calls from ground or low perch; early in breeding season may call for hours, both day and night. Male also has "growling-mew" call, like grunting squeal of small pigs, used when aggressive and in sexual display. Also various grunts, whistles, cheeps, clicks and quacking notes.

Habitat. Breeding habitat essentially dry to moist meadows and other grasslands, including alpine meadows, marsh fringes and cleared forest areas; prefers dense herbage from head height to c. 50 cm tall. Avoids very marshy areas, standing water, and open ground with rocks, gravel or sand. Locally inhabits fields of cereals, potatoes or fodder plants, especially after breeding, when adults may also move into tall vegetation along ditches, roads and dams. Occupies similar habitats on wintering grounds: predominantly in dry grassland and savanna, often in areas burnt during dry season; in Zambia occurs in dry to moist grass 0·3-2 m high; also frequents rank grass (especially near rivers, sewage ponds and pools), pastures, hay and lucerne fields, fallow fields, neglected cultivation, airfields, and even suburban gardens; in South Africa also in moist to shallowly flooded sedges and reedbeds. On migration, also found in wheatfields and at golf courses. From sea-level up to c. 3000 m.

Food and Feeding. Earthworms, molluscs, Isopoda, Diplopoda, Arachnida and insects (including Coleoptera, Diptera, Dermaptera, Orthoptera, Odonata, Dictyoptera and Hymenoptera); also small frogs, small mammals and birds (in captivity), green parts of plants, and seeds (especially grasses and grain). Diet similar in wintering areas; in South Africa takes many ants, termites and dung beetles (Scarabaeinae). In wintering areas normally forages within cover, occasionally on open grassy tracks or dirt roads; takes food from ground, low-growing plants and interior of grass tussocks; shifts and probes litter with bill; runs to catch active prey. Most active at dawn and dusk, after rain and during drizzle.

Breeding. Season Apr-Aug. Monogamous pair-bond of seasonal duration formerly assumed, but serial polygyny regularly occurs, males occupying shifting and overlapping home ranges, and mating with 2 or more females, remaining with a female only until second half of laying period. Nest-site in grassland; sometimes in safer sites along hedgerows, near isolated trees, or in bushy or weedgrown areas. Nest built on ground, in dense continuous vegetation or in tussock; sometimes only a scrape but usually shallow cup of grass, weeds and brambles, lined with dead leaves; often with surrounding stems pulled over top in loose canopy; average external diameter 12-15 cm; depth 3-4 cm; probably built by female only. Usually 8-12 eggs (6-14), laid at daily intervals; clutches of up to 19 by 2 females; incubation 16-19 days, by female only; hatching synchronous; chick has sooty brown-black down, tinged rufous brown on upperparts, grey-brown iris, pale pink bill (soon becoming black-brown), and black legs and feet; chicks precocial, leave nest soon after hatching; cared for by female alone, sometimes by 2 adults (not clear if 2nd is male or female); self-feeding after 3-4 days; independent at fledging or earlier; fledging 34-38 days, when capable of flight; post-juvenile moult then begins and is completed after c. 1 month. Age of first breeding 1 year. 1-2 broods, in W Europe 2 broods normal, first hatching mid-Jun, second in late Jul; replacements laid after egg loss.

Movements. Almost wholly long distance migrant, although numerous Dec-Feb records from W Europe, especially in 19th century when breeding population much larger. Main flyways into Africa: W route via Morocco and Algeria; and more important E route via Egypt; few cross Mediterranean between these flyways. Some, probably from E Palearctic, enter Egypt and Sudan via Arabia and Red Sea. Autumn movements Aug-Nov (peak Sept) in Europe; passes through Morocco and Egypt Aug-Oct (mainly Sept); arrives Sudan Sept-Oct and most pass through Kenya Oct-Dec; few recorded S of equator before mid-Nov. Most reach C & S Africa late Nov-Dec, and leave late Feb-Apr; return passage more rapid, birds crossing Mediterranean late Mar to mid-May; W Palearctic breeding grounds occupied from mid-Apr. Passage recorded Azerbaijan Sept-Nov and Apr-May. Occasionally winters Mediterranean basin and N Africa. Migrates at night, at low altitude; often strikes lighthouses. Vagrant W to Canary Islands, Azores, Madeira, Iceland, Greenland (c. 20 records), North America (c. 17 records) from Baffin I along Atlantic coast and S to Bermuda; S & SE to India/Pakistan (2), Sri Lanka (3), Seychelles, and Australia (New South Wales and off W Australia); New Zealand record not accepted; in Africa very rare or vagrant to Libya (2), W Mauritania (2), Mali, SW Niger, Chad (2), Nigeria (4), W Somalia (4), Ivory Coast, Ghana, Cameroon, Gabon (3), Congo (3), Angola (2), W Namibia (1) and W Cape (1). High degree of vagrancy indicative of dispersive ability and of readiness with which birds are blown off course by opposing winds.

Status and Conservation. VULNERABLE. Although apparently still common and widespread in parts of range, there is clear evidence of very steep long-term population decline, c. 50% over 20 years, detected in Europe, Russia and Africa; this decline continues and status critical in some W European countries. In breeding areas, drainage of sites, agricultural intensification and changes in grassland management are main causes of habitat loss and of heavy losses of breeding birds, eggs and young. Does not appear to be threatened on African wintering grounds, where grassland habitats may be increasing as woods are felled and some agricultural areas no longer farmed, although grassland habitats suffering locally as result of overgrazing and cultivation. Conservation action includes: establishing reserves in key breeding areas; management to protect nests, adults and young from destruction when cutting meadows for hay or silage; supporting traditional land management practices which benefit species; encouraging continued production of hay; investigating mortality on migration, and seeking ways to reduce such mortality. Integrated national and international conservation approach required. In Britain, numbers have recently shown modest increases in areas where conservation management measures have been implemented successfully.

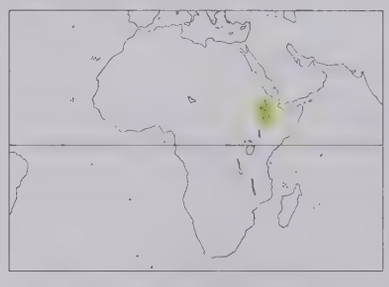
Genus *ROUGETIUS* Bonaparte, 1856



64. **Rouget's Rail**

Rougetius rougetii

French: Râle de Rouget **German**: Rougetralle **Spanish**: Rascón Etíope
Other common names: Abyssinian Rail

Taxonomy. *Rallus Rougetii* Guérin-Méneville, 1843, Ethiopia.
Affinities uncertain. Monotypic.

Distribution. Ethiopia and Eritrea.

Descriptive notes. 30 cm. Combination of unstreaked olive brown upperparts, cinnamon-rufous underparts and white undertail-coverts unique among African rallids. Sexes alike. Immature paler than adult, with brown eye and bill; juvenile undescribed. VOICE. Advertising call a loud, ringing, repeated "wreeeee-creeeeuw", given during day and on moonlit nights but mainly in morning and evening; several birds may call together. Alarm call a shrill, piercing "dideet" or "di-dii".

Habitat. Ethiopian and Eritrean highlands at 2000-4100 m, where frequents marshy situations in montane grassland and moorland. Found in lush grass, reeds and bushes at margins of pools and streams, in marshy meadows, in patches of tussocky marsh grass and lobelias in wet hollows, and in *Alchemilla* bogs; also among *Alchemilla* or heaths on dry ground.

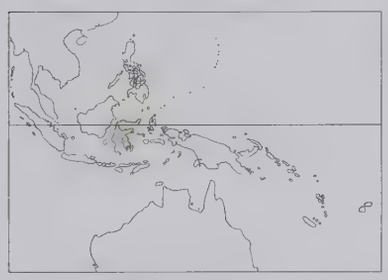
Food and Feeding. Diet includes seeds, aquatic insects (especially water beetles), crustaceans and small snails. Recorded foraging in open meadows and on bare mud; also in shallow water, hopping from stone to stone; seen to dive into water at waterfall like dipper (*Cinclus*), subsequently reappearing in calmer water.

Breeding. Lays Mar-Oct. Monogamous; solitary nester. Nest is a pad of dead rushes on wet ground among high rushes or in rushes over water. Eggs 4-5, laid at daily intervals; incubation performed by female, probably also by male; both parents tend chicks, which apparently remain with adults until fully grown; one chick was accompanied by 10 adults, suggesting some degree of co-operative breeding.

Movements. None recorded.

Status and Conservation. Not globally threatened. Currently considered near-threatened. Widespread in highland areas from Eritrea to Kaffa (Maji Plateau) and regarded as common to locally abundant, but visits in 1989 to areas where species had been not uncommon in 1975 yielded extremely few sightings; the observers concluded that the greatly increased grazing pressure in marshlands and along streams had depleted vegetation cover to the extent that much habitat had become unsuitable. Grassland habitats are also being ploughed up for cereal growing. Such habitat changes have presumably affected populations in some areas, while recent droughts have probably also caused reductions in numbers.

Bibliography. Ash & Gullick (1989), Cheesman & Sclater (1935), Collar *et al.* (1994), Dowsett & Forbes-Watson (1993), von Erlanger (1905), Harrison & Parker (1967), Mackworth-Praed & Grant (1957), van Perlo (1995), Snow (1978), Urban (1980), Urban *et al.* (1986).



Genus *ARAMIDOPSIS* Sharpe, 1893

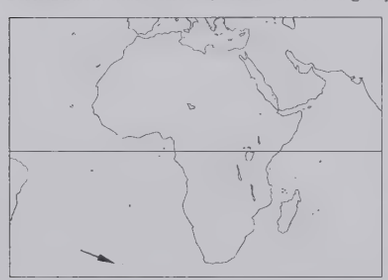
65. **Snoring Rail**

Aramidopsis plateni

French: Râle de Platen **German**: Schnarchralle **Spanish**: Rascón de Platen
Other common names: Platen's/Celebes Rail

Taxonomy. *Rallus plateni* A. W. H. Blasius, 1886, Rurukan, Sulawesi.
Sometimes retained in *Rallus*, but bill shape and plumage are somewhat similar to a pro-*Rallus* group (*Dryolimnas-Atlantisia*), near to which present species is provisionally placed. Monotypic.
Distribution. N, NC & SE Sulawesi.

Descriptive notes. 30 cm. Flightless; heavy legs and feet; appears tailless in the field, with slightly downcurved bill. Sexes similar but female has brighter rufous hindneck and often less white on chin; base of bill and iris reddish (yellowish in male). Occurs alongside similar-sized but quite different *Gymnocrex rosenbergii*; only other sympatric rallids with which may be confused are similar-sized *Gallirallus philippensis*, which can occur near forest and has patterned head, upperparts and breast, and smaller, marsh-dwelling *G. striatus*, which has similarly coloured underparts and chestnut nape, but has distinctively barred upperparts. Immature and juvenile undescribed. VOICE. Distinctive rather quiet call, lasting 1-2 seconds, rendered "ee-orrrr": very brief wheeze followed by longer snoring noise. May be uttered frequently. Possibly similar to call of *Gymnocrex rosenbergii*. Also brief, quiet, deep sigh "hmmmm".
Habitat. Dense liana and bamboo secondary growth on borders of lowland or highland forest; occasionally enters adjacent primary forest. On Minahasa Peninsula recorded from secondary growth on mountainsides skirted at base by plains of elephant grass and small bushes. In Lore Lindu National Park commonest in wet, impenetrable secondary vegetation, and in 1987 observations were made in old secondary growth (little different in structure from primary forest), with dense understorey dominated by rattans, on very wet and peaty ground bordering a fast stream. Reference to species entering rice fields could result from confusion with *Gallirallus philippensis*.
Food and Feeding. Possibly largely crabs; lizards also recorded. Captive bird survived on crabs for some time. Forages for crabs in mountain streams; also seen foraging in a shallow muddy gulley.
Breeding. Only record is of an adult foraging with 2 chicks on 18th Aug 1983.
Movements. None.
Status and Conservation. VULNERABLE. Locally distributed, rare and elusive; known from 11 specimens, all but one collected before 1940, and from 4 sightings between 1983 and 1992. Vulnerable to deforestation, which is already rather widespread in parts of Sulawesi, and also to introduced or feral predators. On Minahasa Peninsula was apparently quite common locally in past but, even as long ago as 1941, was described as threatened by increasing deforestation along R Menado, and was said to have been almost extirpated in some areas by large-scale snaring.
Bibliography. Andrew, P. (1992), Andrew, P. & Holmes (1990), Collar & Andrew (1988), Collar *et al.* (1994), Coomans de Ruiter (1947a), Lambert (1989), Ripley (1977), Stresemann (1941), Watling (1983), White & Bruce (1986).



Genus *ATLANTISIA* Lowe, 1923

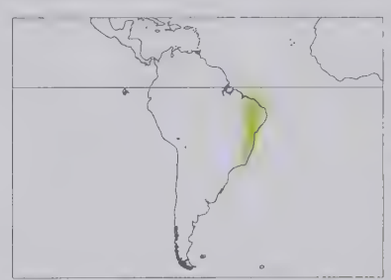
66. **Inaccessible Rail**

Atlantisia rogersi

French: Râle atlantis **German**: Atlantisralle **Spanish**: Rasconcillo de Tristan da Cunha

Taxonomy. *Atlantisia rogersi* Lowe, 1923, Inaccessible Island, Tristan da Cunha.
Monotypic.
Distribution. Inaccessible I, Tristan da Cunha group.

Descriptive notes. 13-15·5 cm; male 35-49 (40·5) g, female 34-42 (37) g. Smallest flightless bird in the world. Plumage decomposed and hair-like; adults easily distinguishable by chestnut-brown back and obvious white barring on flanks and belly. Sexes similar; female smaller and paler grey, most noticeably on head, throat and breast, with faint brown wash on underparts. Immature male blackish grey with no brown on underparts, no white barring, and orange-red iris; immature female medium to pale slate grey with brown wash, buffy or faint white barring, and brown or orange-red iris. Juvenile black, with no white barring; iris brown. VOICE. Highly vocal. Pair members give loud trill when meeting and in threat display to other adults. Aggressive calls include loud squealing followed by prolonged twitter, a hard "tchick", and a "weechup". Contact calls include variants of quiet, repeated "tchik" and "chip" notes; alarm call a hard "chip".
Habitat. Occurs in all native vegetation types at all altitudes. Population density highest in coastal tussock-grass (*Spartina arundinacea*), sometimes mixed with ferns (*Blechnum penna-marina*), and in patches of sedges (*Carex thouarsii*, *Scirpus sulcatus*) on the peaty plateau; also occurs in fern-bush and island-tree thickets (with *Phylica* and *B. palmiforme*) on the plateau, and in *Empetrum* and *Scirpus* heath at highest altitudes. Apparently absent from short dry tussocks on cinder cones. Also forages on boulder beaches. Frequently makes use of natural connecting cavities under boulder beaches, and small tunnels (formed by regular use) through *Blechnum* and sedge mats, for access and concealment.
Food and Feeding. Earthworms, amphipods, isopods, mites, centipedes, insects (weevils, beetles, flies, moths, caterpillars); also berries of *Empetrum* and *Nertera*, and seeds of dock (*Rumex*). Does not eat fish or bird carrion. Forages in every available habitat, including very short vegetation, boulder beaches and marshy seepage zones. Foraging actions slow and deliberate, rather mouse-like, and species appears to occupy the ecological niche of a mouse; when foraging out of cover, is extremely wary. Active mainly during day but also forages at night.
Breeding. Lays Oct-Jan. Monogamous; pair-bond permanent; apparently has loose, flexible territorial system. Nest built on ground, at base of tussock grass clump or in ferns under dense cover of fallen tussock grass; oval or pear-shaped, with entrance at narrower end and access track or tunnel extending up to 0·5 m through vegetation; nest thinly domed or sturdily roofed; constructed of vegetation in which sited (either dead tussock leaves or dead sedges); one nest had external length 17 cm, external width and height 13 cm, cavity diameter 9 cm and entrance diameter 4 cm. Eggs 2, large (c. 25% of female's mass); both sexes incubate (period unknown); eggs hatch 12·5-32 hours apart; black downy chicks have dark brown iris, and black bill, legs and feet; chicks leave nest within 1 day of hatching; fed and cared for by both parents; fledging period unknown; at least some young still with parents when subadult. Immature plumage may be retained for 1-2 years, suggesting delayed maturity. In 1982, of 8 eggs found, 5 (63%) hatched, indicating low fertility and low breeding success; chick mortality high, chiefly from predation by Tristan Thrushes (*Nesocichla eremita*); wet weather also believed to cause losses.
Movements. None.
Status and Conservation. VULNERABLE. Abundant within its very restricted range and in no immediate danger. Total population estimated at c. 8400 birds, living at high density; population probably at carrying capacity, with regulatory mechanisms such as low fertility and delayed maturity operating to limit productivity. Most important potential threat is risk of mammalian predators (especially cats and rats) becoming established on the island as result of the infrequent visits by Tristan islanders. Two other *Atlantisia* rails, *A. elpenor* of Ascension I and *A. podarces* of St Helena, have become extinct since advent of man to the islands. Last century, goats and pigs were present on Inaccessible and did much damage to vegetation, but eradicated by 1950. Only significant natural predator of adults is Brown Skua (*Catharacta antarctica*), which apparently does not pose a threat. In 1872 and 1909 the island's tussock grass was burnt; these events would probably have killed many rails. Alien plants and invertebrates occur but apparently have no adverse effect, while introduced centipedes may be important food item of the rails. Proposed conservation measures include introduction of the rails to Gough I or Nightingale I, as safety measure, but this might adversely affect these islands' endemic invertebrates. Captive breeding has also been recommended to build up reserve stocks. Inaccessible has no protected area status, and agricultural development is still advocated; granting of full protection to the island, and prohibition of agriculture, strongly recommended to help ensure survival of the island's birds.
Bibliography. Anon. (1995p), Barrow (1910), Broekhuysen & Macnae (1949), Collar & Andrew (1988), Collar & Stuart (1985), Collar *et al.* (1994), Elliott (1953, 1957), Flint (1967), Fraser (1989), Fraser *et al.* (1992), Hagen (1952), Holdgate & Wace (1961), Lowe (1928), Olson (1973a), Richardson (1984), Rothschild (1928), Ryan *et al.* (1989), Voous (1962), Wace & Holdgate (1976).



Genus *ARAMIDES* Pucheran, 1845

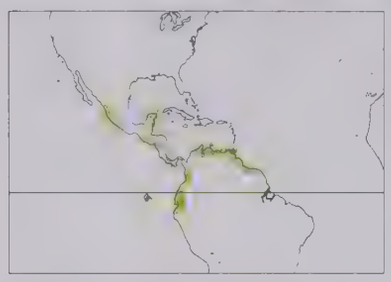
67. **Little Wood-rail**

Aramides mangle

French: Râle des palétuviers **German**: Küstenralle **Spanish**: Cotara de Manglar

Taxonomy. *Gallinula mangle* Spix, 1825, coast of Bahia, Brazil.
Genus sometimes merged into *Eulabeornis*. Monotypic.
Distribution. E Brazil.

Descriptive notes. 27-29 cm; 1 female 164 g. Sexes alike. Smallest member of genus; differs from all congeners in having greenish bill with red base, and from all except *A. calopterus* and *A. axillaris* in underwing-coverts black narrowly barred white or cinnamon, instead of rufous with black bars; lacks grey underparts of *A. saracura* and *A. calopterus*, and extensive grey on head and foreneck of *A. cajanea* and *A. ypecaha*; *A. axillaris* rufous on head, neck and underparts; *A. wolfi* darker, especially on underparts, and has yellow patch on forehead. Immature and juvenile not described. VOICE. Not described.
Habitat. Mainly coastal swamps and lagoons, including mangrove swamps; details of inland habitats not recorded. Larger sympatric *A. cajanea* occurs locally in mangroves, but apparently occurs more widely in swampy forests, woodland, on riverbanks, at pools and on dry ground with grass and bushes; also sympatric *A. saracura* inhabits forest.
Food and Feeding. Nothing known. At low tide, in estuary of R Traripe, Bahia, birds seen emerging from mangroves to feed on banks of river.
Breeding. Unknown.
Movements. None recorded.
Status and Conservation. Not globally threatened. Status unclear; known from NE Pará, Maranhão, Ceará, Bahia, Pernambuco and Alagoas S to São Paulo; between these limits probably less widespread than indicated on map, as species apparently confined largely to coastal localities in NE & E Brazil, with only a few inland localities known. In view of its potentially restricted distribution, the almost total lack of knowledge about its natural history, and the possibility of threats to its wetland habitats (similar to those facing *A. wolfi*), species should at least be considered Data Deficient and worthy of urgent investigation.
Bibliography. Blake (1977), Forrester (1993), Hellmayr & Conover (1942), Meyer de Schauensee (1982), Pinto (1964), Ripley (1977), Ruschi (1979), Sick (1985c, 1993).



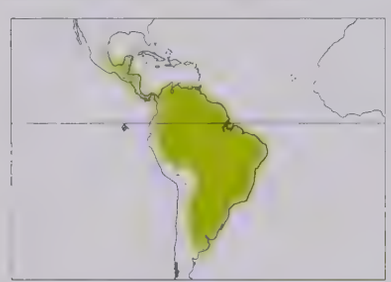
68. **Rufous-necked Wood-rail**

Aramides axillaris

French: Râle à cou roux **German**: Braunkappenralle **Spanish**: Cotara Cuellirrufa

Other common names: Rufous-crowned Wood-rail

Taxonomy. *Aramides axillaris* Lawrence, 1863, Barranquilla, Colombia.
Genus sometimes merged into *Eulabeornis*. Monotypic.
Distribution. Coastal Mexico and Belize; Honduras to Panama; NW Colombia locally S to W Ecuador and NW Peru (unconfirmed), and E to Guyana (including Trinidad).



Descriptive notes. 28-30 cm; male 262-327 g, unsexed mean 275 g. Sexes alike. Only slightly larger than *A. mangle*, like which has underwing-coverts black, barred white or rufous. Differs from all congeners in lacking grey on head, neck, breast, sides and upper belly, these regions being rufous to chestnut; also has orange-brown, rather than red, eye. Immature and juvenile duller than adult; crown dull grey-brown; side of head pale grey; mantle darker grey; throat greyish buff; neck and underparts ashy grey-brown; eye brownish. VOICE. Incisive, loud "pik-pik-pik" or "pyok-pyok-pyok", also described as a yelp, repeated c. 8 times, often antiphonally; also gruff "kik" of alarm. Often calls at night.
Habitat. Mangrove swamps, coastal marshes, lagoons and mudflats, and swamp forest; in South America, also dense forest undergrowth, forest edge and deciduous woodland. Mainly occurs in coastal and low altitude areas in Central America, but in South America ascends to 1800 m in open cloud forest.
Food and Feeding. Eats mainly crabs. Most active at dawn and dusk; seldom leaves dense cover but immatures venture onto open mudflats to catch crabs.
Breeding. Trinidad, Jul, Oct; Peru, Feb (unconfirmed). Nest a bowl or platform of small twigs, lined weed stems and dead and green leaves; placed 1·8-3 m up in small tree or vine tangle, or on dead stump; sometimes over water. Eggs 5. No further information available.
Movements. None recorded.
Status and Conservation. Not globally threatened. Although common in a few isolated localities, generally seems to be uncommon to rare throughout range.
Bibliography. Best *et al.* (1993), Blake (1977), ffrench (1973), Haverschmidt (1968), Haverschmidt & Mees (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Howell & Webb (1995a), Meyer de Schauensee & Phelps (1978), Monroe (1968), Parker *et al.* (1995), Peterson & Chalif (1973), Ridgely (1981), Ridgely & Gwynne (1989), Schaldach (1963), Slud (1964), Snyder (1966), Stiles & Skutch (1989), Tostain *et al.* (1992), Wetmore (1965).

69. Grey-necked Wood-rail

Aramides cajanea

French: Râle de Cayenne **German**: Cayenneralle **Spanish**: Cotara Chiricote
Other common names: Cayenne Wood-rail

Taxonomy. *Fulica Cajanea* P. L. S. Müller, 1776, Cayenne, French Guiana.
Genus sometimes merged into *Eulabeornis*. The form labelled as "*A. gutturalis*", known only from a single specimen from Lima, Peru, is a poorly prepared specimen of present species. Eight subspecies recognized.
Subspecies and Distribution.
A. c. mexicanus Bangs, 1907 - S Mexico.
A. c. albiventris Lawrence, 1867 - Yucatán to Belize and N Guatemala.
A. c. vanrossemi Dickey, 1929 - S Mexico (Oaxaca) to S Guatemala and El Salvador.
A. c. pacificus A. H. Miller & Griscom, 1921 - Caribbean slope of Honduras, and Nicaragua.
A. c. plumbeicollis Zeledon, 1888 - NE Costa Rica.
A. c. latens Bangs & Penard, 1918 - San Miguel and Viveros (Pearl Is, Panama).
A. c. morrisoni Wetmore, 1946 - San José and Pedro González (Pearl Is, Panama).
A. c. cajanea (P. L. S. Müller, 1776) - Costa Rica to Colombia, E through Venezuela and Trinidad to Brazil, and S to N Argentina and Uruguay.

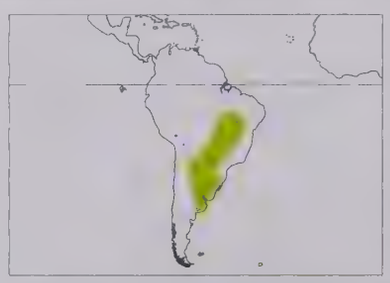
Descriptive notes. 33-40 cm; 350-466 g. Sexes alike. Large wood-rail and only member of genus with entirely grey head and neck (with rufous or dark patch on occiput and grey extending to upper mantle) and, in two races, white on belly; underwing-coverts cinnamon with black bars. Immature similar to adult. Juvenile duller than adult: belly sooty black, flecked with buff; bill and legs dusky; eyes brownish. Races separated on colour of occiput, brown or black in *cajanea*, *latens* and *morrisoni*, rufescent in the rest; presence of white patch between black belly and orange breast in *albiventris* and *mexicanus*; intensity of rufous on mantle, brightest in *plumbeicollis*; overall colour, *latens* palest; and size, *latens* and *morrisoni* smallest, *vanrossemi*, *cajanea* and *mexicanus* largest. VOICE. Very vocal, calling most often at dawn, dusk, and at night; often in chorus or duet. Commonest call a prolonged and varied series of loud, crazed-sounding, rollicking, popping and clucking notes, variable in form and rendered "chirin co chirin co-co-co", "kook-kooky, kook-kooky, ko-ko-ko", etc. Alarm call a loud, harsh cackle or clucking shriek.
Habitat. Swampy forest, forest streams and rivers, secondary growth and deciduous woodland; coastal swamps and mangroves; marshes and marshy thickets, particularly in forested areas; rice fields, and even cane fields and scrubby pastures as long as they include wet areas; also seasonal pools near woodland; in Colombia sometimes occurs some distance from water. Normally in dense cover. Lowlands up to 2000 m, rarely 2300 m.
Food and Feeding. In mangroves preys heavily on crabs; elsewhere takes molluscs, arthropods (including Diplopoda, cockroaches and locusts), frogs, seeds, berries and palm fruits; once a water snake 30 cm long. Also takes maize, rice (dry or cooked) and bananas. Hammers large snails with bill to extract them from shell; jumps high to break off clusters of berries. Normally wary and secretive but sometimes forages openly in short grass close to thickets, wades in streams or forages on muddy tracks. Probes and moves aside leaf litter and other debris with partly open bill. Sometimes accompanies other birds following army ants. Apparently often feeds at night.
Breeding. Mexico, breeding condition Jan, May; Costa Rica, Apr-Sept; Panama, Apr; Colombia, breeding condition Mar-Jun; Venezuela, Jul-Sept; Trinidad, May-Aug; Surinam, Mar-Jun. Monogamous; pair-bond apparently permanent. Nest a deep bowl of twigs, dried weed stems and similar materials, or a compact, bulky mass of dead leaves and twigs with a shallow central depression; usually placed 1-7 m up in a bush, vine, low tree or on tree stump, often over or near water, sometimes on ground; external diameter 30-36 cm. Eggs 3-7; incubation 20+ days, by both parents (in captivity, male incubated by day and female by night); black downy chicks have brownish head, dull reddish bare skin around dark eyes, and black bill with flesh-coloured base; chicks leave nest after 1-2 days; young up to 40 days old sometimes use a brood nest; chicks fed and cared for by both parents; in captivity, young independent at 29 days, when 75% grown; at 25 days, one downy young appeared greyish, it was almost fully grown at 7 weeks and disappeared c. 1 week later.
Movements. None recorded, but records at 2300 m in Colombia probably of wanderers from lower elevations.
Status and Conservation. Not globally threatened. Apparently still fairly common to common over much of its extensive range, although must be adversely affected by habitat destruction; locally distributed in Guyana. In 1970's race *latens* known only from four specimens; present status unknown. Able to adapt to habitat modification: in Costa Rica persists in remnant streamside woods amid pasture or agricultural lands.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Contreras *et al.* (1990), Dickey & van Rossem (1938), ffrench (1973), Friedmann & Smith (1950), Haverschmidt (1968), Haverschmidt & Mees (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Howell & Webb (1995a), Kilham, L.A. (1979), Lowery & Dalquest (1951), Meyer de Schauensee & Phelps (1978), Monroe (1968), Olson (1974a), de la Peña (1992), Ridgely (1981), Ridgely & Gaulin (1980), Ridgely & Gwynne (1989), Rutgers & Norris (1970), Sick (1985c, 1993), Skutch (1994), Slud (1964), Snyder (1966), Stiles & Skutch (1989), Tostain *et al.* (1992), Wetmore (1965).

70. Brown Wood-rail

Aramides wolfi

French: Râle de Wolf **German**: Esmeraldasralle **Spanish**: Cotara Morena
Other common names: Brown-backed Wood-rail

Taxonomy. *Aramides wolfi* Berlepsch and Taczanowski, 1884, Chimbo, Ecuador.
Genus sometimes merged into *Eulabeornis*. Monotypic.
Distribution. W Colombia to SW Ecuador and extreme NW Peru.



Descriptive notes. 33-36 cm. Sexes alike. Relatively large wood-rail, mainly brightish to darkish brown above and below, with ashy grey head and nape, and bare yellow patch on forehead; underwing-coverts chestnut with black bars. Differs from *A. cajanea*, *A. ypecaha*, *A. saracura* and *A. calopterus* in having no grey on foreneck or underparts; from *A. axillaris* in size and also in lack of rufous or chestnut on head; and from *A. mangle* in size, overall darker colouring, blackish lower flanks and belly, and bill colour. Immature and juvenile undescribed. VOICE. Frequently repeated "kui-co-mui", apparently much like call of *A. cajanea*.
Habitat. Forest, secondary growth, forested rivers and mangroves; also riverine marsh and swampy woodland. Recorded up to 900 m.
Food and Feeding. No information available.
Breeding. Not described. Black downy chick has grey-black legs and feet, and reddish brown bill with yellow tip.
Movements. None recorded.
Status and Conservation. VULNERABLE. A very poorly known species which has a restricted range and appears to have become extremely rare, at least in Ecuador, owing to extensive destruction of its mangrove habitats. Its inability to survive in isolated patches of humid forest is predicted from observations of one such habitat island in Ecuador. It has been unreported for years from Colombia, and is recorded only once from Peru (Puerto Pizarro, Department of Tumbes, Sept 1977), so that a recent record from Ecuador (Feb 1994) is welcome evidence of its survival. There is an urgent need for further investigation of its status and natural history.
Bibliography. Blake (1977), Boyd & Alley (1948), Butler (1979), Clay *et al.* (1994), Collar *et al.* (1994), Graves (1982), Hellmayr & Conover (1942), Hilty & Brown (1986), Leck (1979), Meyer de Schauensee (1982), Olivares (1957), Ripley (1977), Ripley & Beehler (1985).

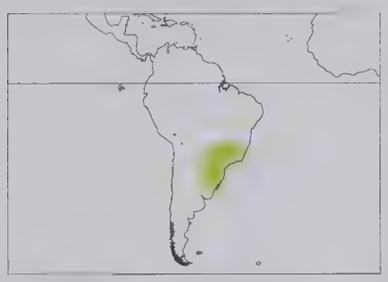
71. Giant Wood-rail

Aramides ypecaha

French: Râle ypécaha **German**: Ypecaharalle **Spanish**: Cotara Ipacaá

Taxonomy. *Rallus ypecaha* Vieillot, 1819, Paraguay.
Genus sometimes merged into *Eulabeornis*. Monotypic.
Distribution. E & SE Brazil, Paraguay, Uruguay and NE Argentina.

Descriptive notes. 41-45 (possibly up to 53) cm; 1 female 765 g. Sexes alike; female slightly smaller. Largest *Aramides*; handsome bird, with pale bluish grey face and foreneck, olive upperparts, and delicate brownish pink flanks and upper belly; underwing-coverts chestnut with black bars; stance upright, gait elegant. *A. cajanea* has rufous or brown-black patch on nape, but grey hindneck; *A. saracura* and *A. calopterus* darker and extensively grey below, and latter has striking reddish chestnut on side of neck and upperwing-coverts. Immature slightly duller than adult; legs brownish red; bill has brownish tinge. Juvenile not described. VOICE. Calls during day and also in evening, when birds congregate in selected spots and set up an astonishingly powerful, even deafening, chorus of screams, shrieks and wheezes, rushing frenziedly about with wings spread and bill raised vertically. Calls described as: reminiscent of a hysterical human saying "all..wacky....all..wacky"; also a piercing, high, single "eeeeeeok", a bark, a low "keaaw" and an explosive "puk".



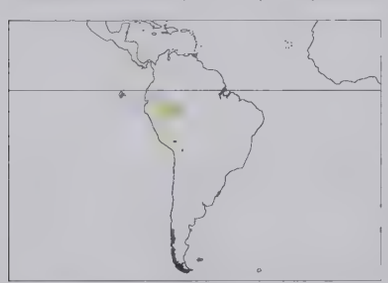
Habitat. Open marshes, lightly wooded swampy areas, fields and pastures near water and cover, and gallery forests; more likely than other *Aramides* species to appear in the open. Restricted to lowland areas.
Food and Feeding. Not recorded in the wild. In captivity, eats insect larvae, eggs, minced meat, apple and meal.
Breeding. Nest of grasses and weed stems, c. 30 cm in diameter, built 1+ m above water, in shrub or broken-down vegetation. Eggs 4-5; chicks dark mahogany brown. Other information from captive breeding: eggs laid at daily intervals; incubation 24 days, by both sexes; chicks left nest after 3-4 days; fed and cared for by both parents for 8-9 weeks; last brood stayed with parents for over 3 months; chicks half-grown at 5 weeks; renesting occurred when young of first brood 6 weeks old; 3 clutches laid in season.
Movements. None recorded.
Status and Conservation. Not globally threatened. Formerly common to abundant in much of its range; in 1980's was common in Rio Grande do Sul, Brazil, where it is a frequent victim of steel traps set in marshes for fur-bearing animals. Often kept in captivity in South America. No recent information on status, but species must have decreased in numbers as a result of extensive habitat destruction.
Bibliography. Belton (1984), Blake (1977), Brown (1974), Canevari *et al.* (1991), Contreras *et al.* (1990), Friedmann (1927), Hellmayr & Conover (1942), Hudson (1920), Klimaitis & Moschione (1987), Meyer de Schauensee (1982), Narosky & Yzurieta (1987), Olrog (1984), de la Peña (1992), Pinto (1964), Ripley (1977), Rutgers & Norris (1970), Shore-Baily (1926), Sick (1985c, 1993).

72. **Slaty-breasted Wood-rail**

Aramides saracura

French: Râle saracura **German**: Saracuraralle **Spanish**: Cotara Saracura
Other common names: Saracura Wood-rail

Taxonomy. *Gallinula saracura* Spix, 1825, Brazil.
Genus sometimes merged into *Eulabeornis*. Monotypic.
Distribution. SE Brazil, from S Minas Gerais E to Espírito Santo and S to Rio Grande do Sul, whence W to NE Argentina (Misiones) and Paraguay.



Descriptive notes. 34-37 cm; 1 male 540 g. Sexes alike. Only *Aramides* with grey of head and neck extending as far as belly apart from *A. calopterus*, which has maroon-chestnut ear-coverts and sides of neck, and median and greater upperwing-coverts. Differs from all congeners in having green bill with bluish base, and duller reddish or yellowish brown legs and feet; underwing-coverts chestnut with black bars. Immature and juvenile undescribed. Voice. Variety of loud, resounding, noisy cries, including "po-quit kwaa kwaa kwaa", "po-peek" and "po-pereek". Often calls continuously for several minutes; usually in duet but not in unison. Also an irritated, rapidly repeated series of "quir" notes. Calls most frequently during day.
Habitat. Forests and woodland patches; prefers swampy or boggy areas or stream edges, but is not dependent on such sites. Occasionally enters house gardens. Not usually seen in open marshes.
Food and Feeding. Not recorded.
Breeding. One nest recorded: found at Novo Hamburgo (Rio Grande do Sul), spring 1961; situated 2 m above ground in thick bush; eggs 4 or 5.
Movements. None recorded.
Status and Conservation. Not globally threatened. Shy and infrequently observed; status unknown over most of range, but common in N & E Rio Grande do Sul in 1980's. Status elsewhere in need of investigation, especially in view of the potential adverse effects of continued destruction of its forest habitat. Because of this, and because nothing is known of its natural history, species should probably be classified as a Data Deficient species.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Hayes (1995), Hellmayr & Conover (1942), Lowen *et al.* (1995), Meyer de Schauensee (1982), Narosky & Yzurieta (1987), Olrog (1984), de la Peña (1992), Pinto (1964), Ripley (1977), Sick (1985c, 1993).

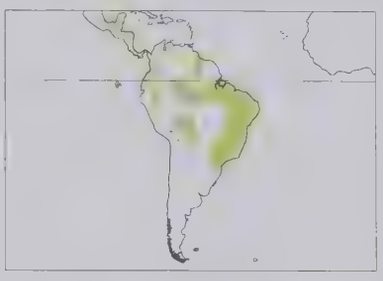
73. **Red-winged Wood-rail**

Aramides calopterus

French: Râle à ailes rouges **German**: Rotflügelralle **Spanish**: Cotara Alirrufa

Taxonomy. *Aramides calopterus* P. L. Sclater & Salvin, 1878, Sarayacu, Ecuador.
Genus sometimes merged into *Eulabeornis*. Monotypic.
Distribution. E Ecuador, NE Peru (Loreto) and Brazil in SW Amazonas (upper R Jurua and R Urucu).

Descriptive notes. 31-33 cm. Sexes alike. Rather dark; separated from all congeners except *A. saracura* in grey of head and neck extending to belly; maroon-chestnut ear-coverts, sides of neck, and median and greater upperwing-coverts; underwing-coverts black with white bars, a character shared only with *A. mangle* and *A. axillaris*. Immature similar to adult but with blackish bill, legs and feet. Juvenile undescribed. Voice. Not described.
Habitat. Seasonally flooded *igapó* forest, forest in the vicinity of streams and creeks.
Food and Feeding. No information available.
Breeding. Unknown.
Movements. None recorded.
Status and Conservation. Not globally threatened. Very rarely observed; status unknown over most of range, but described as rare in Amazonas earlier this century and uncommon on upper R Urucu, Amazonas, in late 1980's; status elsewhere in urgent need of investigation. In view of its scarcity in some areas, its restricted distribution in threatened habitats and the lack of knowledge of its natural history, species should be classified as a Data Deficient species.
Bibliography. Blake (1977), Butler (1979), Gyldenstolpe (1945), Hellmayr & Conover (1942), Meyer de Schauensee (1982), Parker *et al.* (1982), Peres & Whittaker (1991), Ripley (1977).



Genus *AMAUROLIMNAS* Sharpe, 1893

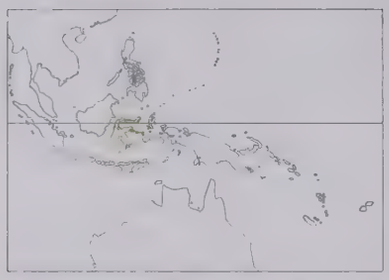
74. **Uniform Crake**

Amaurolimnas concolor

French: Râle concolore **German**: Einfarbralle **Spanish**: Cotara Café

Taxonomy. *Rallus concolor* Gosse, 1847, Jamaica.
Sometimes included, with *Aramides*, in *Eulabeornis*. Possibly derived from *Aramides* stock, and has identical bill structure to the smaller *Aramides* species. Nominate *concolor* of Jamaica recently extinct. Two extant subspecies recognized.
Subspecies and Distribution.
A. c. guatemalensis (Lawrence, 1863) - S Mexico S to Ecuador.
A. c. castaneus (Pucheran, 1851) - Venezuela, the Guianas, Brazil, E Peru and E Bolivia.

Descriptive notes. 20-23 cm; 1 male 133 g, unsexed mean 95 g. Sexes alike. An entirely brown to rufous brown bird; superficially resembles a diminutive *Aramides* species in build, posture and bare parts colours, but has no grey in plumage and lacks the barred underwing-coverts, and the black hindbody and tail, characteristic of *Aramides*. Differs from rather similar *Anurolimnas castaneiceps* and *A. viridis* in brown-tinged face, more extensively rufous underparts, yellowish green bill, and different voice. Immature similar to adult but more dusky on both upperparts and underparts, with white shaft streaks to feathers of throat and breast, and yellow eyes. Juvenile has brownish eyes and dull legs. Races separated on size, with *guatemalensis* smallest of the three; colour of upperparts, rufous in *concolor*, olivaceous in other races; and colour of underparts, most rufous in *castaneus*. Voice. Loud, arresting whistled calls, reminiscent of *Aramides*. Song is series of 6-20 upslurred "tooee" whistles, loudest during middle of sequence; pair members give clear, but not loud, whistled "tooo" notes to each other; alarm call a sharp, nasal "kek".
Habitat. Forested swamps, moist and flooded forests, damp ravines, and heavy vine-tangled thickets along edges of streams; locally at edges of mangroves; often found away from water in dense second growth adjoining forest, especially favouring areas with hanging dead and decaying leaves in *Heliconia* thickets, and also in dense thickets bordering cultivation. Essentially confined to lowlands, occurring from sea-level up to c. 1000 m.
Food and Feeding. Earthworms, insects, spiders, small frogs and lizards; also seeds and berries. Normally remains in cover; forages deliberately, walking slowly and pecking into leaf litter, detritus and dead leaves hanging from plants; also probes in wet earth to depth of bill and digs with bill in soft mud.
Breeding. Costa Rica, breeding condition Jul, most song Aug-Dec, one probable nest Nov: Pearl Is (Panama), eggs found (possibly of this species) in Sept. Probably monogamous and territorial. Costa Rica nest was a loose cup of leaves filling hollow in top of vine-covered stump in treefall clearing in swamp forest, c. 5 m from stream and 1 m from dense thicket; contained 4 eggs, which agreed in size and colour with the only egg of this species definitely known.
Movements. None recorded.
Status and Conservation. Not globally threatened. Formerly considered to be locally distributed; by 1970's *guatemalensis* was regarded as very rare except in NE Costa Rica, where it was locally fairly common, while *castaneus*, known from only a few specimens, was also regarded as rare. In 1980's, *guatemalensis* described as rare in Panama and Colombia, while *castaneus* described as apparently rather common in coastal Alagoas, Brazil. Because of its secretive habits species is undoubtedly overlooked, and is possibly more widely distributed than currently known, but certainly adversely affected by destruction of its forest habitats. Given present state of knowledge, it should be considered Data Deficient and worthy of investigation, and possibly rare and threatened in some parts of its range. Nominate race was last reported from Jamaica in 1881, its extirpation presumably being due to the introduction of a mongoose species. The only record of race *castaneus* from French Guiana is a specimen from Cayenne, collected in 1833.
Bibliography. Blake (1977), Dickerman (1971), Gosse (1847), Hellmayr & Conover (1942), Hilty & Brown (1986), Howell & Webb (1995a), Howell *et al.* (1992), Kiff (1975), Meyer de Schauensee & Phelps (1978), Monroe (1968), Orians & Paulson (1969), Ridgely (1981), Ridgely & Gwynne (1989), Sick (1985c, 1993), Slud (1964), Snyder (1966), Stiles (1981), Stiles & Skutch (1989), Teixeira *et al.* (1986), Tostain *et al.* (1992), Wetmore (1965).



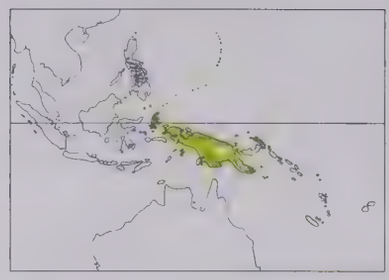
Genus *GYMNOCREX* Salvadori, 1875

75. **Bald-faced Rail**

Gymnocrex rosenbergii

French: Râle de Rosenberg **German**: Rosenbergralle **Spanish**: Cotara Cariazul
Other common names: Rosenberg's (Bare-eyed) Rail

Taxonomy. *Rallina rosenbergii* Schlegel, 1866, Kema, Sulawesi.
Sometimes merged, with *Aramides*, in *Eulabeornis*; genus shows some similarities to *Aramides*, possibly being derived from same stock. Monotypic.
Distribution. N & NC Sulawesi and Peleng (Banggai Is).
Descriptive notes. 30 cm. Can fly for short distances. Highly distinctive appearance, with conspicuous patch of pale cobalt blue bare skin behind eye, and black underparts. Sexes similar. Immature and juvenile undescribed. Voice. A snoring sound, which could possibly be confused with call of *Aramidopsis plateni*; also a quiet clucking call when disturbed.
Habitat. Primary and old secondary forest; also bushy, abandoned rice fields. In Lore Lindu National Park recorded with *Aramidopsis plateni* in old secondary forest, but differing in its preference for drier areas with a thick understorey of small saplings, some bamboo clumps, and less dense rattan; when



disturbed, one bird ran into the wetter, more impenetrable habitat occupied by the other rail species. Recorded from lowlands and hills.
Food and Feeding. Very little information available. Apparently feeds principally on insects and snails.
Breeding. No information available.
Movements. None.
Status and Conservation. VULNERABLE. Difficult to observe and apparently rare, but almost certainly greatly under-recorded. Known from one Sulawesi specimen and three from Peleng, other specimens having been lost; also recent records from Lore Lindu and Dumoga-Bone National Parks, Sulawesi. Presumably vulnerable to forest destruction and degradation, which are already quite widespread in parts of Sulawesi. May be trapped for food in some areas.
Bibliography. Andrew, P. (1992), Collar & Andrew (1988), Collar *et al.* (1994), Coomans de Ruiter (1947a, 1947b), Eck (1976a), Lambert (1989), Rozendaal & Dekker (1989), Stresemann (1941), Watling (1983), White & Bruce (1986).

76. **Bare-eyed Rail**

Gymnocrex plumbeiventris

French: Râle à ventre gris **German**: Rostschwingenralle **Spanish**: Cotara Moluqueña

Taxonomy. *Rallus plumbeiventris* G. R. Gray, 1862, Misool Island, off north-west New Guinea.
Sometimes placed in *Eulabeornis*, but has more in common with *Aramides*. Validity of subspecies questionable. Two subspecies recognized.
Subspecies and Distribution.
G. p. plumbeiventris (G. R. Gray, 1862) - N Moluccas, Misool, Aru Is, New Guinea (except S), Karkar and New Ireland.
G. p. hoeveni (von Rosenberg, 1866) - Aru Is and S New Guinea (Setekwa R to Fly R).
Descriptive notes. 30-33 cm; estimated 300 g. Bare orbital skin pink; eyering is salmon or reddish; long bill; axillaries and underwing-coverts barred greyish black and white; much individual variation

in plumage. Sexes alike. A distinctively plumaged rail, similar in overall colouring and pattern to *Aramides* rails; also somewhat similar to much larger *Eulabeornis castaneoventris*, which, however, has grey head, entirely pinkish brown underparts, greenish bill and yellow or green legs. All similar-sized sympatric rails of wet habitats have barring on underparts, except *Amaurornis olivaceus* which is olive brown above and grey below, with buffy-rufous belly and undertail-coverts, greenish yellow legs and a short bill. Immature and juvenile undescribed. Race *hoeveni* duller and has underparts washed rufous brown. VOICE. Loud gulping "wow-wow-wow-wow", only heard at start of wet season and probably a territorial call. When foraging, a repeated pig-like grunt.
Habitat. Floor of primary forest; also marshy forests, swamps and wet grassy areas near rivers and lakes. Occurs in lowlands, up to 1200 m; in E New Guinea also recorded from Mt Hagen area at 1600 m.
Food and Feeding. Eats insects; probably also a variety of other small animals. Seen to attack a Common Paradise-kingfisher (*Tanysiptera galatea*) which was digging for food.
Breeding. Misool, Nov; Karkar, Feb; breeds in wet season. Territorial, at least when breeding; occurs in pairs or family parties. In Sepik region, New Guinea, nest said to be of grass, built on the ground when water level low, and eggs said to be white; however, this does not agree with nest at Karkar, which was situated between roots of large tree and contained patterned eggs. Possible nest near Port Moresby in Feb was a few fragments of dead leaves on bare ground, and contained 1 egg. Nothing further recorded.
Movements. Sedentary; locally nomadic in New Guinea. In Port Moresby area mostly seen Dec-May, but records also for Aug-Sept; birds vacate lowland rain forest near Brown R during long periods of dry weather, when ground becomes very hard. One bird found perched in tree in urban Port Moresby, Jan, indicative of movements.
Status and Conservation. Not globally threatened. Very little information available, but species is apparently not uncommon throughout its sizeable range, though very shy and difficult to observe.
Bibliography. Andrew, P. (1992), Beehler *et al.* (1986), Coates (1985), Gilliard & LeCroy (1966), Gregory (1995b), Rand & Gilliard (1967), Ripley (1964, 1977), Rothschild & Hartert (1915), White & Bruce (1986).

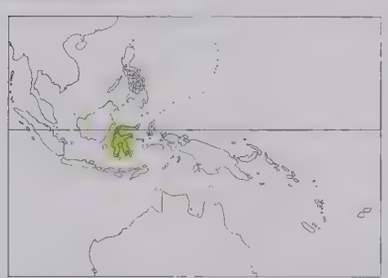
Genus *AMAURORNIS* Reichenbach, 1853

77. Brown Crake

Amaurornis akool

French: Râle akool **German**: Braunbauch-Kielralle **Spanish**: Gallineta Akool

Taxonomy. *Rallus Akool* Sykes, 1832, Deccan.
Two subspecies recognized.
Subspecies and Distribution.
A. a. akool (Sykes, 1832) - India, Bangladesh and W Myanmar.
A. a. coccineipes (Slater, 1891) - SE China to NE Vietnam.



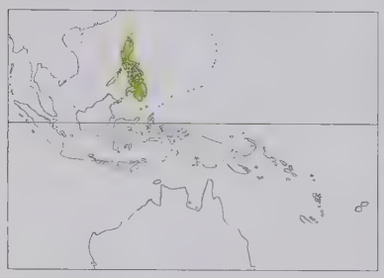
Descriptive notes. 26-28 cm; male 114-170 g, female 110-140 g. Very plain with olive brown upperparts, white throat, dark slate grey underparts shading to olive brown from belly to undertail-coverts, and indistinct pale supercilium. Sexes alike; female averages smaller. Smaller sympatric *A. bicolor* has rufous brown upperparts contrasting with grey head, neck and underparts; tail black; also differs in bare part colours. Immature similar to adult but with brown iris. Juvenile not described. Race *coccineipes* larger, with brighter, redder legs. VOICE. Short plaintive note, heard at daybreak and just before sunset; shrill rattle (attributed to this species but not proved); and long vibrating whistle, gradually falling in pitch.
Habitat. Dense swamps, *Pandanus* palm groves, sugar cane fields, riparian reedbeds and other dense herbage, and irrigation channels. Occurs from lowlands up to 800 m, possibly higher.
Food and Feeding. Worms, molluscs, adult and larval insects, and seeds of marsh plants. Largely crepuscular, emerging cautiously at edges of reedbeds and bushes to feed in early morning and evening.
Breeding. Mar-Oct, chiefly May-Aug; varies with locality. Monogamous. Nest a pad of grasses, rush blades and sticks, with slight central depression, well concealed in grass tussocks in or near edge of swamp; 1 nest was 1·5 m above ground, in flood-deposited debris on small *Acacia* tree on riverbank. Eggs 5-6; incubation by both sexes; chick has black down.
Movements. Resident, but possibly also migrant over relatively short distances, N populations wintering in S of range; extent of seasonal occurrence not clear.
Status and Conservation. Not globally threatened. Infrequently seen because of its shy and secretive nature, but formerly regarded as fairly common throughout range; no information available on current status.
Bibliography. Ali & Ripley (1980), Étchécopar & Hüe (1978), Harvey (1990), Inskipp & Inskipp (1991), King *et al.* (1975), Meyer de Schauensee (1984), Perennou *et al.* (1994), Ripley (1977, 1982), Ripley & Beehler (1985), Roberts, T.J. (1991), Smythies (1986).

78. Isabelline Bush-hen

Amaurornis isabellinus

French: Râle isabelle **German**: Isabellkielralle **Spanish**: Gallineta Isabelina
Other common names: Sulawesi/Isabelline Waterhen

Taxonomy. *Rallina isabellina* Schlegel, 1865, Gorontalo, Sulawesi.
Monotypic.
Distribution. Sulawesi.



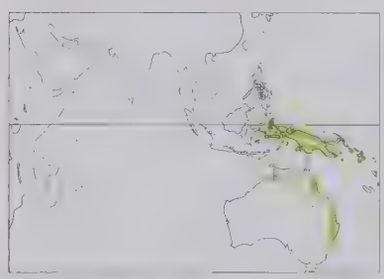
Descriptive notes. 35-40 cm. Sexes alike. Largest *Amaurornis*; paler plumage than congeners, and easily distinguishable by grey-tinged, olive-brown upperparts and entirely vinous chestnut to rufous underparts, including underwing-coverts and axillaries; bill pale green, legs and feet brownish green. Immature and juvenile undescribed. VOICE. Very striking, loud, discordant call, apparently resembling that of *Gallirallus torquatus* but usually ending with loud, clear "tak-tak-tak-tak", from which local name "Taktak" is presumably derived. Several birds usually call together.
Habitat. Grass with low bushes near streams and rivers with forested edges; also in *alang-alang* (*Imperata cylindrica*) grasslands and at edges of rice and maize fields; may occur far from water. Relatively common in dry, rank vegetation, especially old, fallow gardens in first stages of reversion to forest. Occurs from sea-level up to 800 m.
Food and Feeding. Noted foraging along a vehicle track in secondary woodland and *alang-alang*.
Breeding. Young found in May, including record of 2 adults with 5 chicks in late May 1986. No further information available.
Movements. None recorded.
Status and Conservation. Not globally threatened. Definitely known only from N Sulawesi S to Tawaya, and from the SE; occurrence elsewhere in Sulawesi requires investigation. Current status unknown, but species was regarded as relatively common at least locally in 1980's. In view of its restricted range, and lack of information on its ecology, species should probably be regarded as Data Deficient, in urgent need of investigation.
Bibliography. Andrew, P. (1992), Andrew, P. & Holmes (1990), Ripley (1977), Rozendaal & Dekker (1989), Stresemann (1941), Watling (1983), White & Bruce (1986).

79. Plain Bush-hen

Amaurornis olivaceus

French: Râle des Philippines **German**: Philippinenkielralle **Spanish**: Gallineta Filipina
Other common names: Bush-hen

Taxonomy. *Gallinula olivacea* Meyen, 1834, Manila, Philippines.
Formerly considered conspecific with *A. moluccanus*, but sufficiently distinctive in plumage to merit separation; probably best considered as forming superspecies. Monotypic.
Distribution. Philippines, except Palawan.



Descriptive notes. 24-31 cm. Sexes alike. Very similar to *A. moluccanus*, but somewhat larger and darker, with more olive-tinged upperparts, dark slaty grey underparts, including thighs, and dark rufous brown undertail-coverts; bill pale green; iris blood red; legs and feet yellowish brown. Immature and juvenile undescribed. VOICE. No description available, but presumably similar to that of *A. moluccanus*.
Habitat. Waterside grass clumps, flooded scrub and swampy grassland; nests in swampy conditions but also ranges through neighbouring grassland and forest edge.
Food and Feeding. Not recorded; likely to be similar to *A. moluccanus*. Shy and secretive.
Breeding. Feb, May and Sept. Nests in swampy conditions. No further details available; presumably similar to *A. moluccanus*.
Movements. None recorded.
Status and Conservation. Not globally threatened. Formerly considered common, but regarded as rare in 1991. In view of this suggested change in status, and general lack of information about biology and ecology, species should probably be regarded as Data Deficient; current status should be investigated in detail.
Bibliography. Dickinson, Kennedy & Parkes (1991), Dickinson, Kennedy, Read & Rozendaal (1989), DuPont (1971), Parkes (1971), Rand & Rabor (1960), Ripley (1977).

80. Rufous-tailed Bush-hen

Amaurornis moluccanus

French: Râle des Moluques **German**: Rotsteiß-Kielralle **Spanish**: Gallineta Moluqueña
Other common names: Eastern/Rufous-vented Bush-hen

Taxonomy. *Porzana moluccana* Wallace, 1865, Ambon and Ternate, Moluccas.
Formerly considered conspecific with *A. olivaceus*, but sufficiently distinctive in plumage to merit separation; probably best considered as forming superspecies. Four subspecies recognized.
Subspecies and Distribution.
A. m. moluccanus (Wallace, 1865) - Sangihe Is, Moluccas, Misool I and W & N New Guinea.
A. m. nigrifrons (Hartert, 1926) - Bismarck Archipelago and Solomon Is.
A. m. ultimus Mayr, 1949 - E Solomon Is.
A. m. ruficrissus (Gould, 1869) - S & E New Guinea, and NE & E Australia.

Descriptive notes. 23-30 cm; male *ruficrissus* 129-208 (177) g, *ultimus* 189-248 g; female *ultimus* 135-192 g, other races 161-205 (183) g; wingspan 45-49 cm. Sexes alike; female slightly smaller. Very similar to *A. olivaceus* but smaller and paler, with browner (less olive) upperparts, paler grey underparts, thighs vinaceous to rufous as undertail-coverts; olive yellow legs and feet. Immature very similar to adult, but throat whitish. Juvenile *ruficrissus* also similar to adult but has white throat; in worn plumage has slightly browner upperparts than adult and olive brown or light brown breast and belly; iris dark brown; bill blackish brown; legs and feet olive grey. Races separated on: bill colour, *ruficrissus* has reddish, swollen base to culmen; colour of undertail-coverts, more rufous in *ruficrissus*, pinkish red in nominate, tawny or vinaceous in other races; shade of underparts; and shade of upperparts, more olive-tinged in *nigrifrons*; in non-breeding *ruficrissus* green of bill fades, and red patch on culmen shrinks in size and fades to grey-brown. VOICE. Common call a loud shriek or wail, repeated 8-10 times; often given by pair in antiphonal duet. Also persistent and monotonous piping while feeding; clicking call given near nest; and soft but far-carrying clucking, often given by several birds in unison. Calls day and night.
Habitat. Dense stands of grass and reeds, sometimes bamboo, with pockets of dense bushes, near still or running fresh water; flooded scrub and swampy grasslands; floor of dry to swampy rain forest, often near marshes and lagoons, or in remnant patches or secondary growth; also sometimes in farmland adjacent to forest, *Lantana camara* thickets, sugar cane, and pasture and cleared land far from water; also recorded near human habitation, even in suburban gardens. On islands in Torres Strait occurs in areas bordering mangroves. Usually inhabits tallest, densest available vegetation, up to 2-4 m tall. Primarily in lowlands, but occurs up to 1500 m in New Guinea.
Food and Feeding. Earthworms, Orthoptera, Coleoptera, Lepidoptera (adults and larvae), frogs; also vegetable matter, including seeds of grass (Poaceae) and green shoots. Forages within or at edges of wetland vegetation, in cane fields and pasture, on ground in forest, at roadsides, and in shallow water; occasionally swims. Reaches or leaps up to take seeds or insects on vegetation or in air; runs grass heads through bill to remove seeds; probes into leaf litter. Shy and secretive; diurnal and crepuscular.
Breeding. Bacan (Moluccas), Sept; New Guinea, Sept-Apr; Australia, Oct-Apr. Normally seen in pairs or family groups; probably monogamous; territorial at least during breeding season. Nest usually

On following pages: 81. White-breasted Waterhen (*Amaurornis phoenicurus*); 82. Black Crake (*Amaurornis flavirostris*); 83. Sakalava Rail (*Amaurornis olivieri*); 84. Black-tailed Crake (*Amaurornis bicolor*); 85. Little Crake (*Porzana parva*); 86. Baillon's Crake (*Porzana pusilla*); 87. Spotted Crake (*Porzana porzana*); 88. Australian Crake (*Porzana fluminea*); 89. Sora (*Porzana carolina*); 90. Dot-winged Crake (*Porzana spiloptera*); 91. Ash-throated Crake (*Porzana albicollis*); 92. Ruddy-breasted Crake (*Porzana fusca*); 93. Band-bellied Crake (*Porzana paykullii*).

near or over water; often in bushy vegetation; also near forest edge or in secondary growth; often adjacent to tree, stump or fence post. Nest bowl-shaped, of grass, sometimes with dry leaves; built in tall, dense grass, sometimes in reeds or weeds, or on branches of *Lantana*; grass stems are bent down to form base and sides and loosely interwoven into rough canopy; ramp of trampled vegetation often present. External diameter 20-30 cm, depth 10-13 cm; cavity diameter 10-15 cm, depth 4-6·5 cm; built 10-200 cm above ground or water. Eggs 4-7; 1 clutch of 13 probably from 2 females; incubation up to 25 days, by both sexes, possibly mostly by female; hatching asynchronous; chicks semi-precocial; downy chick black, possibly fading later to black-brown on body and wings, iris dark brown, bill, legs and feet blackish; fed and cared for by both parents; usually fed in cover; no information on chick growth and development; post-juvenile moult recorded Australia, Mar-Apr. Hatching success (Australia) 32%; causes of loss include predation, flooding and desertion. May nest twice per season (Australia): first clutch usually 6-7 eggs, second usually 4-5; re-lays 14-21 days after clutch loss; one pair made 4 nesting attempts in 10 weeks.

Movements. Considered resident over most of range, and recorded throughout range in all seasons. Possibly nomadic in Australia, moving into some regions with onset of rains; may retire to areas with permanent water in dry season and move out to seasonally wet habitats in rains; thought to cross Torres Strait between Australia and New Guinea regularly; arrivals reported Cape York late Jan, and birds noted flying at night S from Cape York region at onset of wet season. Vagrant to Palau (W Micronesia), a bird found dead in sea, May 1979.

Status and Conservation. Not globally threatened. Formerly regarded as common and widespread in New Guinea, and common in Solomon Is (Santa Isabel). No current accurate estimates of abundance in Australia, where species may be widespread along coast of Northern Territory and Queensland, local and uncommon to reasonably common. In Australia, obviously well able to exploit man-modified habitats, especially on farmland, at artificial wetlands, and in gardens.

Bibliography. Beehler *et al.* (1986), Beruldsen (1975, 1976), Blakers *et al.* (1984), Clarke (1975), Coates (1985), Czechura (1983), Diamond (1972b), Diamond & Terborgh (1968), Draffan *et al.* (1983), Fraser & Mendel (1976), Gill (1970), Gilliard & LeCroy (1966, 1967), Hadden (1981), MacGillivray (1914), Marchant & Higgins (1993), Mayr (1949), McAllan & Bruce (1988), Mckean & Read (1979), Morgan & Morgan (1968), Serventy (1985), Sibley (1951), Storr (1973), Webb (1992), White (1922b, 1946), White & Bruce (1986), Wolters (1982).

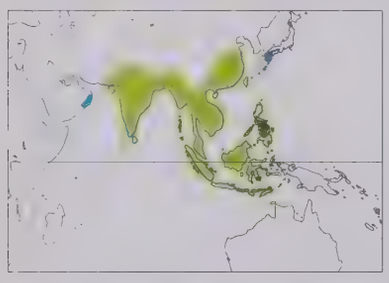
81. White-breasted Waterhen

Amaurornis phoenicurus

French: Râle à poitrine blanche **German**: Weißbrust-Kielralle **Spanish**: Gallineta Pechiblanca

Taxonomy. *Gallinula phoenicurus* Pennant, 1769, Sri Lanka.

Possible races *chinensis* and *javanicus* included within nominate due to overlapping measurements, but may well be valid. Four subspecies recognized.



Subspecies and Distribution.

A. p. phoenicurus (Pennant, 1769) - Pakistan, India, Maldives and Sri Lanka to E China, Taiwan and Ryukyu Is, and S through SE Asia and Philippines to Greater Sundas; N populations winter to S, ranging W to Arabia. Currently expanding N into Japan.

A. p. insularis Sharpe, 1894 - Andaman and Nicobar Is.

A. p. midnicobaricus Abdulali, 1978 - C Nicobar Is.

A. p. leucomelanus (S. Müller, 1842) - Sulawesi, W Moluccas and Lesser Sundas.

Descriptive notes. 28-33 cm; male 203-328 (228·5) g, female 166-225 (196·5) g. Relatively large, distinctive species; unmistakable, with combination of dark slate grey upperparts and flanks, prominent white face and underparts, and rufous rear flanks, vent and undertail-coverts. Female smaller, sometimes with duller bill. Some birds have grey sides of breast strongly barred with olive; partial albinism seems to occur in some areas, e.g. Andamans, Nicobars and Wallacea. In non-breeding season, male's bill becomes olive, washed brown on upper mandible. Immature duller than adult: upperparts more olive-brown, white of face obscured by brown feather tips; underparts tinged brownish; rufous areas duller; bill darker and duller. Juvenile similar but white of underparts, especially chin, throat and sides of breast, more heavily tinged dull brown; bill dark; legs and feet brownish yellow. Races separated on: extent of grey on head, in *leucomelanus* usually extending at least to forehead, and in birds from Lesser Sundas to ear-coverts and lores, not extending below eyes in nominate, and reaching only half way over top of head in *midnicobaricus* and *insularis*; extent and shade of grey on flanks, most extensive in *leucomelanus*, blackish in *insularis*; and colour of underparts, more olive in *midnicobaricus*. Head pattern very variable, and unstable mixed populations exist in Sulawesi and Lesser Sundas. Considerable individual variation and overlap with nominate race apparently prevents recognition of the races *chinensis* and *javanica*. VOICE. Characteristic very loud call comprises variety of roars, grunts, croaks and chuckles, followed by a monotonous "kru-ak, kru-ak, kru-ak-a-wak-wak"; calling may continue for 15 minutes or more; calls most in early morning and in evening, also through night; often calls from perch in top of shrub or bamboo. Very vocal during breeding season; silent thereafter.

Habitat. Reedy or grassy swamps, marshes, tall grass with reeds and shrubs, bamboo stands, wet scrub, rice fields and sugar cane, sewage ponds, and shores of rivers, ponds, ditches and lakes; also thick forest (Andaman and Nicobar Is), forest edges and clearings, mangrove swamps, and scrub and bushes far from water. Often occurs close to human habitation, e.g. at village ponds, and enters compounds and public parks; runs about under roadside hedges. Occurs from lowlands up to 1500 m, to 2000 m in Nilgiri Hills, SW India.

Food and Feeding. Worms, molluscs, insects (beetles, grasshoppers, etc.) and their larvae, spiders and small fish; also grass seeds, and shoots and roots of marsh plants. Usually not particularly shy, and often seen out of cover. Gleans from ground; pecks seeds from standing grass. Forages in the open along water margins; feeds on beaches at low tide (Maldives). Climbs in bushes and trees, swims, and occasionally dives.

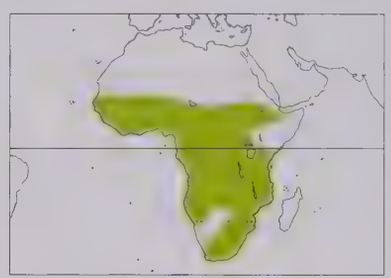
Breeding. India and Pakistan, Jun-Oct (SW monsoon); Andaman and Nicobar Is, Jun-Jul; Ryukyu, Apr-Oct; Sumatra, Jan, May, Jul, Sept, Nov; Java, all months except Apr, Oct and Nov; Lesser Sundas, downy chicks Apr-May; in Borneo, and probably on other tropical islands, may breed in almost any month. Normally seen singly or in pairs, sometimes in groups of up to 5; presumed monogamous, with pair-bond at least for duration of breeding season when apparently territorial. Nest a shallow cup-shaped pad of twigs, creeper stems and *Typha* leaves, placed on ground in grass or tangled undergrowth at margin of pond, ditch or flooded rice field, or concealed in shrub, bamboo clump or *Pandanus* palm thicket up to 2 m above ground, sometimes far from water. Eggs 4-9; incubation 20 days, by both sexes; downy chick black, with blackish bill and legs; chicks leave nest soon after hatching; fed and cared for by both parents. Probably multi-brooded in Ryukyu Is, which has aided rapid expansion there in recent years.

Movements. Resident throughout most of range, but N populations winter S to Lesser Sundas, occurring W to Arabia, where 13 recorded in Oman (Oct-Jan), 1 United Arab Emirates (Nov) and 1 Yemen (Mar). Wintering birds occur in Sumatra Nov-Apr. Extent of migration from northernmost breeding areas and seasonality of occurrence not clear; current expansion northwards into Japan indicative of mobility of species; recorded E to Bonin Is.

Status and Conservation. Not globally threatened. Formerly regarded as common throughout range. Currently common in Borneo, Sumatra, Java and Bali, and fairly common though local in Philippines. Accidental in Japan before 1970, after which has undergone major range extension, becoming common breeding resident in Ryukyu Is (Okinawa and in Yaeyama Is); now so common on Iriomote-jima that is thought to be ousting *Rallina eurizonoides*; expansion northwards is continuing, and now also occurs fairly regularly on main Japanese islands, having bred on Kyushu.

Bibliography. Abdulali (1978), Ali (1977), Ali & Ripley (1980), Bang (1968), Brazil (1991), Deignan (1945), Dickinson *et al.* (1991), Étchécopar & Hüe (1978), Evans (1994), Gallagher & Rogers (1980), Hellebrekers & Hoogerwerf (1967), Holmes & Nash (1991), King *et al.* (1975), Kirwan (1994), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Madoc (1976), van Marle & Voous (1988), Medway & Wells (1976), Perennou *et al.* (1994), Phillips (1978), Rabor (1977), Rensch (1931), Ripley (1982), Roberts, T.J. (1991), Schmutz (1977), Smythies (1981, 1986), Stresemann (1941), Watling (1983), White & Bruce (1986), Wildash (1968), Yan Anhou & Pang Bingzhang (1986).

82. Black Crake



Amaurornis flavirostris

French: Râle à bec jaune **German**: Mohrensumpfhuhn **Spanish**: Polluela Negra Africana

Taxonomy. *Gallinula flavirostra* Swainson, 1837, Senegal.

Sometimes included in *Porzana*, or placed in monospecific *Limnocorax*, but inseparable from *Amaurornis* on skeletal characters. Forms superspecies with *A. olivieri*. Monotypic.

Distribution. Sub-Saharan Africa, from N edge of Sahel zone S to Cape, except in desert regions of NE & SW.

Descriptive notes. 19-23 cm; male 78-118 (96·5) g, female 70-110 (81) g; 159 both sexes 69-118 (89·5) g; weight varies greatly during year. Sexes alike. Non-breeding birds have duller red legs and feet. Very similar to *A. olivieri*, but upperparts washed olive-chestnut (in the field appearing slaty black, like rest of plumage) as opposed to rich dark brown; bright red orbital ring, legs and feet. Immature paler than adult; upperparts olivaceous brown; throat whitish; head, neck and underparts grey; bare parts duller than in adult. Juvenile entirely brown; bill blackish, changing to darkish green; iris grey to brown, changing to dark red; legs and feet blackish, changing to dull red. VOICE. Very characteristic advertising call is a duet: one bird gives harsh repeated chatter "krrrok-krraaa", the other joins in with soft, purring notes. Either sex may give either call; duet not always antiphonal; sometimes other family members join in; all calling birds may crouch in circle, heads facing inwards. Alarm a sharp "chip"; contact calls soft, "pu" or "bup". Much less vocal outside breeding season.

Habitat. Occupies many types of freshwater wetland, normal requirements including moderate vegetation cover and some permanent flooding. Inhabits rank grass, sedges, reedbeds, papyrus, swampy thickets, bushes and other vegetation beside flowing and still waters; occurs in dense undergrowth of boggy clearings in forest; in open areas may occupy grassy marshes. Often found on ponds covered with *Nymphaea* and other floating vegetation; likes tangled vegetation, in which climbs, roosts and sometimes nests. Very adaptable, and in dry regions will occupy tiny streams with thin cover. Occurs close to human habitation and is quite bold and tolerant of disturbance, emerging to feed some distance from cover. Occurs from sea-level to 3000 m; in Natal, South Africa, most widespread and numerous below 1200 m, rarely recorded above 1800 m.

Food and Feeding. Worms, molluscs, crustaceans, adult and larval insects, small fish, frog tadpoles and small frogs; also seeds and other parts of water plants. Takes eggs and nestlings, including those of herons; kills small birds caught in mist-nets. Scavenges carcasses of crabs, crayfish and small birds. Often feeds in the open along shorelines, on floating vegetation, in short grass or cultivation, and on dry or burned ground; may venture some distance from cover. Takes food from surface of ground, water and vegetation, and from shallow water; probes into mud and dead vegetation; shifts fallen vegetation to search beneath. Readily perches and feeds on backs of hippopotami (*Hippopotamus amphibius*); perches on warthogs (*Phacochoerus aethiopicus*), apparently gleaning ectoparasites. Diurnal; markedly active after rain.

Breeding. In suitable conditions breeding may occur throughout year, with seasonal peaks in most regions, during or following rains: Senegal and Gambia, Dec-Mar, May-Jun, Aug-Sept; Sierra Leone, Jan, Mar, Oct, Dec; Liberia, Nov; Ghana, Jun, chicks Mar; Nigeria, Jan, Jun, Aug-Nov; Gabon, Mar, Jul; Zaire, almost all months; Sudan (Darfur) Oct; Ethiopia, Apr-Oct; Burundi, Mar; Uganda and W Kenya, all months (peaks Apr, Nov); rest of Kenya and NE Tanzania, all months (peaks Apr-Jun, Oct); rest of Tanzania, Apr, Oct-Nov; Zambia, Nov-Aug (peak Dec-Mar); Malawi, Mar-May, Jul-Sept, Dec; Mozambique, May-Jun; Zimbabwe, all months except May and Jul (peak Jan-Feb); Botswana, Aug-Oct; South Africa, Aug-May (peaks Nov, Jan-Mar). Monogamous; territorial when breeding. Nest a deep, bulky bowl of reeds, rushes, sedges, creepers, grasses or other water plants; placed in vegetation over water with rim 20-50 cm above water, but sometimes floating; also on ground or in grass tussock near water; sometimes up to 3 m high in bushes, possibly as protection against sudden flooding. External diameter 10-30 cm, depth 8-18 cm; cup depth 5-9 cm. Both sexes build, sometimes helped by young of previous broods; male may build extra nests or platforms for roosting. Usually 3 eggs (2-6), laid at daily intervals; 2 females once laid 6 and 4 eggs in same nest; incubation 13-19 days, by both parents, sometimes assisted by immatures; hatching asynchronous; black downy chicks have grey iris, pink bill with black band around centre, and slate legs and feet; chicks leave nest 1-3 days after hatching; fed and cared for by parents, helped by young of previous broods, for at least 3-6 weeks; juvenile plumage attained by 4-6 weeks; young fly at 5-6 weeks; may still beg for food when 2-3 months old; post-juvenile moult occurs between 2 and 4 months of age. Able to breed within 1 year of hatching. Up to 4 broods recorded per season; clutches may be laid when young of previous brood are as little as 3 weeks old. Co-operative breeding normal, young remaining within family group until end of breeding season, sometimes (Natal) until 16 months old.

Movements. Largely sedentary but also locally migratory. In drier N parts of range, in N Ghana, N Nigeria and Sahel zone of Sudan, appears with rains and disappears in dry season; moves in Zimbabwe when habitats dry out; occupies temporary waters in E Africa and NE Namibia; presumed

migrant captured at night, Tsavo West (SE Kenya), in Dec. Seasonal variations in calling frequency, and in relative visibility of birds, may explain fluctuating reporting rates in other areas. Vagrant to Madeira, Jan 1895.

Status and Conservation. Not globally threatened. Commonest and most widespread crake in Africa; less secretive than other terrestrial wetland rallids of region, and has well known advertising call, so occurrences are relatively well documented. Common to abundant over most of range, but very localized and rare in drier W & C regions of S Africa. In favourable conditions, population density may be very high in some areas. Must have been affected by loss of wetland habitats, but is under no immediate threat anywhere. Readily occupies artificially created wetlands and temporary habitats.

Bibliography. Ash & Miskell (1983), Bannerman & Bannerman (1965), Benson & Benson (1975), Benson & Wagstaffe (1972), Benson *et al.* (1971), Britton, P.L. 83. **Sakalava Rail**

Amaurornis olivieri

French: Râle d'Olivier **German**: Malegassensumpfhuhn **Spanish**: Polluela Negra Malgache
Other common names: Olivier's Crake

Taxonomy. *Porzana Olivieri* Grandidier and Berlioz, 1929, Antsalova, Province of Maintirano, west Madagascar.
Although sometimes placed in *Porzana*, has close affinities with *A. flavirostris*, with which forms superspecies. Monotypic.

Distribution. WC Madagascar.

Descriptive notes. 19 cm. Distinctive: dark slate grey plumage with rich dark brown from mantle to rump and on upperwing-coverts; greenish yellow bill, pinkish red legs and eyelids, and red eye. Sexes alike. Immature and juvenile not properly described, but probably browner overall than adult. VOICE. Unknown.

Habitat. Streams and marshes offering stretches of open water, patches of floating vegetation especially water-lily (*Nymphaea*) leaves for foraging, and adjacent dense cover of reedbeds (*Phragmites*) for shelter; also among grass and bushes emerging from water in a clearing of a flooded palm-covered valley.

Food and Feeding. Food unknown. Apparently forages on floating vegetation near cover, as does *A. flavirostris*, but is less active and bold.

Breeding. Lays Mar; well grown young also seen late Mar. One nest was placed 50 cm above ground level in bulrushes (*Typha*) near water, in marshy area dominated by *Nymphaea* and *Phragmites* and with stretches of open water. This nest held 2 eggs, probably a complete clutch; downy chicks black.

Movements. None described.

Status and Conservation. CRITICALLY ENDANGERED. Known from three widely separated localities in the Sakalava country of lowland W Madagascar: Antsalova and the region of L Masama and L Bemamba; Ambararatabe near Soalala; and Nosy-Ambositra on R Mangoky. Rare and localized, with very few records. Like Madagascar Grebe (*Tachybaptus pelzelnii*), has possibly suffered from loss of lilypad habitat owing to rice cultivation and the impact of introduced fish. May suffer from systematic exploitation for food: the eggs from the only recorded nest were eaten by local people. Not seen since 1962, despite searches since mid-1980's in suitable habitat. Not very shy, so thought unlikely to have been overlooked in accessible habitat, but some potential wetland habitats are not severely threatened, and populations may survive between Antsalova and Mahajanga.

84. **Black-tailed Crake**

Amaurornis bicolor

French: Râle bicolore **German**: Zweifarben-Kielralle **Spanish**: Polluela Bicolor
Other common names: Elwes's Crake

Taxonomy. *Porzana bicolor* Walden, 1872, Rungbee, Darjeeling.
Sometimes retained in *Porzana*. Monotypic.

Distribution. NE India and Myanmar E to SC China (S Sichuan, Guizhou, Yunnan), and S to N Thailand, NW Vietnam and N Laos; recent possible record from EC Nepal.

Descriptive notes. 20-22 cm. Rufous brown upperparts contrast with ashy grey head, neck and underparts; tail black; bill pale bluish green with pale tip and red patch near base; iris blood red; orbital skin pink; legs and feet dull to bright red. Sexes alike. Sympatric *A. akool* larger and duller, with uniformly olive brown upperparts, including head and neck, and olive brown from belly to undertail-coverts. Paler and larger than rather similar *A. olivieri* of Madagascar. Immature similar to adult but with brown iris. Juvenile not described. VOICE. Song has initial rasping "waak-waak" call, followed by long descending trill, with interval of 5-15 minutes before repetition; given mainly at dusk, but also heard in early morning.

Habitat. Forest patches in and around rice cultivation; swampy patches and streams in forest; grass-bordered streams and pools, often shaded by trees; small marshes in grass and cultivation; sometimes wet grassland; often in very dense cover, but will feed in open. Recorded from lowlands, but primarily a highland species, occurring at 1000-3600 m.

Food and Feeding. Worms, molluscs, insects, and seeds of marsh plants. Recorded feeding with rapid pecking motion, wings drooped, tail cocked and frequently jerked. A great skulker; emerges at edge of cover to feed in early morning and evening, but if alarmed, rapidly retreats to cover, if necessary flying or swimming; recently recorded feeding at open site near people in mid-afternoon.

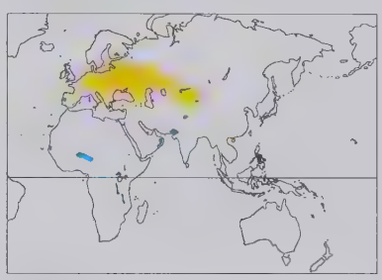
Breeding. Mid-May to Aug in Khasi Hills, SC Meghalaya (NE India); 2 adults with 3 young in early Aug at Doi Inthanon (NW Thailand). Monogamous. Nest a rough pad of loosely assembled twigs and grass, with a slight central depression; built on wet ground in forest undergrowth; sometimes placed 1-2 m (once c. 7 m) above ground in bushes or trees; both sexes build. Eggs 5-8; incubation by both sexes; green-glossed black downy chick has hazel eye, pale bill and dusky legs.

Movements. Resident, but to date recorded as occurring in N Vietnam and Laos only in winter; extent of seasonal occurrence not clear.

Status and Conservation. Not globally threatened. Infrequently recorded because of its skulking habits, but formerly regarded as locally common. Several recent records (from mid-1980's) from Doi Inthanon National Park, NW Thailand, where species has been recorded year round, and breeding confirmed. No further information on current status, but habitat destruction has probably affected its numbers adversely.

Bibliography. Ali (1977), Ali & Ripley (1980), Étchécopar & Hüe (1978), Inskipp & Round (1989), King *et al.* (1975), Lekagul & Round (1991), Meyer de Schauensee (1984), Ripley (1977, 1982), Ripley & Beehler (1985), Sériot *et al.* (1986), Smythies (1986).

Genus *PORZANA* Vieillot, 1816



85. **Little Crake**

Porzana parva

French: Marouette poussin **German**: Kleines Sumpfhuhn **Spanish**: Polluela Bastarda

Taxonomy. *Rallus parvus* Scopoli, 1769, probably from Carniola.
Monotypic.

Distribution. Locally in Europe E across Transcaucasus, SE Transcaspia, W Tadjikistan, Kazakhstan and W Xinjiang (Tien Shan and Tarim Basin E to Lop Nur), NW China. Winters from Mediterranean S to W Africa (Senegal, Niger, Nigeria) and E Africa (Uganda, Kenya), and E through Arabia to W Pakistan and NW India.

Descriptive notes. 18-20 cm; male 30-72 (50) g, female 36-65 (49·5) g; wingspan 34-39 cm. Marked sexual dimorphism in plumage: male has blue-grey face and underparts, with narrow white bars on rear flanks and black and white barring on undertail-coverts; in female blue-grey replaced by buff except for pale ash grey supercilium, lores and cheeks, and whitish chin and throat, while barring from flanks to undertail-coverts paler and less distinct. Slim shape, produced by relatively long neck, wings, tail and legs, is useful distinction from sympatric *Porzana* species. Unlike *P. porzana* and *Aenigmatolimnas marginalis*, has barred undertail-coverts. Confusion most likely with *P. pusilla* but has paler, duller brown, more uniform upperparts and upperwing-coverts, lacking contrasting white markings except on centre of mantle, but with obvious pale olive brown stripe along scapulars (these characters noticeable at rest and in flight); broad pale inner edge to tertials, red spot at base of green bill; green legs and feet; much greater primary projection in folded wing; longer tail (often not obvious in the field); and stronger, less fluttering flight; male also separable by fainter underpart barring starting only on lower flanks and belly. All ages separable from juvenile *P. pusilla* on structure, and on upperpart pattern, including pale lines on scapulars and tertials; adult female also differs from juvenile *P. pusilla* in having pale brown-buff underparts; juvenile less strongly barred than *P. pusilla* on underparts and has fewer white markings on upperparts and wings. From post-juvenile moult through first breeding season male and female retain some juvenile whitish markings on scapulars and upperwing-coverts (absent in full adult); male has olive wash on belly and pale edges to some blue-grey underparts feathers; female has paler buff underparts. Birds in first winter have red-brown iris. Juvenile resembles female but has more white spots on upperwing-coverts and scapulars, almost white supercilium, darker brown cheeks and ear-coverts, buff and cream mottling on sides of breast, and dark brown and whitish barring from breast to rear flanks and undertail-coverts; iris becomes olive green and then brown; bill becomes olive green and then horn with greener lower mandible; legs and feet olive brown, becoming olive green. VOICE. Advertising call of male a loud, barking "quack" or "quek" repeated every 1-2 seconds for up to several minutes before accelerating and descending in pitch, ending on softer, more guttural notes; sings mainly at night, sometimes during day. Female's advertising call a fast, hard trill, often preceded by 1-2 sharp "quek" notes; also a sharp "kik" often given in duet with mate. Alarm a sharp "tyiuck"; contact calls include subdued trills, "quek" and "gug" notes.

Habitat. In breeding season occurs typically in temperate and steppe zones, usually in lowlands but occasionally to c. 2000 m. Frequents dense emergent vegetation of freshwater wetlands, including margins of lakes and rivers, and flooded woodland; in breeding season differs from sympatric congeners in favouring monospecific or mixed stands of tall plants such as *Scirpus*, *Typha*, *Carex*, *Sparganium*, and also *Phragmites* which has both dead and living stems; such stands may be in fairly deep water and include horizontal stems which form bridges. Outside breeding season may share similar habitat with *P. porzana* and *P. pusilla*, and also occurs in seasonally inundated grassland. Frequents rice fields in both breeding and wintering areas. Prefers more deeply flooded habitats than *P. porzana*. Moves freely over floating vegetation and climbs easily up stems. On migration occurs in atypical habitats.

Food and Feeding. Mostly insects, especially water beetles (Hydrophilidae) and also Hemiptera, Neuroptera, and adult and larval Diptera, and also seeds of aquatic plants (*Carex*, *Sparganium*, *Polygonum* and *Nymphaea*); worms, gastropods, spiders and water mites (Arachnida), and aquatic vegetation such as young shoots. Forages while swimming, wading or walking over stems and leaves; takes food from mud, water surface or vegetation but does not probe; also dives.

Breeding. C Europe, May-Aug; bred once in Egypt, Apr. Monogamous and territorial, pair-bond maintained only during breeding season. Nest a shallow cup of plant stems and leaves; placed in thick vegetation near or over water, often raised on tussock or platform of dead material; external diameter 11-20 cm, internal diameter 10-16 cm, height 2-9 cm. In favourable habitat, nests frequently only 30-

35 m apart. Both sexes probably build; male also builds brood platforms around breeding nest. Usually 7-9 eggs (4-11), laid at daily intervals; replacements laid after egg loss; incubation 21-23 days (15-17 days per egg), by both sexes; hatching asynchronous; black downy chick has green gloss on upperparts, head and throat, with iris grey-brown to brown-black, bill white with yellow or pink tinge and grey base, legs and feet grey-brown to blackish; chicks precocial and nidifugous; fed and cared for by both parents while small; become self-feeding after a few days; probably brooded in nest for much of breeding period; young can fly at 45-50 days, when fully fledged, but are independent and probably deserted by parents before this. 2 broods quite frequent. Post-juvenile moult Sept-Nov or Nov-Mar. Age of first breeding 1 year.

Movements. Distribution imperfectly known due to secretive behaviour, and few wintering sites known (map tentative). W Palearctic breeders probably winter in Mediterranean basin, Africa (including Egypt), Arabia (Oman and possibly elsewhere), Iraq and Iran; winters occasionally in C Europe, and W to Britain. S movements late Aug-Nov, probably peaking Sept-Oct; occurs as migrant on all larger Mediterranean islands; passes through N Africa (Morocco to Egypt) late Aug-Oct, Sudan Sept-Nov and Somalia Sept-Oct; present Oman Aug-Apr. Presumed wintering birds recorded Senegal Sept-Nov, N Nigeria Dec and Feb-Mar, S Niger Sept, Oct and Jan, W Uganda Dec (1901) and C Kenya Jan (1983); probably winters regularly S to equator in Kenya and Uganda. Like *P. porzana*, probably itinerant in African wintering areas in response to habitat changes. Return passage noted N Africa Mar-May (sometimes Jun) and Mediterranean late Feb-May; also 1 presumed migrant Ethiopia Apr; most arrive on breeding grounds late Mar-Apr. Most N African records are in spring, suggesting that autumn migrants may overfly region. Vagrant or uncommon (overlooked?) winter visitor to Liberia (no dates), Zambia (Mar 1980) and possibly Ivory Coast (1 questionable Jun record); accidental Ireland, Denmark, Norway, Finland, Lebanon, Syria, Azores, Canary Is and Madeira. Little information on movement of E populations: in Azerbaijan passage noted Nov and Mar-Apr; formerly remained during warm winters but no recent information. Normally migrates singly; concentrations rarely recorded, possibly because species secretive.

Status and Conservation. Not globally threatened. Current status poorly known; formerly thought to be less severely affected than congeners by wetland drainage and reclamation, and in some areas possibly favoured by habitat changes. Formerly regarded as uncommon to scarce breeder in Europe, but increases reported in Netherlands after 1942, and in Hungary with introduction of rice cultivation and expansion of fish ponds. In former USSR, in past regarded as rare in N but common to fairly abundant in S, with total numbers fairly large; in Azerbaijan currently regarded as uncommon in summer, probably breeding. Transient in much of W Xinjiang, but may breed in Tarim Basin; uncommon in winter, W Pakistan (Baluchistan, Sind) and NW India (Gilgit, 1 record Bombay). Rarely recorded Oman, on passage and in winter. Apart from considerable numbers recorded on passage through N Africa, including many recent records from Algeria and Libya, records from Africa are very few: total of 15 birds recorded Senegal, 12 N Nigeria, 4+ S Niger, 7 W Uganda, 3 C Kenya, 1 Zambia; uncommon Sudan (recorded only in autumn); rare Ethiopia and Eritrea; 2 old records NW Somalia. However, apparently large numbers breeding in W of former USSR, considerable passage through N Africa, and occurrence in deserts of Algeria and Libya suggest broader sub-Saharan distribution and greater numbers than currently known. Bred Algeria mid-19th century, and recent breeding suspected; bred once Egypt.

86. Baillon's Crake

Porzana pusilla

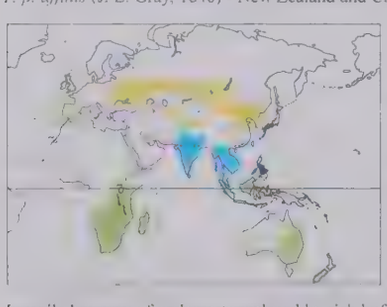
French: Marouette de Baillon **German**: Zwergsumpfhuhn **Spanish**: Polluela Chica
Other common names: Marsh/Tiny Crake

Taxonomy. *Rallus pusillus* Pallas, 1776, Dauria.

Forms superspecies with recently extinct *P. palmeri* of Laysan I (Hawaii). Race *mayri* possibly synonymous with *palustris*. Possible race *obscura*, of sub-Saharan Africa and Madagascar, doubtfully valid. Six subspecies normally recognized.

Subspecies and Distribution.

P. p. intermedia (Hermann, 1804) - Europe E to Asia Minor, and S locally in Morocco, Tunisia and Ethiopia, then from E Zaire to C Kenya and S to Angola, Namibia and South Africa, and also Madagascar; European birds winter in Africa.



P. p. pusilla (Pallas, 1776) - R Dnestr E through C & E Asia to Amurland, N China, N Korea and Japan, S to Iran and N India and irregularly in Sumatra and Sulawesi; winters in India, Sri Lanka and Myanmar, and from S China to Indonesia and Philippines.

P. p. mira Riley, 1938 - Borneo.

P. p. mayri Junge, 1952 - New Guinea.

P. p. palustris Gould, 1843 - E New Guinea, Australia and Tasmania.

P. p. affinis (J. E. Gray, 1846) - New Zealand and Chatham Is.

Descriptive notes. 17-19 cm; male 23-45 (35·5) g, female 17-55 (34) g, unsexed 20-52 (33) g; wingspan of *intermedia* 33-37 cm, of *palustris* 23-25 cm. Sexes similar but female often has rufous-brown streak, varyingly from over ear to complete eyestripe; sometimes paler grey on underparts than male (nominate race); pale patch on chin larger in female and in both sexes in non-breeding season, but may not be a consistent character. Separable on plumage, size and structure from sympatric congeners; legs and feet often said to be flesh-coloured, but usually greenish grey, olive or yellowish and thus may resemble those of *P. parva*. Immature like adult. Juvenile has grey of underparts replaced by rich buff to white, often mottled from face to breast, and (in *intermedia* and some nominate) dark barring extending forwards to upper flanks and breast; iris and bill initially brownish, and legs and feet brown to grey-flesh, but bare parts rapidly attain adult colours. Races separated on size and colour: nominate and *intermedia* largest, with underpart barring extending further up belly; *palustris* small and pale; nominate has some rufous brown on sides of breast and as streak from lores to ear-coverts; *intermedia* richly coloured and boldly patterned; *mira* has white throat and breast; races from Australasia and New Guinea paler grey on underparts. Voice. Advertising call of male a hard, dry rattle (in African birds identical to rattle call of *Rallus caerulescens*) lasting 1-3 seconds and repeated every 1-2 seconds; calls mainly at night. Probable alarm call a series of loud, rapidly repeated grating notes, often in a phrase such as "kraa-kraa-kraa-chachachachacha". Alarm call of both sexes a sharp "tac" or "tyiuk".

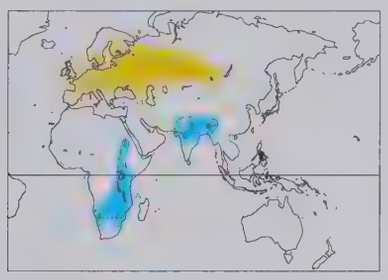
Habitat. Freshwater to saline, permanent to ephemeral palustrine wetlands with dense vegetation and often floating plants, including marshes, swamps, flooded meadows, margins of open water, peat bogs, interdune pans, irrigated crops, temporarily inundated depressions and marshy artificial wetlands; occasionally salt-marsh. Breeding habitat usually characterized by relatively fine, low, dense, tussocky or continuous vegetation such as flooded sedges and grasses (*Eleocharis*, *Carex*, *Cyperus*, *Juncus*, *Scirpus*, *Phalaris*, *Leersia*, etc.). Outside breeding season occurs in wider variety of habitats, including: tussocky cover interspersed with mud patches around ponds and lakes; interior and edges of tall reedbeds (*Phragmites*, *Typha*, sometimes with *Sesbania* bushes) with extensive mud and shallow puddles, in Kenya; flooded *Polygonum* beds; damp grassland; sewage ponds; and dense grassy vegetation of parks, golf courses, airfields, etc. in Australia. Occurs up to 1500 m, but to 2450 m in New Guinea.

Food and Feeding. Mostly adult and larval aquatic insects, including Coleoptera, Hemiptera, Odonata, Plecoptera, Phryganeidae (caddisflies) and Culicidae; also Annelida, molluscs, small crustaceans, small fish, green plant material, and seeds (including *Carex*); in captivity also small lizards and geckos. Forages on mud, probing and taking prey from surface, and in shallow water, occasionally to belly depth, immersing bill to seize prey; probes into bases of decaying plants and among or under detritus, dead stems and roots; often forages while walking on floating vegetation and broken reeds, and while swimming; reported to dive for food. Non-breeding birds in C Kenya fed largely on the most abundant small aquatic invertebrates available, including Ostracoda and Copepoda longer than 1·5 mm, showing preference for feeding in very shallow drying puddles, where prey most concentrated. Normally forages close to, or within, dense cover; most active in early morning and from late afternoon to evening.

Breeding. Europe, May-Jul; Morocco, May, breeding condition Apr; Egypt (formerly), Apr; Ethiopia, Jul; Tanzania, breeding condition Apr; Malawi, Jun, breeding condition Mar; Zimbabwe, Jan-Mar; Botswana, breeding condition Jan; South Africa, Sept, Nov-Mar; in former USSR from May; Kashmir, May-Aug; Sumatra, Feb; Japan, May-Aug; Australia, Sept-Jan, exceptionally also Feb-Mar; New Zealand, Oct-Nov; nests during or just after wet season. Monogamous and territorial; pair-bond maintained only while breeding. Nest a shallow cup or platform of material available nearby, e.g. dead leaves, dry rush stems, grass or water weed; often with vegetation pulled over to form canopy; on ground in thick vegetation close to water, in soft grass or on tussock in water; built 4-60 cm above water level; sometimes anchored in water amongst growing rice crops or on floating vegetation; occasionally in or under low bush. Rather flimsy; material added during incubation, especially if water rises. External diameter 9-15 cm, height 8-15 cm, internal diameter 7-10 cm, cup depth 1-3 cm. Both sexes probably build. Some nests have adjoining platform where young sit after hatching. Eggs 4-11 (mean 7·4) in Europe, 4-7 (5·9) Australia, 2-7 (4) Africa; laid at daily intervals; incubation 16-20 days, by both sexes; hatching asynchronous (W Palearctic) or within 24 hours (Australia); black downy chick has bottle-green gloss, iris bluish brown to black, bill bone white to straw yellow, legs and feet grey-brown to black; young precocial and nidifugous; fed and cared for by both parents, and brooded when small; become self-feeding after a few days; independent before fledging; fledging c. 35-45 days. Age of first breeding 1 year. 2 broods recorded in former USSR.

Movements. Extent of migrations unclear (map highly conjectural). In Europe, most *intermedia* move S late Aug to Oct, migrants occurring all round Mediterranean and probably overflying N Africa to winter in sub-Saharan Africa, where distribution poorly known because of close resemblance to resident birds; presumed Palearctic birds obtained in Somalia in Sept, N Sudan in Apr and Sept-Oct, and Senegal in Nov and Jan, but Kenya occurrences referable to African breeding population; return passage Mar-May, most returning migrants in N Africa being recorded Mar-Apr; returns to C Europe May. Migrants recorded Asia Minor, and birds of unknown origin winter in Iraq and Israel; occurs Oman Aug-Dec. African populations usually considered resident but at least local movements recorded in E, C and S Africa in response to seasonal habitat changes. Nominate birds winter to S of breeding range; migrants recorded in Azerbaijan, Apr; recorded once from Egypt; in Japan most occur May-Sept; regarded as winter visitor to Philippines and Sumatra, but recorded Philippines Aug, Oct, Jan and Mar-Jun, and probably breeds irregularly in Sumatra; local seasonal movements recorded in S Vietnam. Race *palustris* possibly migratory in Australia, where many disappear from S part of range Apr-Sept, probably migratory immatures recorded Northern Territory Jul, and some birds probably cross Torres Strait; erratic movements also recorded in response to vegetation changes, drought and flooding; sometimes hits lighthouses, bridges and buildings; vagrant to Macquarie I. Migratory status of races *mira*, *mayri* and *affinis* unknown.

Status and Conservation. Not globally threatened. Some races rare or poorly known. In W Palearctic, *intermedia* now regarded as rare and very local, having declined considerably since 19th century; formerly bred N Algeria (L Zana) and Egypt (Nile Delta) and may still do so; breeds Morocco and possibly Tunisia; uncommon to rare Ethiopia; widely distributed and still locally common in sub-Saharan Africa, but status unclear in some areas; local in Madagascar. Status of nominate race largely unclear but in past bred abundantly in Kashmir; no recent records from Azerbaijan, apparently uncommon in Indonesia and Philippines, and uncommon to rare in Japan. Race *mira* known from type specimen collected from R Mahakam in E Borneo in 1912 but may be relatively widespread in that area and perhaps elsewhere in Borneo; also suggested to occur in Malay Peninsula, N Sumatra and Java. Race *mayri*, endemic to New Guinea, probably very rare and local, known only from Wissel Lakes region and Weyland Mts, Irian Jaya. In Australia, *palustris* widespread and apparently locally common in E, SE & SW, but reclamation of wetlands has reduced available habitat; apparently rare and local in Tasmania and New Guinea. Race *affinis* probably widespread throughout New Zealand. Like most other wetland rallids, present species locally threatened throughout range by habitat destruction and modification, and overall numbers are declining. Frequently uses ephemeral or seasonal wetlands, and such habitats are frequently drained, overgrazed or cultivated; however, species does also occupy artificially created wetlands.



Bibliography. Ali & Ripley (1980), Archer & Godman (1937-1961), Barlow & Sutton (1975), Becker, P. 87. Spotted Crake

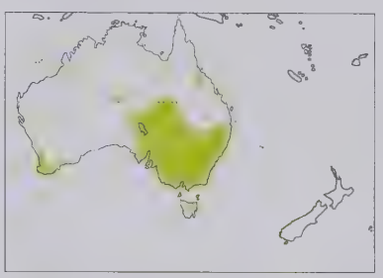
Porzana porzana

French: Marouette ponctuée **German**: Tüpfelsumpfhuhn **Spanish**: Polluela Pintoja
Other common names: Eurasian Spotted Crake

Taxonomy. *Rallus Porzana* Linnaeus, 1766, France.
Monotypic.
Distribution. British Is and Spain E across S Scandinavia, N Mediterranean and Balkans to W & C Russia, Caucasus and Iran, continuing to Kazakhstan, SW Siberia (Suva) and NW China (W Xinjiang). Winters from Mediterranean and Middle East S to W Africa, and from Ethiopia S to South Africa and W to Angola and Namibia; Pakistan, India and W Myanmar; irregularly on SW Caspian Sea.



Descriptive notes. 22-24 cm; unsexed 57-147 (87·5) g; wingspan 37-42 cm. Rather plump crake, readily distinguished from sympatric rallids on size, structure and plumage: spotted appearance, lack of extensive grey on underparts (can be somewhat greyer than illustrated), buff undertail-coverts; yellow bill with greenish tip and orange-red spot at base of upper mandible; white leading edge to wing well visible in flight. Sexes similar; male in non-breeding plumage has less grey and more spotting on face and underparts; female has less grey and more spots than male on these areas in both plumages. Rare variations in colour of undertail-coverts from dark feather tips to black and white barring. *P. carolina* differs most obviously in colour and pattern of head, neck and breast, and lack of red on bill. Immature similar to non-breeding adult but has more white spots on side of head, and narrower black margins to white markings on breast; bill changes from yellow-brown with yellow base to olive green with orange base. Juvenile similar to immature but has streak over eye brown or cream with tiny white spots, neck mottled grey-brown and off-white, breast olive brown to bright brown with white or buff markings, and flanks less contrastingly barred; eye greenish; bill olive brown to greenish horn, darker at tip and more orange at base; legs dull green. Voice. Advertising call of male a short, sharp ascending whistle "whitt", suggesting whiplash, repeated about once per second for up to several minutes; given mainly from dusk through night; female has softer version, sometimes given in duet. Also quiet "hui" notes, a loud repetitive ticking call, a hard "eh" of alarm and a warning "tshick".
Habitat. Freshwater wetlands with dense cover of sedges and rushes (*Carex*, *Eleocharis*, *Cyperus*, *Juncus*, etc.), grass (e.g. *Panicum*, *Poa*, *Deschampsia*), *Polygonum*, *Iris*, *Equisetum* and other emergents; sometimes with trees such as *Acacia*, *Sesbania*, *Betula*, *Salix* and *Alnus*; frequents areas where substrate moist, muddy or flooded to c. 15 cm. Optimum conditions found in wetlands with range of water depths or where suitable foraging areas produced by variations in water level. Occurs in marshes (permanent or seasonal) and fens, at sewage ponds, pools in flooded grassland, and at margins of dams, lakes and sluggish rivers. On migration may occur in atypical habitats. In African winter quarters often occupies ephemeral habitats, with rapidly changing water levels, not normally inhabited by breeding Afrotropical rallids. Recorded up to 2420 m.
Food and Feeding. Omnivorous; mainly small aquatic invertebrates and parts of aquatic plants. Takes earthworms, molluscs, Arachnida, insects and their larvae (Trichoptera, Odonata, Diptera, Coleoptera, Hemiptera, Lepidoptera and ants), and small fish stranded in drying pools. Plant material includes algae, shoots, leaves and roots, and seeds (*Panicum*, *Oryza*, *Carex* and *Schoenoplectus*). Forages in water up to 7 cm deep, and on wet to dry mud, usually keeping close to cover; picks food from surface of substrate and immerses head in water; sometimes feeds 10-15 m from cover with groups of shorebirds such as Wood Sandpipers (*Tringa glareola*); stretches up to strip seeds from grass inflorescences; also walks on floating vegetation and gleans from underside of water-lily (*Nymphaea*) leaves; swims occasionally. Most active early and late in the day.
Breeding. Europe, Apr-Jul; former USSR, May-Jul. Monogamous; pair-bond maintained only during breeding season. Territorial when breeding and also in winter quarters. Nest a thick-walled cup of dead leaves and stems of available vegetation; placed in thick vegetation close to or over standing water, in tussock or built up well above water level; concealing vegetation often pulled over to form canopy; external diameter 12-14 cm, height 8-10 cm. Both sexes build. Usually 8-12 eggs (6-14), laid at rate of 1 per 1·5 days; replacements laid after clutch loss; incubation 18-19 days per egg, up to 24 days for clutch, by both sexes; hatching asynchronous, taking 3 days; black downy chick has green gloss on head, throat and upperparts, iris grey to brown-black, upper mandible red at base, yellow in middle and white at tip, lower mandible black with red-brown base, white band and black band in middle, and white tip, legs and feet grey-brown to black; chicks precocial and nidifugous; fed and cared for by both parents; remain in nest until all clutch hatched, then leave in 8-10 hours; become self-feeding after several days; fledging up to 45 days; post-juvenile moult late Jul to Oct. Hatching success 83%. Age of first breeding 1 year. Usually double-brooded.
Movements. European birds move S to SW in autumn; some winter S Europe and N Africa (Egypt and Morocco), others in W, E & SE Africa; relative paucity of wintering records from Africa attributed to secretiveness and inaccessibility of habitat. Autumn dispersal begins Jul; some birds halt in Aug to moult, and are flightless for 2-3 weeks; marked S movement Aug-Sept; most reach or pass Mediterranean by mid-Nov; passage recorded Egypt and Sudan Sept-Oct, Kenya Nov-Jan. Recorded Sudan and Ethiopia Sept-May; E Africa Nov to early May; C to S Africa Nov-Apr, with peak numbers Jan-Mar. In W Africa occurs Senegal Sept-Feb; isolated Sept-Mar records Mauritania, Mali, Chad, Niger, Liberia, Ivory Coast, and Nigeria (several); probably commoner and more widespread than records indicate. Itinerant in African wintering areas; in Zambia arrives at flooded sites soon after local rain and departs when conditions become too dry, maximum period of residence being 23 days. Passage through N Africa and Mediterranean more marked in spring, suggesting that more birds overfly these regions in autumn; return movements recorded Morocco to Libya and Sudan Mar-May, Kenya Apr-May, and Europe Mar-Apr; European breeding grounds reoccupied Apr. Birds of unknown origin pass through Iraq and Near East; passage Saudi Arabia and Aden Apr and Nov, Oman Sept-Dec; may overwinter regularly. Movements noted former USSR Aug-Oct and Mar-May, in Azerbaijan Oct-Dec and Mar-Apr; sometimes winters in Azerbaijan. Arrives N India Sept-Oct; return movements noted NW Pakistan Mar-Apr. Vagrant to Iceland, Greenland (9 records), Lesser Antilles and Seychelles; regarded as vagrant to Djibouti, Somalia, Socotra, Yemen and C Thailand. One individual found at same wintering site, Transvaal, in 2 successive years.
Status and Conservation. Not globally threatened. Numbers fluctuate widely in most areas, due to nature of preferred habitat, but decreases evident over most of European range during present century due to wetland drainage; now local and uncommon to rare in most regions. In Africa regarded as locally common in winter in Egypt, Senegal and Burundi but scarce elsewhere except in major known wintering region comprising Zambia, Malawi, Zimbabwe and probably Mozambique, within which region possibly not uncommon but overall numbers difficult to assess because of erratic occurrence and annual fluctuations. Generally uncommon in S Africa but locally common at temporary pans in extreme NE Namibia; 1 unconfirmed oversummering record Lesotho. Wintering habitat in Africa probably decreasing as result of wetland destruction. Formerly numerous in S & C USSR, and locally abundant further N and in Transcaucasia; still common in Azerbaijan and elsewhere, but decreasing in some areas. Status in other regions difficult to assess: in past, said to be commoner than supposed in India and Pakistan. In long term, vulnerable to changes in water levels, whether caused by wetland modification and drainage or by climatic changes, but can occupy artificially created habitats, especially in winter quarters.

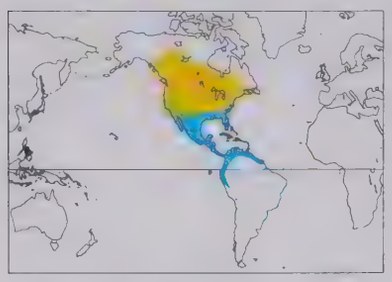
88. Australian Crake

Porzana fluminea

French: Marouette d'Australie **German**: Flußsumpfhuhn **Spanish**: Polluela Australiana
Other common names: Australian Spotted/Water Crake

Taxonomy. *Porzana fluminea* Gould, 1843, New South Wales.
Monotypic.
Distribution. Australia and Tasmania.



Descriptive notes. 19-23 cm; male 50-75 (65·5) g, female 50-61 (57) g, unsexed 57-81 (68) g; wingspan 27-33 cm. Female somewhat smaller than male; also differs in having duller olive upperparts, brown stripe across upper lores, grey of face to breast paler and more uniform, more extensive white spotting on breast and throat, and duller, less swollen, spot at base of culmen. Male may show slight seasonal variation in appearance of spot at base of culmen: swelling may disappear and colour may fade to brownish yellow. Sympatric *P. pusilla* smaller and paler, with richer cinnamon brown upperparts, paler grey underbody, no spots on sides of neck and breast, barred undertail-coverts, and no red or orange spot at base of bill. Immature very similar to adult, but has narrow white fringes to grey breast feathers in fresh plumage; upperwing-coverts patterned like juvenile. Juvenile similar to adult on upperparts but white spots lack black borders and are thus less striking; rump and uppertail-coverts lack white marks; secondary coverts all have white tips; grey areas of face and underparts have white spotting and whitish feather tips; sides of breast olive brown, spotted white; belly off-white; underpart barring dark brown and white; bill grey-olive with darker culmen and tip; iris dark brown. Juvenile female has less cinnamon, more olive, ground colour to upperparts and breast. Voice. Poorly known. Common call a sharp, metallic double note. Also a chattering call similar to "ratchet call" (rattle) of *P. pusilla*; a prolonged wheezing note; and a sharp or querulous single-note call.
Habitat. Well vegetated margins of permanent or ephemeral freshwater, brackish or saline wetlands. Occurs at estuaries, tidal creeks, mangroves, salt-marshes, swamps, marshes, lakes, ponds, lagoons, clay-pans and floodplains; also among water-lilies (*Nymphaea*). Prefers edges of drying wetlands rather than more deeply flooded areas. Sometimes in scrubby cover round salt-marshes and salt-works; may occur some distance from water. Often at artificial wetlands, such as salt-works, sewage ponds, gravel pits, and drains; occasionally in grassy areas, e.g. lawns, pastures, golf courses; also recorded at rubbish dump.
Food and Feeding. Molluscs, crustaceans, adult and larval insects (Dermaptera, Orthoptera, Hemiptera, Coleoptera, Diptera, Lepidoptera, Hymenoptera including ants), spiders, and frog tadpoles; also algae, plant material and seeds. Forages mainly at wetland margins on mud or peat, or in shallow water; near or among grass, marsh vegetation or shrubs; also among floating plants. Wades and swims, probing and lunging under water and at emergent vegetation. Unobtrusive, but generally bolder than other crakes; diurnal; particularly active early and late in day.
Breeding. Aug-Apr, most Aug-Jan. Monogamous; pair-bond may be maintained outside breeding season; probably territorial when breeding. Nest varies from flat, flimsy structure to cup of fine woven material; of wet or dry rushes, or dry grass; sometimes has dome or canopy of interlaced rushes; external diameter 7-9 cm, depth 5 cm; some have ramp from substrate to rim. Usually built 2-50 cm above water, in rushes, sedges, grass, low bushes, among overhanging tree branches, or in water-lilies; often in centre of clump or tussock; one built on ground. Eggs 3-7, probably laid at daily intervals; incubation by both sexes, period unknown; hatching asynchronous; black downy chicks have greenish sheen on upperparts (later, body colour fades to dark brown), iris black, bill black with red base, legs and feet dark olive-green or blue-black; chicks precocial; tended by both parents, possibly until after fledging; no information on growth or development; post-juvenile moult recorded Jan-Apr. May sometimes rear 2 broods per year.
Movements. Possibly dispersive. No seasonal movements suggested; in some areas present all year, but in others apparently occurs only in autumn and winter; higher reporting rates in summer possibly related to increased calling. May move across Torres Strait, where recorded on Booby I in Jan and May, and across Bass Strait, where recorded on King I and Flinders I. Numbers fluctuate with changing habitat conditions: becomes abundant after floods and heavy rain, and known to congregate at edges of drying wetlands. May be irruptive, as exceptional numbers sometimes appear and depart suddenly.
Status and Conservation. Not globally threatened. Endemic to Australia, occurring mainly in SE & SW, and sparsely elsewhere. Locally rare to common. Habitat loss has occurred through wetland drainage and modification, but species readily occupies artificial wetlands; construction of these provides some compensation for wetland losses, and has also allowed expansion of range into previously uninhabitable areas.
Bibliography. 89. Sora

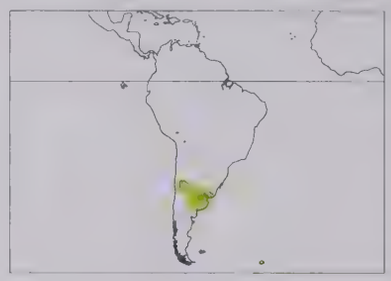
Porzana carolina

French: Marouette de Caroline **German**: Carolinasumpfhuhn **Spanish**: Polluela Sora
Other common names: Sora/Carolina Rail/Crake

Taxonomy. *Rallus carolinus* Linnaeus, 1758, Hudson Bay.
Monotypic.
Distribution. SE Alaska, Canada and USA. Winters from S USA, Mexico and West Indies S to C Peru and E to the Guianas.



Descriptive notes. 19-25 cm; unsexed 51-126 (85) g; wingspan 35-40 cm. Black mask and small white patch behind eye. Sexes similar but female slightly smaller, with darker bill and less prominent head pattern; more white dots on upperparts and upperwing-coverts. Non-breeding adult in fresh plumage has grey tips to black throat feathers and white tips to grey breast feathers. Similar to *P. porzana* in size and bulk, but longer-necked and with striking head pattern, and yellow bill with greenish tip; grey foreneck and breast with no spots. Head pattern and extensive barring on flanks separate from smaller *P. fluminea*. Immature like adult but black patch on chin and throat less extensive and mottled grey; cheeks and sides of neck paler grey, and grey breast often tinged olive. Juvenile has upperparts and wings like adult but with more white streaks; predominantly olive brown to buff on head, neck and breast in areas where adult is grey; has black only on lores and at eye; white chin and throat, duller flank barring than adult, brown iris, and green-yellow bill. Juvenile differs from juvenile *P. porzana* in having crown and side of head brown with no spots and streaks, central crown streak and lores black, breast uniform buff, and bill green-yellow. Voice. Characteristic breeding-season territorial and contact call, given by both sexes, a high-pitched descending whinny; occasionally heard in non-breeding season. Also plaintive, ascending, whistled "kerwee" given in spring, various peeping calls and a short, sharp "keek" when alarmed.
Habitat. Preferred habitats throughout year are freshwater emergent wetlands but often occurs in marshes of brackish and salt water during migration, and occasionally when breeding. Optimal habitat in North America is marshes with shallow and intermediate water depths, and high interspersion of fine-leaved and robust emergents, flooded annuals, and patches of open water; attracted to areas with abundant floating and submerged vegetation, probably because of good substrates for invertebrate prey near water surface. Dominant plants at freshwater nest-sites include *Typha*, *Carex* and sometimes *Scirpus*; in marshes of brackish or salt water, nests occasionally in *Spartina* or *Phragmites*. Also feeds in upland fields and row crops in late summer, and visits grass fields, rank weed growth and brushy hillsides; migrants feed in cultivated rice fields; wintering birds also occur in mangroves, and at mudflats, drainage ditches and edges of ponds. Breeds up to altitude of 3500 m in USA; recorded to 4080 m in C Peru (L Junín).
Food and Feeding. Omnivorous; common plant foods include duckweed (*Lemna*), and seeds of wild or cultivated rice (*Zizania*), *Polygonum*, sedges and grasses; invertebrate foods include molluscs, crustaceans, and insects (Diptera, Odonata, Coleoptera, Orthoptera and Lepidoptera). Plant material forms large part of diet in summer and autumn; autumn migrants in salt-marshes feed more on invertebrates; spring migrants in Missouri take largely invertebrates and seeds of *Carex*. Forages on mud and in shallow water, and on floating vegetation by raking mats of duckweed with feet and pulling aside other vegetation with bill; strips seeds from grass panicles and picks seeds from substrate; swims and dives readily. Diurnal; emerges from cover to feed in early morning and evening.
Breeding. USA Apr-Jul. Monogamous and territorial; pair-bond maintained during breeding season. Nest a loosely woven basket of available vegetation, either supported by surrounding stems or built within vegetation clump; usually built over standing water near borders of vegetation types or patches of open water. External diameter c. 15 cm, height c. 13 cm but may be built up to 48 cm high to overcome flood conditions; internal diameter 7-8 cm and depth 5 cm; ramp of vegetation often constructed to lip of nest. Several brood nests or resting platforms often constructed nearby. Usually 10-12 eggs (5-18), laid at daily intervals; incubation 16-19 days, by both sexes, starting when clutch incomplete; hatching asynchronous, over 2-17 days; one adult tends first-hatched chicks while other continues incubation; chick has glossy black down with orange throat bristles, black iris, bill whitish with red cere (later darkening to greenish), legs and feet pink (changing to grey and then yellow-green); chicks precocial; leave nest soon after all are hatched; cared for by both parents; become self-feeding after a few days but are also fed for 3 weeks and brooded for up to 1 month; feathers begin to emerge at 2-3 weeks; dispersal of family group from home range occurs when young 16-32 days old; able to fly at 4-5 weeks; full juvenile plumage attained in 6th week; post-juvenile moult begins at 12-14 weeks.
Movements. Migratory. Movement begins late summer and early autumn, when birds gather in numbers around lakes and freshwater and brackish marshes; birds are cold-sensitive and depart with advent of frosts in Sept-Oct. Migrates on broad front, over land and sea; prone to drifting in strong winds and occasionally taken far out to sea. Present Mexico mid-Aug to May, Panama Sept-Apr, Costa Rica Oct-Apr, West Indies and Venezuela Sept-May, and Colombia Oct-May (oversummering recorded). Return noted to S USA from Mar; spreads N in Apr, reaching Canada early May. Main passages Atlantic coast (Maryland) mid-Apr to mid-May, and mid-Aug to late Oct. Accidental EC Alaska, Queen Charlotte Is, S Labrador, Bermuda, Greenland and W Europe.
Status and Conservation. Not globally threatened. Most abundant and widely distributed North American rail. Current population trends uncertain, but habitat continues to decline throughout much of range, at least in North America, where habitat loss and degradation probably limit population size. Presence of power plants discharging hot water into rivers may allow birds to extend wintering range into colder regions. Traditionally a game species, hunted in 31 USA states and 2 Canadian provinces, with bag limits of 10-25 birds per day; as interest and participation in hunting are currently low, annual kill is probably within sustainable levels; surveys to monitor harvest and population trends have been lacking but improved estimates of harvest are now possible. Some are killed in traps for fur-bearers, while pesticides and ingested lead shot may also pose threat. Preservation and proper management of emergent wetlands are major priorities to safeguard and improve habitats; standardized taped-play-back surveys could be used to monitor population trends. Elsewhere, species common to frequent throughout Mexico, where possibly breeds locally in N Baja California; local in Costa Rica; locally common in Venezuela and at 2000-3000 m in Andes of Colombia and Ecuador.

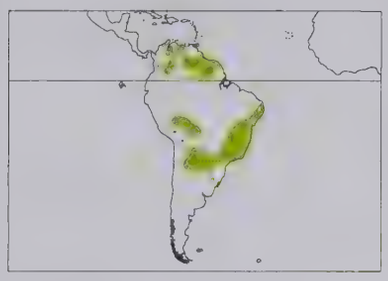
90. Dot-winged Crake

Porzana spiloptera

French: Marouette maillée **German**: Fleckensumpfhuhn **Spanish**: Polluela Overa
Other common names: Dot-winged Rail

Taxonomy. *Porzana spiloptera* Durnford, 1877, Belgrano, Buenos Aires, Argentina.
Sometimes placed in genus *Laterallus*. Monotypic.
Distribution. S Uruguay and N Argentina.



Descriptive notes. 14-15 cm. Small dark crake, with blackish streaks (feather centres) on dark olive brown upperparts; white markings on upperparts confined to upperwing-coverts and remiges; black and white bars on undertail-coverts. Sexes alike. Superficially very similar to *Laterallus jamaicensis* in size and overall colour, but latter has nape and upper back chestnut to russet, rest of upperparts dark brown to black, and white markings from lower back to tail; *L. j. murivagans* and *L. j. tuerosi* have cinnamon undertail-coverts. *Coturnicops notatus* also similar in size and colour but has white chin, white markings on head, neck and breast, white barring on rest of underparts, and black legs and feet. Larger *Neocrex erythrops* has unmarked olive brown upperparts, paler grey underparts, olive green bill with red base, and coral red legs and feet. Presumed immature described as blackish brown above, with feathers tipped vinaceous buff to vinaceous cinnamon; many upperwing-coverts with subterminal white bar; face, chin and throat whitish, washed grey-buff; breast and belly dull grey; flanks vinaceous grey with buff to cinnamon bars; undertail-coverts blackish with vinaceous tips and dull white to buff markings. Voice. Unknown.
Habitat. Freshwater and brackish wetlands, including tidal and temporary marshes, swamps, wet marshy meadows, and wet to dry grassland; also cord grass and riparian scrub. Holotype taken in a garden almost in city of Buenos Aires. In R Luján marshes, habitat is dominated by *Spartina densiflora* and some *Eryngium*, and birds have occurred in dense *Spartina* up to 70 cm tall, with permanent brackish surface water; elsewhere, found in *Paspalum* grass.
Food and Feeding. Recorded as feeding on insects, seeds and marsh weeds. No information on feeding habits.
Breeding. Only recorded nest was found near Buenos Aires, but no further details were given. In addition, a juvenile was seen with an adult at Punta Norte, Cape San Antonio (NE Argentina), some time in 1987/88.
Movements. None recorded.
Status and Conservation. VULNERABLE. In Argentina, recorded from only 6 provinces, 3 of them doubtfully: the single records from La Rioja and San Juan possibly refer to *L. jamaicensis*; occurrence in San Luis unconfirmed. In Córdoba, up to 10 birds observed at one locality in 1973/74; in Santa Fé one collected in 1906. In Buenos Aires Province, species known from 15 localities, records from up to 7 of them falling within the last 10 years; records are all of 1-2 birds. In Uruguay, recorded only from Arroyo Pando (Canelones Department) before 1926, and Arroyo Solís Grande in 1973. Status of this poorly known and secretive crake is unclear. Formerly regarded as locally frequent to abundant in Buenos Aires Province, where currently considered locally rare (or very difficult to locate) to fairly common; lack of sightings may be attributable to paucity of observers. Formerly considered rare in La Rioja but common at the one known site in Córdoba; status in other provinces unclear. Regarded as rare and local in Uruguay. Reclamation and burning of marsh areas, flooding, intrusion by cattle, overgrazing, burning, disturbance by visitors, and projected development are cited as current risks to survival. Numbers apparently declining both at R Luján and Punta Rasa, areas considered to hold healthy populations. Reserves exist at 3 sites known to hold the species. Distributional surveys urgently needed within species' limited range; voice should be recorded; and possibly beneficial effect of better management of cattle should be studied.
Bibliography. Blake (1977), Canevari *et al.* (1991), Chebez (1994), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Durnford (1877), Gibson (1920), Gore & Gepp (1978), Hartert & Venturi (1909), Hellmayr & Conover (1942), Meyer de Schauensee (1982), Narosky (1985), Narosky & Yzurieta (1987), Nores & Yzurieta (1980), Olrog (1984), de la Peña (1992), Wege & Long (1995).

91. Ash-throated Crake

Porzana albicollis

French: Marouette plombée **German**: Wieselsumpfhuhn **Spanish**: Polluela Turura
Other common names: White-necked/White-throated Crake

Taxonomy. *Rallus albicollis* Vieillot, 1819, Paraguay.
Race *olivacea* includes proposed race *typhoeca*. Two specimens from extreme SE Peru are as large as *albicollis* but show plumage characters of *olivacea*. Two subspecies recognized.
Subspecies and Distribution.
P. a. olivacea (Vieillot, 1819) - Colombia, Venezuela and Trinidad to the Guianas and extreme N Brazil.
P. a. albicollis (Vieillot, 1819) - E & S Brazil, N & E Bolivia, Paraguay and extreme N Argentina; probably this race in SE Peru.
Descriptive notes. 21-24 cm; male 90-114 g; 1 female 105 g. Sexes alike. Slightly smaller *P. carolina* has white streaks on upperparts, distinctive face pattern, more extensive white flank bars, white and buff undertail-coverts, bright yellow bill, and greenish legs and feet. *Neocrex erythrops*, the only other sympatric, short-billed crake of similar size with grey breast and barred flanks, has unmarked olive-brown upperparts, olive green bill with red base, and coral red legs and feet. Larger *Cyanolimnas cerverai* has unpatterned brownish olive upperparts, dark slate flanks with faint white bars, white undertail-coverts, yellowish green bill with red base, and red legs and feet. Immature similar to adult but duller, with brownish wash on grey underparts. One presumed juvenile has off-white chin, predominantly olive brown face, throat, foreneck and underparts, and no barring from flanks to undertail-

coverts but deeper brown wash in these regions. Races separated on overall colour and size, *albicollis* being larger and darker. Voice. Song a repeated, loud, fast series of vibrating notes, sounding like machine-gun "d'd'd'd'd'-ou". Call a sharp "tuk". Calls most in early morning and evening.

Habitat. Freshwater marshes, marshy lakes, Moriche swamps, rice fields, drainage ditches, savanna, dry to damp taller grass of grazing lands, tall reeds along roadsides, and secondary growth. In marshy habitats appears to prefer drier areas, and in Surinam regarded as less of a marsh bird than other small rails. Inhabits lowlands up to 1200 m.

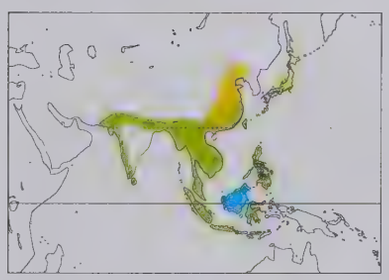
Food and Feeding. Insects and their larvae (Lepidoptera, Formicidae, Coleoptera), and grass seeds. Occasionally emerges partially into the open near cover, presumably feeding.

Breeding. Trinidad and Tobago, probably Jul-Oct; Guyana, Feb-Jul with peak in May, but possibly nesting throughout year. Nest a large open bowl of roughly woven coarse dry grass and sometimes a few leaves; placed on or just above ground between clumps of savanna grass or in reeds; often near base of tree stump, sheltered by roots. External diameter c. 20 cm, depth c. 10 cm; cup diameter c. 10 cm, depth c. 5 cm. Eggs usually 2-3, possibly up to 6. No other information.

Movements. Nothing definitely recorded, but some seasonal movements possible in Colombia, records from NE Meta being Dec-Mar and from W Meta Mar-Sept, while birds reported to move into *Typha* marsh during dry season at Ciénaga Grande. In French Guiana an exhausted bird was found on a bridge in Jul.

Status and Conservation. Not globally threatened. Race *olivacea* formerly regarded as quite common to abundant in Guyana, local in Colombia and rare in Trinidad; no information about past status of race *albicollis*. Apparently not uncommon in extreme SE Peru (Pampas de Heath) in 1977. Little information available on current status of species: common along littoral zone in French Guiana and probably of local occurrence in many other regions. Distribution is probably more continuous than currently thought. Species is solitary, shy and difficult to observe.

Bibliography. Belton (1984), Benson & Winterbottom (1968), Blake (1977), Canevari *et al.* (1991), Contreras *et al.* (1990), Darlington (1931), ffrench (1973), Graham *et al.* (1980), Haverschmidt (1968), Haverschmidt & Mees (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Meyer de Schauensee (1962), Meyer de Schauensee & Phelps (1978), de la Peña (1992), Sick (1985c, 1993), Snyder (1966), Tostain *et al.* (1992).



92. Ruddy-breasted Crake

Porzana fusca

French: Marouette brune **German**: Zimtsumpfhuhn **Spanish**: Polluela Pechirrufa
Other common names: Ruddy Crake(!)

Taxonomy. *Rallus fuscus* Linnaeus, 1766, Philippines.
Sometimes placed in *Amaurornis*. Possible race *bakeri* included in nominate. Four subspecies recognized.

Subspecies and Distribution.
P. f. fusca (Linnaeus, 1766) - Pakistan and N India to SC China (Yunnan) and Vietnam, Malay Peninsula, Philippines and W Indonesia.
P. f. zeylonica (Stuart Baker, 1927) - W India and Sri Lanka.
P. f. erythrothorax (Temminck & Schlegel, 1849) - Japan, E & S China and Indochina; N populations winter to S.
P. f. phaeopyga Stejneger, 1887 - Ryukyu Is.

Descriptive notes. 21-23 cm; unsexed mean 60 g. Sexes alike but female generally paler, with whiter throat. *P. paykulli* similar in size but has white bars (sometimes missing) on some upperwing-coverts, bold black and white barring on lower underparts, and orange-pink legs and feet. *Rallina fasciata* larger and brighter, with bold black and white barring on remiges, upperwing-coverts and underparts, darker bill, and more prominent red orbital ring. *R. eurizonoides* has white bars on inner webs of remiges, bold underpart barring and grey legs. Immature similar to adult but darker; duller on underparts; chin, throat and centre of belly white; iris red-brown. Juvenile has darker upperparts than adult; supercilium and sides of head and neck dull white; underparts mostly dull white, barred dusky brown; flanks and thighs dull olive brown; undertail-coverts as adult; iris brown. Races separated on size and on shade of underparts, dark in nominate and *zeylonica*, which are also smallest. Voice. Usually silent, but in early morning and evening during breeding season utters hard "tewk" or "kyot" notes (likened to knocking on a door) every 2-3 seconds, often speeding up and usually followed by bubbling call similar to that of Australasian Grebe (*Tachybaptus novaehollandiae*); utters short "chuck" when foraging.

Habitat. Reedy swamps, marshes and stream banks, reedbeds, wet grassland at edges of lakes, ditches and canals, edges of rice paddies; also bushland and forest paths, possibly during post-breeding dispersal; sometimes on dry cultivated vegetable fields, in Japan. Normally occurs in lowlands, but breeds up to c. 2000 m in Himalayas.

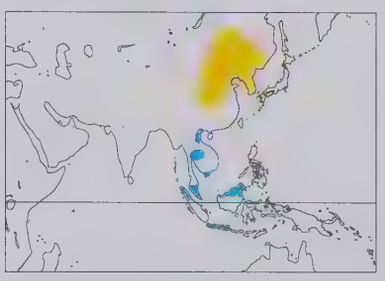
Food and Feeding. Eats molluscs, aquatic insects and their larvae, seeds, and shoots of marsh plants. Probably feeds mainly in cover; occasionally ventures out to edges of reedbeds; may be mainly crepuscular.

Breeding. Kashmir and NW Pakistan, Jun-Aug; Bengal and NE Pakistan, Jun-Sept; Japan, Mar-Sept; Philippines Aug-Sept; Sumatra, Dec, Mar; Singapore, Nov. Probably monogamous. Nest a pad of dry grass, rush, rice straw, roots and leaves of aquatic plants; placed on swampy ground among grass, reeds or rice; sometimes among low bushes; growing plants sometimes bent over to form canopy. Both sexes build. Eggs 3-9; incubation 20 days; glossy black downy chick has bronze-green sheen on upperparts, underparts browner, bill black with pink base and tip, legs and feet reddish black; both parents feed and care for young.

Movements. Largely resident, but migratory in some regions. Status of some populations unclear, especially on Asian mainland (demarcation on map between resident and seasonal occurrences is largely hypothetical). N populations of *erythrothorax* move S to winter in S China (S of Yangtze R) and Indochina; this race is summer breeding visitor to Japan (May-Oct), small numbers also wintering in S; in Sri Lanka numbers of *zeylonica* augmented by migrants which arrive Oct-Nov and leave Mar-Apr. Probably resident throughout Wallacean range; scarce winter visitor to Borneo. Race *phaeopyga* resident in Ryukyu Is. Vagrant to Christmas I (Indian Ocean), with 2 specimens, Aug and Sept.

Status and Conservation. Not globally threatened. Extremely shy and difficult to flush, thus poorly known, but formerly considered common to abundant over much of its range. Currently regarded as locally common to abundant in Sumatra, Java and Bali, and uncommon Philippines; race *erythrothorax* is the commonest rallid in Japan.

Bibliography. (1991), Smythies (1986), White & Bruce (1986).



93. Band-bellied Crake

Porzana paykullii

French: Marouette mandarin **German**: Mandarinsumpfhuhn **Spanish**: Polluela Mandarín
Other common names: Siberian Ruddy/Chinese Banded Crake

Taxonomy. *Rallus Paykullii* Ljungh, 1813, Banjarmasin, Borneo, and Jakarta, Java.
Sometimes placed in genus *Rallina*; further study of relationships required. Monotypic.

Distribution. Russian Far East (SW Amurland and S Ussuriland), NE China (Heilongjiang, Hebei and N Henan) and Korea. Winters in SE Asia, Sumatra, Java and Borneo. One specimen from Basilan, Philippines, is a *Rallina fasciata*.

Descriptive notes. 20-22 cm. Sexes similar; in female, dark bars of underparts brown rather than black, and white markings on coverts may be less conspicuous. Outermost primary mottled white on outer web; white tips to greater and median upperwing-coverts sometimes inconspicuous or absent. Similar to *Rallina fasciata* and *R. eurizonoides*, which are larger, with chestnut crown and nape, and more extensive underpart barring; *R. fasciata* also has richer brown upperparts, boldly barred primaries and outer secondaries, more extensively barred upperwing-coverts, more extensive underpart barring with broader white bars, and red legs and feet; *R. eurizonoides* has no bars on upperwing-coverts, barring on inner webs of remiges, and greenish grey to black legs and feet. Sympatric *P. fusca* has unbarred wings, and only narrow and inconspicuous white barring on flanks, belly and undertail-coverts, and red legs and feet. Immature similar to adult but chestnut of face, neck and breast duller; legs purplish brown. Juvenile darker on upperparts, with more extensive white tips to upperwing-coverts; face, neck and breast buffy brown with obscure dark brown bars; barring on flanks, belly and undertail-coverts less regular than in adult, and white bars tinged buff; chin, throat and belly off-white. Voice. Call distinctive: likened to intermittent drumbeats and also to sound of a wooden rattle; uttered most frequently at dusk and dawn, and at night.

Habitat. Breeds in lowland marshes and meadows with tussocks, thickets or small trees; also in marshy or damp situations in mountains, woodland and forests. Avoids open water; prefers damp to dry situations with thick grass; often found near villages and along field edges and fences. Wintering habitat described as wet grass and paddyfields (Greater Sundas), and grassy hummocks with bushes or small trees in meadows and swamps (Vietnam). Apparently mainly a lowland species.

Food and Feeding. Mostly crustaceans and insects (including Coleoptera); also seeds. Forages in damp situations, sometimes in drier areas near gardens and dwellings. May be partly nocturnal.

Breeding. In Russian Far East, breeds from late May. Usually solitary; presumed monogamous; sometimes occurs in densely populated colonies. Nests in hummocky, not too damp meadows, and swamps with thickets. Nest usually built in depression in ground in grass or shrubs; lined with fine twigs and grass stalks. Eggs 5-9. No further information.

Movements. Winters in C Thailand, Vietnam (Tonkin and Cochinchina), Peninsular Malaysia, N Sumatra, Java and N Borneo. Also one record from S Sulawesi, Apr 1979. Winter distribution imperfectly known. Transient in Inner Mongolia and Shandong, southwards through S China.

Status and Conservation. Not globally threatened. Currently considered near-threatened. Very little information available on status and distribution. In past, locally common in USSR, occasional in Borneo. Currently regarded as scarce in Greater Sundas, where recorded in N Sumatra, N Borneo and Java; only two records from Sumatra, both specimens, the second in Jan 1918. Status and distribution urgently require investigation, especially in wintering range.

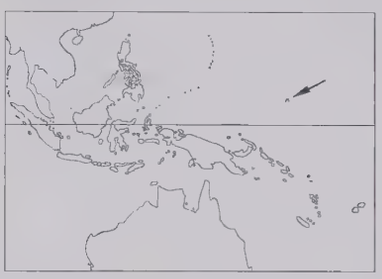
94. Spotless Crake

Porzana tabuensis

French: Marouette fuligineuse **German**: Südsee-Sumpfhuhn **Spanish**: Polluela de Tongatapu
Other common names: Sooty Crake

Taxonomy. *Rallus tabuensis* Gmelin, 1789, Tongatapu Group, Tonga.
Forms superspecies with *P. atra* and *P. monasa*. Geographical variation slight, and validity of subspecies requires confirmation. Possible race *plumbea* of S Australia and New Zealand included in nominate *tabuensis*. Three subspecies currently recognized.
Subspecies and Distribution.
P. t. tabuensis (Gmelin, 1789) - Philippines (Luzon) through Australia, Tasmania, New Zealand and Chatham Is to New Caledonia and SW Pacific islands and E through Micronesia and Polynesia.
P. t. edwardi Gyldenstolpe, 1955 - W & C New Guinea.
P. t. richardsoni Rand, 1940 - Oranje Mts in C Irian Jaya (W New Guinea).



Descriptive notes. 15-18 cm; male 34-56 (45·5) g, female 21-58 (40) g; wingspan 26-29 cm. Sexes alike. Easily distinguished from all sympatric small crakes: reddish chocolate brown upperparts, dark slate grey head, neck and underparts, white outermost primary and leading edge of wing, black and white bars on undertail-coverts, red iris and orbital ring, black bill, and salmon pink legs and feet. Immature like adult. Juvenile similar to adult but dark brown from forehead to hindneck and on lores; brownish wash on face and sides of throat; white chin and throat; upperparts less red-brown than in adult, and underparts dark grey-brown; some have narrow white supercilium extending to above eye; bill black with pink base; iris brownish orange; legs and feet grey-brown to brownish flesh. Races separated on: size, *tabuensis* smallest; and colour of upperparts, olive brown in *richardsoni*, deep chocolate in *edwardi*. Voice. Calls distinctive. Commonest calls, given during breeding season: loud trilling purr, resembling motor or sewing machine and preceded by soft quarrelling sequence; and single or repeated loud, sharp, high-pitched "pit", often interspersed with harsh nasal "harr" and trilling whistle. Also has soft bubbling and murmuring contact calls.
Habitat. Usually dense vegetation in, or at margins of, freshwater or saline wetlands, either permanent or ephemeral. Occurs in marshes, swamps, salt-marsh and peat bogs; also at margins of rivers, streams, tidal creeks, ponds and lakes. May prefer wetlands with shallow, slow-flowing water; overstorey of willows (*Salix*), or tall reedbed vegetation such as *Typha orientalis*, may be important requirement of breeding habitat in New Zealand. Frequently inhabits artificial wetlands such as salt-works, sewage farms, rice paddies, taro ponds, irrigation channels, farmland, golf courses, lawns and gardens. Also occurs on fern-covered hillsides, and in heathy flats and coastal scrub; on some islands occupies low forest and also rocky or stony habitats without standing water. Ranges from sea-level up to c. 3300 m in New Guinea, where most widespread in highlands.
Food and Feeding. Molluscs, crustaceans (ostracods and amphipods), Collembola, adult and larval insects (Ephemeroptera, Coleoptera, Diptera and Orthoptera), spiders; eggs of shearwaters, petrels and terns; seeds, fruit and shoots of grasses and aquatic plants. Also recorded feeding on carcass of cow. Crepuscular and diurnal; usually feeds on ground, but also in trees (Kermadec Is), foraging among foliage and nests of noddies (*Anous*); swims readily. Forages on mud and in shallow water, in or near marsh vegetation, along tidelines adjacent to dense vegetation, at margins of still and flowing water, and in short grass; also in and around petrel burrows; searches leaf litter in forests, scratching with feet and moving or turning over litter with bill; sometimes feeds in thickets.
Breeding. Australia, Sept-Jan; New Zealand, Aug-Jan; New Caledonia, Oct; Vanuatu, probably Sept-Feb; Society Is, Jul. Monogamous; possibly pairs for life. Record of 3 adults accompanying young. Territorial, possibly throughout year. Nest shallowly to deeply cupped, of woven dry grass and rushes; placed in clump of sedges or rushes, centre of grass tussock, or small bush in reedbed; often placed over water, sometimes on ground; also against stump of tree-fern, under tangled ferns, brambles or dense bushes. External diameter 10-23 cm, depth 5-20 cm; cup diameter c. 8 cm, depth c. 4 cm; height above water 3-150 cm. Role of male in building uncertain; female bends reeds to form canopy over nest; one or more ramps of nesting material constructed from water to rim; pair often build several roosting nests for use by family. Usually 3-4 eggs (2-6), laid at daily intervals; later clutches larger than earlier ones; island populations may lay smaller clutches than mainland birds; incubation 19-22 days, by both sexes; hatching synchronous, or asynchronous in large clutches; black down of chick has greenish sheen, bill black with pink saddle at base of upper mandible (later pink base to both mandibles), iris black or blue-grey, legs and feet dark brown-grey, pink at rear of tarsus; chicks leave nest after 1-2 days; fed and cared for by both parents, probably being attended until 4-5 months old; first feathers appear at c. 15 days; captive birds were almost fully feathered at 40 days, but remiges were not fully grown at 66 days; post-juvenile moult recorded Sept-May. May have 2 broods in Australia and New Zealand; if nesting delayed, may raise 1 large brood rather than 2 smaller broods; relays after clutch loss.
Movements. Generally regarded as resident over much of range. In Australia relatively few records in S during winter may suggest movement, while possibly regularly migratory in Queensland (recorded in N only Oct-May) and on islands in Torres Strait, where casualties recorded Dec-Feb and May; sudden or seasonal changes in numbers may occur in response to rainfall or receding water, and irruptions, probably induced by good rainfall, are recorded; birds also sometimes occur well outside normal range. On Poor Knights Is (N New Zealand) young disperse to drier habitats. One from Tiur (SE Moluccas) in Jan 1899 was presumably vagrant; species known to be highly dispersive, having spread widely E across Pacific through Polynesia, and vagrancy is to be expected.
Status and Conservation. Not globally threatened. In Australia suitable habitat lost through drainage of wetlands, but species probably still plentiful in many areas, though overlooked: birds readily occupy artificial wetlands, farmland and sometimes garden habitats, and in some areas rise in water table due to irrigation has possibly enhanced habitat. Widespread and sparse to common in New Zealand, where wetland habitats have been reduced; on Aorangi, Poor Knights Is, increased from 1930's with development of low mixed forest after human occupation ceased and pigs were removed (pigs adversely affected habitat by restricting regeneration of low forest, destroying nesting cover and disturbing leaf litter); declined from 1950's as low mixed forest was replaced by tall forest. Has become rare on Norfolk I, where population reduced by rats, and extinct on Raoul I (Kermadecs). Elsewhere formerly regarded as either genuinely uncommon or overlooked, except that *edwardi* was thought fairly common within its restricted range. Currently regarded as rare in Philippines, but possibly more widespread than is known. Distribution and status in New Guinea imperfectly known; apparently locally rare to common. Appears to have suffered population reductions and local extinction throughout Pacific islands, often where it has encountered man and his introduced commensals. Local and uncommon in Vanuatu, where could face extinction as result of swamp pollution or destruction. In E Polynesia disappeared from Gambier Is in 1920's but still occurs in Marquesas and Tuamotus, and on Oeno (Pitcairn group), where population very small. In 1985 rediscovered on Ta'u I, American Samoa, where population small and probably decreasing as habitat diminishes with reduction in subsistence agriculture.

95. Kosrae Crake

Porzana monasa

French: Marouette de Kusaie **German**: Kosraesumpfhuhn **Spanish**: Polluela de las Carolinas
Other common names: Kusaie/Ponape/Kittlitz's Crake

Taxonomy. *Rallus monasa* Kittlitz, 1858, Kosrae Island, Caroline Islands.
Formerly sometimes placed in monotypic genus *Aphanolimnas*. Forms superspecies with *P. atra* and *P. tabuensis*. Monotypic.
Distribution. Kosrae (Kusaie) I in E Caroline Is.

Descriptive notes. 18 cm. Flightless crake; plumage largely black, with bluish grey reflections; chin and throat paler; remiges and rectrices somewhat browner; inner upperwing-coverts brownish with white spots; undertail-coverts spotted white; iris, legs and feet red; bill black. Immature and juvenile not described. Voice. No precise descriptions available, but species was said to have an alluring and resounding voice.
Habitat. Occupied a variety of habitats, including swamps and marshes near sea-level as well as taro patches and wet, shady places in forest.
Food and Feeding. Nothing recorded.
Breeding. No information available.
Movements. None.
Status and Conservation. Almost certainly EXTINCT. Following its discovery, and the collection of 2 specimens, in 1827/28, this crake has not been recorded, despite searches. Formerly considered sacred by the islanders, and thus remained unmolested; within 50 years of the arrival of Christian missionaries, and of rats from whaling ships, the species had most likely become extinct.
Bibliography. Engbring & Pratt (1985), Fuller (1987), Greenway (1967), Neufeldt (1978), Olson (1973b), Pratt *et al.* (1987), Ripley (1977).

96. Henderson Crake

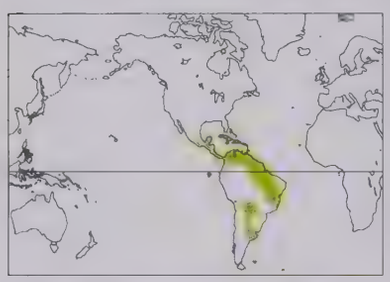
Porzana atra

French: Marouette de Henderson **German**: Tuamotusumpfhuhn **Spanish**: Polluela de la Henderson
Other common names: North's Crake

Taxonomy. *Porzana atra* North, 1908, Henderson Island.
In past sometimes assigned to monotypic genus *Nesophylax*. Forms superspecies with *P. tabuensis* and *P. monasa*. Monotypic.
Distribution. Henderson I, in C Pitcairn Group.

Descriptive notes. 18 cm; male 69-87 (80) g, females 66-88 (74·5) g. Flightless; legs well developed for running. Entire plumage deep black with slight greyish gloss; iris, eyering, legs and feet red; bill blackish, yellowish green at base and along culmen. Sexes alike, but female has less yellowish green on bill (if present, this colour is confined to culmen ridge), and legs plain red to orange (red mottled with black in male); male's red eyering often blotched with black. Immature similar to adult but orbital ring dark, and legs and feet dusky. Juvenile greyer than adult on throat and underparts; iris brown; legs and feet black. Voice. Contact call a nasal "kak", repeated in rapid series as an alarm call. Also has loud, continuous churring call uttered simultaneously as duet by pair members, sometimes joined by other family members. Most vocal at dawn and dusk.
Habitat. Thick *Pisonia* forest to open *Pisonia/Xylosma* forest, and *Timonius* thickets, of the island plateau, and *Pandanus-Thespesia-Argusia* embayment forest on some beaches; also in coconut groves. Absent only from low vegetation and pinnacled limestone at exposed S end of island.
Food and Feeding. Diet includes large nematodes, terrestrial molluscs, insects (Coleoptera, and adult and larval Lepidoptera), spiders, and eggs of the skink *Emoia cyanura*. Opportunistic feeder, taking

On following pages: 97. Yellow-breasted Crake (*Porzana flaviventer*); 98. White-browed Crake (*Porzana cinerea*); 99. Striped Crake (*Aenigmatolimnas marginalis*); 100. Zapata Rail (*Cyanolimnas cerverai*); 101. Colombian Crake (*Neocrex colombianus*); 102. Paint-billed Crake (*Neocrex erythrops*); 103. Spotted Rail (*Pardirallus maculatus*); 104. Blackish Rail (*Pardirallus nigricans*); 105. Plumbeous Rail (*Pardirallus sanguinolentus*); 106. Chestnut Rail (*Eulabeornis castaneoventris*); 107. Invisible Rail (*Habroptila wallacii*); 108. New Guinea Flightless Rail (*Megacrex inepta*); 109. Watercock (*Gallicrex cinerea*).



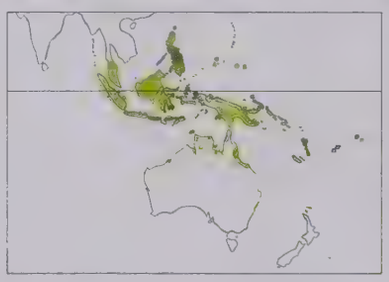
advantage of seasonal increases in prey species. Forages by turning over leaf litter with bill, head-tossing litter aside, and scratching with feet; gleans prey items (including skink eggs) from undersides of leaves. Bold and curious. Active throughout the day.
Breeding. Jul-Feb. Monogamous, with permanent pair-bond; presumably permanently territorial. Possible polyandry once recorded, female making 4 nesting attempts with one male and 1 with a male from an adjacent territory. Some nests spherical, c. 20 cm in diameter with opening c. 10 cm wide, of shredded *Pandanus* palm leaves, placed up to 30 cm above ground in *Pandanus* leaf clump or at base of *Pandanus* trunk; others open-topped, built in low vegetation or up to 60 cm above ground in *Asplenium nidus* ferns. Male does most nest-building. Also builds roosting nests for use after hatching. Eggs 2-3; incubation 21 days, by both sexes; hatching synchronous; chicks have deep velvety black down, and black bill, legs and feet; leave nest soon after hatching; fed and cared for by both parents, helped by young of the previous brood and by other adults in family group; helpers also assist in protecting eggs and chicks from crabs and rats; young fully feathered and capable of independent foraging at c. 1 month, but remain associated with parents for much longer, sometimes being fed occasionally even when 15 weeks old. Many juveniles disperse from natal territories in Mar-Apr, but some remain with parents even when adult. Some pairs lay second clutch when young of first clutch are c. 1 month old; will also lay replacement clutches after loss of eggs or chicks. Annual adult survival at least 43%; reproductive success high, 2·45 chicks surviving for at least 6 months per pair per year. Recruitment rate not known, but probably compensates easily for annual losses, so that population is stable.
Movements. None.
Status and Conservation. VULNERABLE. Endemic to Henderson I, a 37-km² uninhabited raised-reef island with no permanent fresh water. Population estimated at c. 6200 birds in 1992, probably the carrying capacity of the island, as most territories (average size c. 1 ha) held more than 2 adults. Main predator is Polynesian rat (*Rattus exulans*), introduced by man centuries ago; rats take eggs and chicks but apparently do not pose threat to survival of species, and the crakes are very aggressive towards them. However, any inadvertent introduction of a more aggressive predator (e.g. another *Rattus* species) to the island could well result in the crake's rapid decline and extinction, as has happened with many other island rails. Species still vulnerable to possible human impacts: in 1982-83 a millionaire sought to make the island his home.
Bibliography. Bourne & David (1983), Collar & Andrew (1988), Collar *et al.* (1994), Forsberg *et al.* (1983), Graves (1992), Hay (1986), Jones, P. *et al.* (1995), Murphy (1924), Olson (1973b), Pratt *et al.* (1987), Ripley (1977).

97. Yellow-breasted Crake

Porzana flaviventer

French: Marouette à sourcils blancs **German**: Gelbbrust-Sumpfhuhn . **Spanish**: Polluela Pálida

Taxonomy. *Rallus flaviventer* Boddaert, 1783, Cayenne, French Guiana.
Does not closely resemble any other *Porzana* crake; because of similarities in face pattern and bill structure sometimes placed, with *P. cinerea*, in genus *Poliolimnas*, a separation which may be appropriate. Five subspecies recognized.
Subspecies and Distribution.
P. f. gossii (Bonaparte, 1856) - Cuba and Jamaica.
P. f. hendersoni Bartsch, 1917 - Hispaniola and Puerto Rico.
P. f. woodi van Rossem, 1934 - S Mexico to NW Costa Rica.
P. f. bangsi Darlington, 1931 - N Colombia.
P. f. flaviventer (Boddaert, 1783) - Panama and Colombia to Venezuela, Trinidad and the Guianas, and S to N, EC & S Brazil, E Bolivia, Paraguay and N Argentina.



Descriptive notes. 12·5-14 cm; male 22-29 (26) g; female 20-28 (24) g. Sexes alike. Very small crake, with long toes which enable it to walk on floating vegetation; facial pattern of dark line through eye and pale buff-white supercilium diagnostic, and unique among New World rallids. Only other sympatric crake of similar size and overall colour is *Micropygia schomburgkii*, which has more extensive white markings (and no dark streaking) on upperparts, unbarred flanks and undertail-coverts, and red or orange-red legs and feet. Slightly larger *Coturnicops noveboracensis* has white secondaries, lacks white streaks on upperparts, and breeding male has yellow bill. Immature similar to adult but flank barring continues to side of breast. Juvenile has indistinct dusky barring on neck and breast. Races separated on: size, *gossii* and *flaviventer* largest; and on colour shades, *bangsi* has darkest upperparts, *flaviventer* darkest neck and breast, and *hendersoni* palest upperparts. VOICE. Low, harsh, rolled or churring "k'kuk kurr-kurr"; plaintive, squealing, single or repeated "kreer" or "krreh" reminiscent of *P. carolina*; and high-pitched, whistled "peep".
Habitat. Freshwater marshes, grassy edges of lakes and ponds, flooded fields, rice fields, and floating aquatic vegetation such as water hyacinth (*Eichhornia*); rarely in saltwater habitats. Occurs from sea-level up to 2500 m.
Food and Feeding. Small gastropods, insects and seeds, taken from water, mud and vegetation. Forages among emergent plants; emerges from cover in early morning and evening to feed at marsh edge; runs across floating plants and climbs easily in tangled reedy growth.
Breeding. El Salvador, male in breeding condition Aug; Costa Rica, Jul; Trinidad, male in breeding condition Feb; Colombia, "immature" Feb. Nest loosely built among water plants or marsh grass. Eggs 3-5. No other information.
Movements. Normally regarded as sedentary, and no definite movements recorded, but seen only Mar-Jul at Hacienda Corocora, W Meta, Colombia. In Costa Rica probably makes local movements associated with changing water levels. One found at night under village street light, Veracruz (Mexico) in May.
Status and Conservation. Not globally threatened. Formerly regarded as locally abundant in Cuba, locally common in Mexico, and locally common in Trinidad, El Salvador and Panama. Currently regarded as a frequent to uncommon but local resident in Mexico, locally common in Colombia and Costa Rica, and local on the littoral plain in French Guiana; undoubtedly more widespread than is known.
Bibliography. Belton (1984), Biaggi (1983), Blake (1977), Barbour (1923), Canevari *et al.* (1991), Contreras *et al.* (1990), Dickerman (1971), Dickerman & Warner (1961), Dickey & van Rossem (1938), Gochfeld (1972, 1973a), Haverschmidt (1968), Haverschmidt & Mees (1995), Hayes (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Howell & Webb (1995a), Meyer de Schauensee & Phelps (1978), Olson (1970), Orians & Paulson (1969), de la Peña (1992), Peterson & Chalif (1973), Ridgely (1981), Ridgely & Gwynne (1989), Sick (1985c, 1993), Snyder (1966), Stiles & Skutch (1989), Tostain *et al.* (1992), Wetmore (1965), Wetmore & Swales (1931).

98. White-browed Crake

Porzana cinerea

French: Marouette grise **German**: Weißbrauen-Sumpfhuhn **Spanish**: Polluela Cejiblanca
Other common names: Ashy/Grey-bellied Crake

Taxonomy. *Porphyrio cinereus* Vieillot, 1819, Java.
On basis of bill structure and face pattern, which render it distinct from *Porzana* crakes, sometimes placed in genus *Poliolimnas* with *Porzana flaviventer*, which shows similar characters; this separation may well be valid. Until recently several races commonly recognized, notably *brevipes*, *ocularis*, *micronesiae*, *leucophrys*, *meeki* and *tannensis*; but differences between them are slight, not well defined, and subject to overlap. Monotypic.
Distribution. Malaysia and Greater Sundas through Philippines, Sulawesi, Moluccas and Lesser Sundas to New Guinea and N Australia, and E through Micronesia and Melanesia (S to Vanuatu and New Caledonia) to WC Polynesia (Fiji and Samoa); formerly also Volcano Is.

Descriptive notes. 15-20 cm; unsexed 40-62·5 (52) g; wingspan 27 cm. Small, slim-bodied crake with relatively long legs and toes. Easily distinguished from sympatric crakes by striking diagnostic face pattern. In fresh plumage forehead and crown grey, becoming black with wear. Sexes alike. Immature apparently like adult. Juvenile shows adult plumage pattern but grey and black on head replaced by brown, and white facial stripes tinged yellow-brown, making facial pattern less distinct; grey of neck, breast and flanks replaced by buff to pale brown; bill has thin orange band at base; legs and feet olive, blue-green or light blue-grey. A reference to young being "mottled rufous all over" possibly refers to down mixed with emerging juvenile plumage. VOICE. Common call a loud, nasal, chattering, rapidly repeated "chika", made by both members of pair, and sometimes by several pairs in response to disturbance. Also sharp, loud "kek-kro" while feeding; quiet, repeated "charr-r" of alarm; and various plaintive, squeaky cries.
Habitat. Well vegetated coastal and terrestrial wetlands, both freshwater and saline, especially those with abundant floating vegetation; habitat may be seasonal or ephemeral. Inhabits swamps, marshes, creeks, rivers, pools, inundations, lakes, dams and sewage ponds. Uses flooded areas, and observed among flood debris. Also occurs in grassland and agricultural areas, including grazed land, rice fields and taro patches; thickets, mature or degraded forest, palm groves and mangroves. Occurs in lowlands; rarely up to 1830 m in New Guinea.
Food and Feeding. Earthworms, slugs, leeches, insects, water spiders, frog spawn, and small fish; also seeds and leaves of aquatic plants. Forages at mud patches and along margins of water courses, both in and out of cover; frequently forages on floating vegetation, dashing around in stop-start manner; also catches flying insects. Often swims, gleaning from water surface; also floats quietly with neck extended, picking up insects with short, sudden thrusts of bill. Occasionally runs up marsh vegetation or along branches. Active throughout day, particularly in early morning and evening.
Breeding. Borneo, Apr-Jun; Philippines, Jul-Aug, and downy young Oct; New Guinea, Dec-Mar, May, chicks Jun and Oct-Nov; Solomon Is, Jan, Jun-Jul, Sept; Vanuatu, possibly Sept-Mar; Australia, Jan-May, also small young in Sept-Nov, N Queensland. Monogamous; may remain paired outside breeding season; possibly permanently territorial. Nest a saucer-shaped platform of rushes, coarse grass or herbage, lined grass and other fine material; built on ground, on trampled blades of tussock, or in grassy marsh vegetation over water, sometimes more than 1 m deep; once in fork of mangrove tree; growing vegetation often woven into thin canopy. External diameter c. 15 cm, depth c. 3.5 cm; built up to 1 m above ground; runway of reed stems often leads from ground to nest rim. Usually 4 eggs (3-7), laid at daily intervals; incubation c. 18 days, by both sexes; downy chick coal black; a large chick, with emergent body feathers and remiges, had black bill with broad pink-white saddle between nostrils, dark brown iris, black eyering, and grey legs and feet; young fed and cared for by both parents for c. 4 weeks; post-juvenile moult probably begins shortly after fledging. In Australia has 1, sometimes 2, broods per year.
Movements. Imperfectly known; considered resident over much of range but probably partially migratory in some regions. Regarded as wet-season migrant in N Australia: although recorded throughout year, more records in summer months and apparently absent from some areas in winter; regular migration along wetlands of Cape York suggested; occurs on islands in Torres Strait, where 112 birds struck Booby I lighthouse between Dec 1975 and Jun 1976. Vagrant to Bikini, Marshall Is.
Status and Conservation. Not globally threatened. Less shy and elusive than most rails and formerly regarded as locally fairly common to fairly abundant throughout most of range, except in Palau, Mariana and Caroline Is, New Caledonia, Vanuatu, Fiji and Samoa. Putative form *brevipes*, confined to Volcano Is (S of Japan), generally regarded as having been extinct since 1911, although said to have been observed in 1924/25; extinction probably caused by introduced rats and cats. Species apparently disappeared from Guam in 1970's concurrent with the draining and development of many of the island's freshwater wetland habitats. Currently widespread and locally common in Greater Sundas and Philippines; local and uncommon in Vanuatu; status uncertain in Australia, but local and apparently not generally common; status elsewhere possibly largely unchanged.
Bibliography. Genus *AENIGMATOLIMNAS* J. L. Peters, 1932

99. Striped Crake

Aenigmatolimnas marginalis

French: Marouette rayée **German**: Graukehl-Sumpfhuhn **Spanish**: Polluela Culirroja

Taxonomy. *Porzana marginalis* Hartlaub, 1857, Gabon.
Often retained in *Porzana* on basis of plumage characters, but differs in skull structure and in having longer legs and toes. Monotypic.
Distribution. N Ivory Coast patchily E to Cameroon and S to coastal Congo; more continuously from E Zaire to Kenya, S and W to Zimbabwe and extreme SE Angola; scattered localities in South Africa, where may breed in wet years.

Descriptive notes. 18-21 cm; 2 females, 41·5 and 61 g. Both sexes have diagnostic reddish cinnamon lower flanks and undertail-coverts, visible in flight; other distinctive features include white-striped upperparts, short, deep, apple green bill, and very long toes. Sexually dimorphic: male buff-brown to cinnamon-brown on head, neck, and breast; female grey in these regions, with eye-ring often pale green. Non-breeding birds have eye-ring orange and less prominent; legs and feet duller. Immature resembles adult, with less prominent upperpart streaking and dull bare parts; male paler and more rufous on head, neck, breast and flanks; female has only vague pale markings on neck and breast, and has brownish tinge to grey of head, neck and sides of breast. Juvenile plumage duller and less patterned, males being darker brown, females duller grey; bare parts duller. VOICE. Advertising call of female a series of rapidly repeated ticking notes, lasting up to 1 minute. Answering call, presumably of male, a short series of rapidly-repeated, high-pitched, grating "graa" notes. Contact call "chup"; also has grunts and growls of alarm.
Habitat. Typical breeding habitat is seasonally inundated grasslands which dry out and are often burned in dry season. Occurs in temporary pans, short-grass dambos, old rice fields and edges of marshes, ponds and ditches. Avoids dense, tall vegetation in permanent marshes, and areas with water more than 20-30 cm deep; prefers areas with shallow pools, muddy patches and fine grasses up to 1 m tall. Habitat outside breeding season less well known but apparently similar.
Food and Feeding. Earthworms, small snails, spiders, beetles, grasshoppers, flies, moths, insect larvae, small fish, and tadpoles. Forages on grass and mud, at pool edges and in shallow water; walks deliberately, searching ground and short vegetation; probes into mud; immerses head in water; chases flying insects. Feeds very actively from late afternoon to dusk. Chicks are fed on insects and other small invertebrates.
Breeding. Breeds during rains: Ghana, Jun; Nigeria, Aug, breeding condition Jun; Cameroon, breeding condition Jun; Gabon, breeding condition Nov; Kenya, Jun, breeding condition May, nest building Nov; Tanzania, breeding condition Jan; Malawi, Jan-Feb; Zambia, Jan-Feb, breeding condition Dec; Zimbabwe, Dec-Mar; Namibia Feb-Mar. Captive birds show sequential polyandry, female mating with 2 or more males in succession; polyandry probably also prevalent in the wild, where 6 of 9 records of incubating birds refer to males and 2 to probable males; occasional monogamy also possible. Nest a strongly built shallow bowl or platform of grass, sometimes rushes or sedges, c. 8 cm in diameter; typically well concealed in tuft of grass, sometimes green but often old and dry; usually 10-25 cm above water but occasionally floating or above damp ground, rarely on ground; surrounding vegetation pulled down to form roof over nest. Sometimes builds dummy nests which are abandoned before completion. Usually 4-5 eggs (in captivity 2-6), laid at 1-2 day intervals; incubation 17-18 days, usually by male only; parental care in captivity exclusively by male; black downy chick has cream bill with dark band, but bill becomes predominantly greenish after 10 days; chicks leave nest after 4-5 days; in captivity feathers begin to grow at 8 days, young fully grown and able to fly at 6-7 weeks, post-juvenile moult begins at 13-15 weeks and is complete at 21 weeks; age of first breeding 1 year. Clutch losses from predation often high. In captivity normally 1-2, sometimes 3, broods per season; up to 4 clutches if repeat nesting occurs after failures; female can lay more than 6 clutches for 2 males per season.
Movements. Imperfectly known. In W Africa recorded Ghana only in rains but status uncertain; resident Nigeria but breeds in N only in rains, and latitudinal movements probably occur, night migrants being recorded Dec; in N Gabon occurs irregularly Nov-Mar and night migrants recorded; status elsewhere uncertain. Present Kenya May-Sept and Nov; breeds during rains; night migrants recorded May and coastal movements May-Jul. From Tanzania southwards recorded in breeding areas Dec-Mar; much breeding habitat ephemeral so occurrences irregular and periods of residence may be short; odd birds may remain during dry season if suitable habitat persists. Night migrants recorded S Tanzania, May and Dec, and N Zambia, Mar. Sept record from S Namibia, and 7 scattered records from South Africa (Mar-Jun), are attributed to vagrancy, possible coastal and inland migration, and birds displaced from normal wintering areas by drought conditions; rains records from Nyl floodplain, Transvaal, suggest that breeding range may extend to South Africa in years of good rainfall. In S Africa assumed to be a wet-season breeding visitor which retreats towards equatorial regions after breeding. Vagrant to Algeria in Jan, Libya in Feb, and Aldabra in Dec.
Status and Conservation. Not globally threatened. A highly secretive and poorly known species, undoubtedly overlooked but generally uncommon throughout its range, which may be more extensive and continuous than is known. Like *Sarothrura boehmi*, sometimes locally common in large areas of breeding habitat in good rainfall years but, like that species, its numbers must have been adversely affected by habitat loss resulting from overgrazing and the damming and draining of wetlands.

Andersson & Gurney (1872), Benson (1964b), Benson & Benson (1975), Benson *et al.* (1971), Brosset & Érard (1986), Cramp & Simmons (1980), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Étchécopar & Hüe (1964), Ginn *et al.* (1989), Grimes (1987), Hopkinson & Masterson (1975, 1984), Irwin (1981), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Pitman (1965a), Serle (1939b), Short *et al.* (1990), Snow (1978), Taylor (1987), Taylor *et al.* (1994), Urban *et al.* (1986), White (1945), Wintle & Taylor (1993).

Genus *CYANOLIMNAS* Barbour & J. L. Peters, 1927

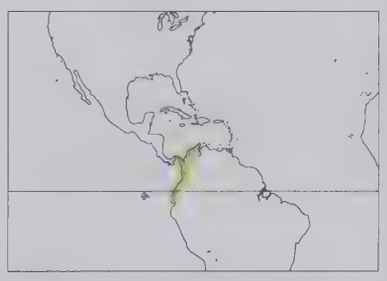
100. **Zapata Rail**

Cyanolimnas cerverai

French: Râle de Zapata **German**: Kubaralle **Spanish**: Gallineta de Zapata

Taxonomy. *Cyanolimnas cerverai* Barbour and J. L. Peters, 1927, Santo Tomás, Peninsula de Zapata, Cuba.
Monotypic.
Distribution. Zapata Swamp, WC Cuba.

Descriptive notes. 29 cm. Apparently almost flightless; wings very short; tail short and decomposed. Dark rail without streaks or spots, faintly barred on lower belly and thighs and with white undertail-coverts. Sexes alike. Easily separable on plumage from sympatric rallids but resembles smaller *Neocrex colombianus* and *N. erythrops*; former differs in unbarred cinnamon-buff flanks and undertail-coverts; latter has much heavier barring from flanks to undertail-coverts. Considered intermediate in plumage characters between *N. colombianus* and larger *Pardirallus sanguinolentus*, which has unbarred dusky brown to blackish rear flanks and undertail-coverts, and a much longer, slightly decurved, greenish yellow bill with blue and red at base. Immature and juvenile undescribed. VOICE. Alarm call a loud "kwowk", much like that of Limpkin (*Aramus guarauna*).
Habitat. Dense bush-covered swamp with low trees, where *Myrica cerifera* and sawgrass (*Cladium jamaicense*) are common, near higher ground.
Food and Feeding. No information available.
Breeding. Sept; males in breeding condition, Jan. One nest found, situated c. 60 cm above water level in a hummock of sawgrass; contained 3 eggs.
Movements. None.
Status and Conservation. CRITICALLY ENDANGERED. Known from only two sites, c. 65 km apart, in Zapata Swamp. Four were collected near Santo Tomás in 1927 and species was easily found in 1931; subsequently no records, despite occasional searches, until 1970's, when voice was recorded and birds were found at a second locality, Laguna del Tesoro. Despite likely occurrence in other areas of the swamp, the very small number of records in recent decades suggests that population is very small. Serious threats include dry-season burning of habitat, potentially devastating for the species and still occurring, and also the existence of introduced predators, namely a mongoose (*Herpestes*) and rats (*Rattus*). The swamp has so far escaped serious drainage. Species has been afforded protection with an area of 10,000 ha in the Corral de Santo Tomás Faunal Refuge, while Laguna del Tesoro is within a Nature Tourism Area; the benefits of this protection are unknown. Survey of the bird's distribution urgently needed, and dry-season burning of its habitats must be controlled. Former distribution was wider, and fossil bones attributable to this species have been found in cave deposits in Pinar del Rio and on I of Pines.
Bibliography. Abreus & Criado (1994), Anon. (1993f), Barbour & Peters (1927), Bond, J. (1971, 1973, 1984, 1985), Clements (1979), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Criado *et al.* (1995), Garrido (1985), King (1978/79), Morton (1979), Olson (1973b, 1974b), Regalado (1981), Ripley (1977), Sulley & Sulley (1992).



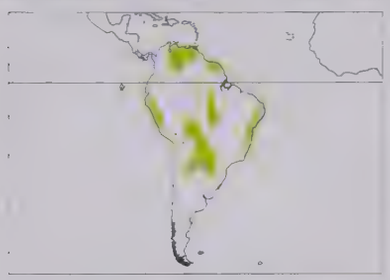
Genus *NEOCREX* P. L. Sclater & Salvin, 1868

101. **Colombian Crake**

Neocrex colombianus

French: Râle de Colombie **German**: Kolumbiensumpfhuhn **Spanish**: Polluela Colombiana

Taxonomy. *Neocrex colombianus* Bangs, 1898, Palomino, Santa Marta, Colombia.
Sometimes placed in *Porzana*. Forms superspecies with *N. erythrops*, and sometimes considered conspecific, but differs in plumage and in bill structure. Two subspecies recognized.
Subspecies and Distribution.
N. c. riplevi Wetmore, 1967 - C Panama and NW Colombia.
N. c. colombianus Bangs, 1898 - N & W Colombia and W Ecuador.



Descriptive notes. 18-20 cm. Sexes alike; underwing-coverts are white. Allopatric *N. erythrops* differs in having flanks to undertail-coverts barred blackish and white, underwing-coverts often barred with black and bill greener with bright red base. Larger *Cyanolimnas cerverai* similar in both plumage and bare parts colours, but has dark slate flanks with faint white bars, and white undertail-coverts. Immature and juvenile undescribed. Races separated on overall colour, *riplevi* markedly darker. VOICE. Not recorded.
Habitat. Marshes, swamps, wet savannas, wet grass, pastures, and overgrown forest edges; not restricted to areas with water. Occurs up to 2100 m.
Food and Feeding. No information; presumably similar to *N. erythrops*.
Breeding. Colombia, male in breeding condition Jan, 3 birds near breeding condition Dec-Jan; in Panama, an apparently non-flying juvenile recorded in Feb 1982.
Movements. Regarded as sedentary. Three birds, all near breeding condition, flew into lighted windows in Colombian W Andes, Dec and Jan.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Very little information available on status and distribution. Nominate race regarded as rare throughout range, with scattered records across most of N Colombia and S on both slopes of W Andes through W Ecuador. Race *riplevi* rare in C Panama, where was apparently known from only one specimen (holotype of race), collected in 1965 at Achiote Road on NW boundary of Canal Zone in W Colón, before several were seen at Tocumen marshes in Feb 1982; also apparently rare in NW Colombia, where known from one specimen, collected at Acandi, Gulf of Urabá, near Panama border. Investigation of current status and distribution, and study of natural history, are urgently required. Possibly occurs in E Costa Rica, where a sighting near Hitoy Cerere in Mar 1985 was claimed to be either this species or *N. erythrops*.
Bibliography. Anon. (1983a), Behrstock (1983), Blake (1977), Butler (1979), Collar *et al.* (1994), Fjeldså & Krabbe (1990), Hellmayr & Conover (1942), Hilty & Brown (1986), Miller (1963), Olson (1973b), Ridgely (1981), Ridgely & Gwynne (1989), Ripley (1977), Ripley & Beehler (1985).

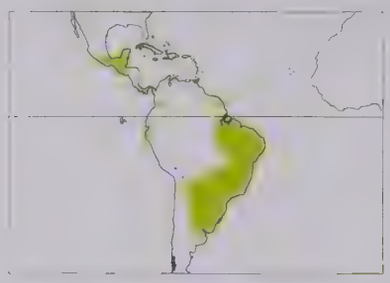
102. **Paint-billed Crake**

Neocrex erythrops

French: Râle à bec peint **German**: Goldschnabel-Sumpfhuhn **Spanish**: Polluela Picopinta

Taxonomy. *Porzana erythrops* P. L. Sclater, 1867, Lima, Peru.
Sometimes placed in *Porzana*. Forms superspecies with *N. colombianus*, and sometimes considered conspecific, but differs in plumage and in bill structure. Two subspecies recognized.
Subspecies and Distribution.
N. e. olivascens Chubb, 1917 - E Colombia, Venezuela and the Guianas through C & E Brazil to N & E Bolivia, NW Argentina and Paraguay; also Costa Rica and Panama, where status unclear.
N. e. erythrops (P. L. Sclater, 1867) - coastal Peru, and Galapagos Is (Santa Cruz and Santa María).

Descriptive notes. 18-20 cm; 2 males 51 and 67 g, 2 females 43 and 61 g, 3 unsexed 55-70 (62) g. Sexes alike; underwing-coverts white, often barred with black. Very similar to allopatric *N. colombianus*, which differs in having unbarred cinnamon-buff flanks and undertail-coverts, unbarred underwing-coverts, and yellower bill with orange base. Larger *Cyanolimnas cerverai* similar in plumage but has dark slate flanks with faint white bars, and white undertail-coverts. Sympatric *Laterallus exilis* smaller, with chestnut nape and upper mantle, variable amount of narrow white barring on upperwing-coverts, dusky green bill, and dusky yellow or brownish legs and feet. Immature not properly described but one had duller bill, grey iris, and pale brown legs and feet. Juvenile has pale grey, faintly barred belly, and darker, greener bill with no red at base. Race *olivascens* darker, with less white on throat. VOICE. Song a long, gradually accelerating and descending series of up to 36 staccato notes followed by 3-4 short churring notes which fall in pitch, the last being a 3-second flat trill. Also loud, frog-like, guttural, buzzy, single notes rendered "qurrrk" and "auuk". Alarm a sharp "twack".
Habitat. Reedbeds, lagoons, grassy marshes, rank grass, wet to dry pastures, rice fields, corn fields, gardens, drainage ditches, overgrown bushy areas, and humid woodlands. In Panama found in same habitat as *Laterallus albigularis*. In South America described as possibly preferring dense swamp vegetation and damp secondary woodland in flooded savanna, and as mainly a crake of grass and thickets. Occurs from tropical to temperate zones; recorded up to 3375 m.
Food and Feeding. Very little information available. Known to feed on Diplopoda, insects (including Coleoptera) and seeds (including grass seeds). Takes invertebrates from soil and leaf litter; forages at puddles, sometimes along dirt roads, and in open patches adjacent to dense vegetation, at dawn and dusk.
Breeding. Venezuela, breeding condition Jul; Galapagos, Nov-Feb. Frequently seen in pairs. Nest a bowl of green grass, placed on or near ground, in grassy vegetation; recorded sites include "agricultural fields" and in Venezuela corn fields. Eggs 3-7; incubation at least 23-25 days.
Movements. No evidence for regular movements, but many records outside normal range indicative of either migration or vagrant habits. One record (presumably *olivascens*) from NC Costa Rica at Río Frío, Sarapiquí lowlands, Aug 1987, and may also occur in E Costa Rica, where sighting near Hitoy Cerere in Mar 1985 was claimed to be either this species or *N. colombianus*; also 2 *olivascens* collected at Changuinola, Bocas del Toro (W Panama), Nov 1981 but not noted in Apr or Jul and believed to be of seasonal occurrence. Several records at c. 2600 m on savannas of Bogotá and Ubaté, Colombia, mostly in Mar-Apr, including one from streets of Bogotá; one at 3375 m in suburban garden of La Paz, Bolivia. In N Venezuela, has been attracted to lighted windows in May-Jun at Rancho Grande (Henri Pittier National Park), and was reported by hunters to be of seasonal occurrence at Caicara, appearing in numbers during Aug. Accidental in USA: *erythrops* from Texas, Feb 1972; probable *olivascens* from Virginia, Dec 1978; has also occurred in Nov (no details available).
Status and Conservation. Not globally threatened. Status in some areas difficult to assess: species very furtive and difficult to observe, but often flies when disturbed. Status unclear in Central America, could be accidental, migrant or rare resident, perhaps overlooked. Race *olivascens* formerly regarded as locally common in Colombia, Venezuela and Argentina (Tucumán), and probably less rare in French Guiana than the one existing record (Aug 1981) suggests; only one verifiable record from Guyana (Aug 1977) and recorded from scattered localities in Amazonian and C & E Brazil. Race *erythrops* possibly rare in Peru but abundant on Santa Cruz, Galapagos; known from Galapagos since 1953, but possibly overlooked for some time before that, and could occur on San Cristóbal and Isabela. Current status and distribution need investigation, as do movements and breeding.
Bibliography. Arnold (1978), Behrstock (1983), Blake (1977), Blem (1980), Bowman (1960), Brosset (1963), Canevari *et al.* (1991), Contreras *et al.* (1990), Fjeldså & Krabbe (1990), Friedmann & Smith (1950, 1955), Harris (1973, 1982), Haverschmidt (1968), Haverschmidt & Mees (1995), Hayes (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Meyer de Schauensee (1962), Meyer de Schauensee & Phelps (1978), Olivares (1969, 1974), Osborne & Beissinger (1979b), de la Peña (1992), Remsen & Traylor (1983), Ridgely & Gwynne (1989), Sick (1985c, 1993), Stiles & Skutch (1989), Teixeira *et al.* (1986), Tostain *et al.* (1992).



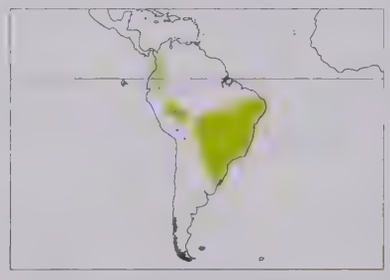
Genus *PARDIRALLUS* Bonaparte, 1856

103. **Spotted Rail**

Pardirallus maculatus

French: Râle tacheté **German**: Fleckenralle **Spanish**: Rascón Overo

Taxonomy. *Rallus maculatus* Boddaert, 1783, Cayenne, French Guiana.
Sometimes placed in *Rallus*. Possible race *inoptatus* of W Cuba included in nominate. Two subspecies recognized.
Subspecies and Distribution.
P. m. insolitus (Bangs & Peck, 1908) - Mexico to Costa Rica.
P. m. maculatus (Boddaert, 1783) - W Cuba, Hispaniola, Jamaica, Trinidad and Tobago; Colombia E to the Guianas and E Brazil, and S to Peru and Argentina.
Also occurs in Panama, subspecies unknown.



Descriptive notes. 25-28 cm; male 148-219 (189) g, female 130-190 (156) g, unsexed 140-198 (171) g. Sexes alike; female probably slightly smaller. Differs from all other rallids in strikingly variegated plumage and long greenish yellow bill with red spot at base. Immature not properly described. Juvenile has brownish iris, and duller bill and legs; plumage variable, of 3 colour morphs: dark morph, with almost plain, dark brown upperparts, and sooty, dark-tipped ventral feathers with no white bars; pale morph, with throat and breast pale greyish brown, and breast weakly barred white; barred morph, with throat grey, spotted white, and breast and belly sharply barred white. Dark morph juvenile (*maculatus*) has almost plain plumage and is similar to *P. sanguinolentus* and *P. nigricans*, both of which, however, have paler upperparts and bright red legs and feet; *P. sanguinolentus* is larger, with grey chin and throat, and grey-brown vent contrasting with slaty grey underparts; *P. nigricans* has black vent and tail. Races separated on upperpart pattern, *maculatus* streaked, *insolitus* spotted; and colour of juvenile undertail-coverts, grey or white tipped buff in *maculatus*, and white tipped grey in *insolitus*. VOICE. Loud, repeated, rasping, groaning screech, usually preceded by grunt or pop, "g'reech" or "pum-kreep", probably territorial or aggressive. Also an accelerating series of deep, gruff, pumping notes, like distant motor starting up; and sharp, repeated "gek" when disturbed. Sometimes calls at night.
Habitat. Inhabits marshes, including those predominantly of *Typha* or *Polygonum*, swamps, rice paddies and other irrigated fields, grassy ditches, and wet grasslands; one occupied site in Costa Rica had *Panicum purpurescens* 45 cm to 1 m tall; also recorded from tall grass on abandoned airfield. Requires dense cover of emergent plants, grass or tangled second growth. Occurs from lowlands up to 2000 m.
Food and Feeding. Earthworms, adult and larval insects (Coleoptera, Hemiptera, Diptera and Odonata), and other invertebrates; small fish; also pondweed *Potamogeton epihydrus*. Normally keeps within cover but may feed in fairly open situations at any time of day, especially in early morning and late evening. Forages at water's edge or while wading; probes in mud.
Breeding. Cuba, late summer to early autumn, at least to Sept; Hispaniola, breeding condition Jun; Trinidad, Jun-Aug; Costa Rica, breeding condition Jul; Colombia, 2 young Dec. Monogamous; apparently territorial, at least during breeding season. Nest a cupped platform of grass or a bowl of dead rushes, built low down in wet grass or other marsh vegetation, often just above shallow water. Eggs 2-7.
Movements. None recorded, but may show widespread dispersal or vagrancy. In Surinam, one entered house at night in Paramaribo, far from suitable habitat, in Jan. Moves locally in response to adverse conditions such as drought (Surinam) or changing water levels (Costa Rica). Accidental in North America, with records from Pennsylvania and Texas, both possibly man-assisted; also Juan Fernández Is (off Chile).
Status and Conservation. Not globally threatened. Locally distributed; in past often regarded as uncommon to rare, but locally common in Zapata Swamp (Cuba), Costa Rica, Colombia and Surinam. Current status unclear in many areas, but locally frequent to uncommon in Mexico, where is more widespread than was formerly known and may be increasing (or previously overlooked); local in French Guiana; few records in Panama. Undoubtedly overlooked, especially when breeding, and probably more widespread within range than existing records suggest. Thought to have been extirpated from Jamaica, but at least one recent sight record. Predation by the introduced mongoose *Herpestes auropunctatus* was thought to have drastically reduced the population in drained agricultural lands of Cuba by 1960's, while disappearance of species from Jamaica was also attributed to mongoose predation.
Bibliography. Belton (1984), Blake (1977), Birkenholz & Jenni (1964), Bond (1980), Canevari *et al.* (1991), Clements (1979), Contreras *et al.* (1990), Dickerman (1971), Dickerman & Haverschmidt (1971), Dickerman & Parkes (1969), Dickerman & Warner (1961), Dod (1980, 1992), Emanuel (1980), ffrench (1973), Friedmann (1949), Haverschmidt (1968), Haverschmidt & Mees (1995), Hayes (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Howell & Webb (1995a), Meyer de Schauensee & Phelps (1978), Orians & Paulson (1969), Parkes *et al.* (1978), de la Peña (1992), Ridgely (1981), Ridgely & Gwynne (1989), Sick (1985c, 1993), Slud (1964), Stiles & Skutch (1989), Tostain *et al.* (1992), Watson (1962), Wetmore (1965).

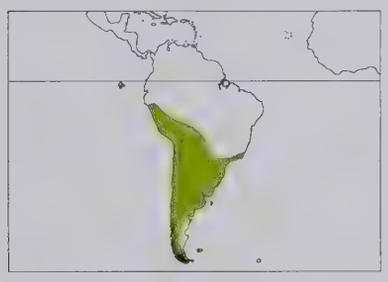
104. **Blackish Rail**

Pardirallus nigricans

French: Râle noirâtre **German**: Trauerralle **Spanish**: Rascón Negruzco

Taxonomy. *Rallus nigricans* Vieillot, 1819, Paraguay.
Sometimes placed in *Rallus*, or referred to genus *Ortygonax*. In past sometimes regarded as conspecific with *P. sanguinolentus*. Two subspecies recognized.
Subspecies and Distribution.
P. n. caucae (Conover, 1949) - SW Colombia (Cauca Valley S to Nariño).
P. n. nigricans (Vieillot, 1819) - E Ecuador, E Peru, N Bolivia, W, SC & E Brazil, Paraguay and extreme NE Argentina.

Descriptive notes. 27-29 cm; 1 male 217 g. Sexes alike. Closely resembles partially sympatric *R. sanguinolentus*, which differs in being larger and having grey chin and throat, broad dusky centres to feathers of mantle to rump and inner secondaries, olive brown uppertail-coverts and tail, grey-brown vent, and more decurved, greenish yellow bill with red and blue at base. Immature similar to adult but browner, especially on lower upperparts. Juvenile not described. Race *caucae* larger, with paler underparts, especially noticeable on vent, and usually larger, whiter throat patch. VOICE. Descriptions include: very fast, metallic "tii'd'dit"; complaining "keeecaaa" resembling call of small hawk; rapid, repeated "chchchee"; sharp double squeak; and very sharp, loud, penetrating, repeated "whueeee" or "wheee", a form of song probably given by male. Often calls in late afternoon.
Habitat. Marshes, vegetation-choked waterways, flooded rice fields, tall damp grass, and swampy, lightly wooded areas. Predominantly lowlands, but occurs at 800-2200 m in Andes, exceptionally 4080 m.



Food and Feeding. No information on food; presumably feeds on insects and other invertebrates. Occasionally forages in the open: on muddy shores with other waterbirds or in small clear areas in marsh vegetation. Recorded venturing 5 m into restaurant garden for food scraps.
Breeding. Brazil, male with somewhat enlarged testes, Jul. Nest of aquatic grasses, placed on or near the ground in tall damp grass. Possible nest of this species (or of *P. sanguinolentus*), from Rio Grande do Sul, Brazil, in Jan, was cup-shaped and placed on low stump among heavy second-growth shoots in swampy scrub. Eggs 3 (2 in captivity); incubation (captivity) 18-21 days; both parents feed and care for young, which leave nest soon after hatching; downy chicks black, with black bare parts.
Movements. None recorded, but a stray record from Junín, NC Peru, at 4080 m.
Status and Conservation. Not globally threatened. Past and present status difficult to assess, as species usually secretive and difficult to observe, but both races generally regarded as uncommon and patchily distributed. Only two records from Bolivia (Pando and N La Paz). Locally fairly common in Rio Grande do Sul, SE Brazil.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Fjeldså & Krabbe (1990), Hellmayr & Conover (1942), Hilty & Brown (1986), Mitchell (1957), Naranjo (1991a), Pacheco & Whitney (1995), Parker & Remsen (1987), Parker *et al.* (1991), de la Peña (1992), Pryor (1969), Ripley (1977), Sclater & Salvin (1879), Sick (1985c, 1993).

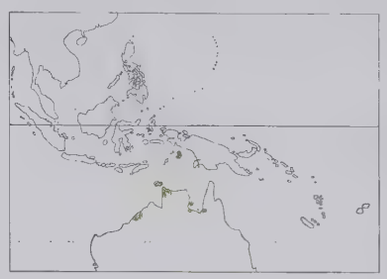
105. **Plumbeous Rail**

Pardirallus sanguinolentus

French: Râle à bec ensanglanté **German**: Grauralle **Spanish**: Rascón Gallineta

Taxonomy. *Rallus sanguinolentus* Swainson, 1838, Brazil and Chile.
Sometimes placed in *Rallus*, or referred to genus *Ortygonax*. In past, sometimes regarded as conspecific with *P. nigricans*. Formerly listed as *P. rytirhynchos*, but this name is unidentifiable. Six subspecies recognized.
Subspecies and Distribution.
P. s. simonsi Chubb, 1917 - Pacific slope of Peru S to N Chile.
P. s. tschudii Chubb, 1919 - temperate zone of Peru (S from upper Marañón) to C & SE Bolivia.
P. s. zelebori (Pelzeln, 1865) - SE Brazil.
P. s. sanguinolentus (Swainson, 1838) - Paraguay, extreme SE Brazil, Uruguay, and Argentina S to Río Negro.
P. s. landbecki (Hellmayr, 1932) - C Chile (Atacama S to Llanquihue), and SW Argentina.
P. s. luridus (Peale, 1848) - S Chile and S Argentina to Tierra del Fuego (including Isla Grande); doubtful record from Falkland Is.

Descriptive notes. 30-38 cm; 3 males 170-213 (197) g, 1 female 233 g. Sexes alike. Very similar to sympatric *P. nigricans*, which differs in being smaller and having whitish chin and throat, lighter and more olivaceous upperparts with no dark feather centres, dark inner remiges (sometimes with narrow olive brown edges), black vent and tail, and straighter, greenish bill with a yellowish base. Immature somewhat duller than adult above, with slightly darker tail; brown-grey below; bill greenish, sometimes with darker base; iris brown; legs red-brown. Juvenile similar on upperparts; underparts all brown, with buffy white throat and belly; bill, legs and feet black. Races separated on: size, *zelebori* smallest, *luridus* largest; upperpart pattern and colour, *luridus* and *landbecki* have no mottling, *landbecki* and *simonsi* more olive-brown; and shade of underparts, paler in *luridus*, *simonsi* and *tschudii*. VOICE. Song a series of high, penetrating, rolling squeals "rrueet'e", "pu-rueet" or "huyr", etc., often with simultaneous low, deep "hoo" notes (duet). Calls are repeated "giyp" or "wit" notes. Sings both day and night, one song often giving rise to chorus.
Habitat. Reed-marsh, sometimes of small area, especially around muddy creeks and ponds with much floating vegetation (*Ranunculus*, *Hydrocotyle*). Locally also in waterside thickets, irrigated areas such as alfalfa crops, ditches through rushy pasture in cultivated parts of semi-arid valleys, and oases in arid regions. May be found wherever there is water and sufficient vegetation cover. Occurs in lowlands, also locally up to 2500 m, and patchily up to c. 4000 m.
Food and Feeding. Grubs, worms and insects. Mainly crepuscular, but also active during night, in marsh or adjacent cultivated fields; can also be seen foraging by day. Sometimes swims.
Breeding. Peru, Oct, chicks Jan; Chile, Oct-Jan; SE Brazil, breeding condition Nov; Argentina, Oct-Dec. Recorded as occurring in pairs. Nest poorly constructed, of dry grasses; built on ground among bushes, reeds and long grass bordering water. Eggs 4-6; downy chicks dark brown, darker on upperparts and wings, bill black, legs and feet pale brown.
Movements. No definite information, but thought to be migratory over part of range; birds of inland marshes on SW *pampas* thought to move N in winter, while those of Atlantic seaboard marshes, where shelter and temperature remain suitable in winter, are sedentary.
Status and Conservation. Not globally threatened. Nominate race, *simonsi* and *landbecki* formerly regarded as locally common; past status of others unknown. Current status difficult to assess in many areas, but abundant on N Altiplano around Junín, Peru (*tschudii*); common on Isla Grande, Tierra del Fuego (*luridus*). Probably more widespread than is currently known.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Contreras, J.R. (1980), Contreras, J.R. *et al.* (1990), Fjeldså & Krabbe (1990), Harris (1981), Hayes (1995), Hellmayr & Conover (1942), Hudson (1920), Humphrey *et al.* (1970), Johnson (1965b), de la Peña (1992), Rasmussen *et al.* (1996), Remsen *et al.* (1985), Roe & Rees (1979), Sick (1985c, 1993), Weller (1967), Wetmore (1926), Zimmer (1930).



Genus *EULABEORNIS* Gould, 1844

106. **Chestnut Rail**

Eulabeornis castaneoventris

French: Râle à ventre roux **German**: Mangroveralle **Spanish**: Cotara Australiana
Other common names: Chestnut-bellied Rail

Taxonomy. *Eulabeornis castaneoventris* Gould, 1844, Flinders River, Gulf of Carpentaria.
Genus sometimes enlarged to include *Aramides*, *Amaurolimnas* and *Gymnocrex*. Two subspecies recognized.
Subspecies and Distribution.
E. c. sharpei Rothschild, 1906 - Aru Is.
E. c. castaneoventris Gould, 1844 - N coasts of Australia from N Western Australia through Northern Territory to NW Queensland.

Descriptive notes. Male 52 cm, 626-910 (752) g; female 44-52 cm, 550-710 (628) g. Largest rallid in its habitat; thickset species with longish tail, long, heavy, greenish bill and pale yellow or green legs; head and upper portion of neck grey; chin white; underparts pinkish brown, varying considerably in brightness. Polymorphic, varying mainly in colour of upperparts: dark chestnut brown in chestnut morph, Northern Territory; olive in olive morph, Western Australia; olive brown in olive brown morph, Northern Territory and Queensland. Sexes similar, but female smaller. Immature undescribed; one possible juvenile identical to adult chestnut morph. Race *sharpei* like chestnut morph; has deeper, heavier bill, green with yellow tip and red around nostrils. VOICE. Poorly known. Normal call a harsh screech, preceded by grunt and usually repeated c. 12 times; sequence also described as beginning with deep drumming (grunting?) followed by loud pig-like squealing, or as barking, trumpeting or donkey-like notes; usually uttered by single bird; heard throughout year at all times of day. Contact call a loud, repeated "chuck", with occasional grunts; gives quiet grunts when disturbed.
Habitat. Tropical estuaries, preferring mangrove forests, tidal channels and flats, especially seaward mudflats; uncommon along creeks with only narrow fringe of mangroves. Occasionally in adjacent grassy flats, reedy swamps and open woodland, sometimes because normal mangrove habitat flooded.
Food and Feeding. Takes mainly crabs and other crustaceans; also small molluscs, insects and centipedes. Both diurnally and nocturnally active. Forages in soft mud or shallow water within mangrove zone, along tidal channels and on tidal flats as tide falls. Moves slowly, often flicking tail; makes short runs to chase prey; most food taken from ground or water; often immerses bill and forehead into mud or water; also gleans and pecks at bases and roots of mangroves, and probes e.g. into crab burrows. Pair members feed close together.
Breeding. Very poorly known. Breeds Sept-Feb. Monogamous; territorial when breeding. Nest a large, loose platform of dead sticks, grass, leaves, bark and seaweed, rather like flat-topped pyramid, built 0·6-3 m above ground in mangrove tree; birds often choose slanting tree for ease of access; platform 35-50 cm across, 20 cm deep; cavity 20 cm across, 6 cm deep. 2 nests 1·5 m up had gangways of sticks running up over prop-roots, from ground to nest. Nest may be refurbished and used for several years. Eggs 4-5, laid at daily intervals; downy chick dark sooty brown; chicks leave nest soon after hatching.
Movements. Probably sedentary; no long distance movements recorded. When feeding, moves to higher ground as tide rises and back to creeks as water recedes.
Status and Conservation. Not globally threatened. Patchily recorded, with several apparent gaps in distribution which may be due to incomplete coverage by observers; status uncertain because birds very shy and difficult to see in dense habitat; more often located by characteristic loud, raucous call. Probably moderately common in good habitat, and density at one site was c. 8 birds/km²; breeding territory size estimated at 10 ha. No known threats to species or its habitat, but lack of recent records from S coast of Gulf of Carpentaria is puzzling. May become accustomed to disturbance from power boats.
Bibliography. Andrew, P. (1992), Beehler *et al.* (1986), Blakers *et al.* (1984), Flegg & Madge (1995), Lindsey (1992), Macdonald (1988), Marchant & Higgins (1993), Olson (1973b), Pizzey & Doyle (1980), Ragless (1977), Rand & Gilliard (1967), Ripley (1977), Ripley & Beehler (1985), Schodde & Tidemann (1986), Serventy (1985), Simpson & Day (1994), Trounson (1987).

Genus *HABROPTILA* G. R. Gray, 1860

107. **Invisible Rail**

Habroptila wallacii

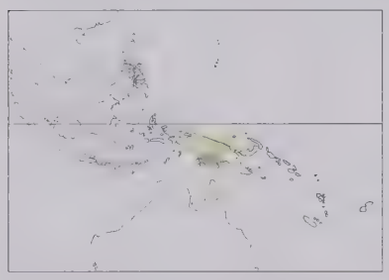
French: Râle de Wallace **German**: Trommelralle **Spanish**: Rascón de Wallace
Other common names: Wallace's/Halmahera/Drummer Rail

Taxonomy. *Habroptila wallacii* G. R. Gray, 1860, Halmahera.
Sometimes placed in *Rallus* for no good reason, but probably derived from *Amaurornis*; very close to *Megacrex*, which is its ecological counterpart in New Guinea. Monotypic.
Distribution. Halmahera (N Moluccas).

Descriptive notes. 35 cm. Sexes alike. Rather distinctive large, flightless rail of striking appearance, with very dark slate and dark brown plumage, and bright red bare parts including eye-ring and frontal shield; bill long and heavy. Immature and juvenile undescribed. VOICE. Described as a low drumbeat interspersed with a loud scream.
Habitat. Dense, impenetrable, swampy thickets, particularly areas of heavy sago swamp; also the edges of marshes, preferring peninsulas of land jutting out into marshy expanses. A report that it occurs in *alang-alang* (*Imperata cylindrica*) grass is thought to have resulted from confusion with *Amaurornis moluccanus*.
Food and Feeding. Diet and feeding habits virtually unknown. Mainly young plant shoots and beetles recorded.

Breeding. The only information is that an adult was reported with 4-5 striped chicks; if correct, this would be an atypical downy plumage for the family.
Movements. None recorded.
Status and Conservation. VULNERABLE. Probably scarce; a report that it was locally common in grassland is believed to have resulted from confusion with the common *Amaurornis moluccanus*. Only recent records are of specimens collected in early 1980's and early 1990's, and a sighting in a sago swamp in 1995. Threatened by habitat destruction, and sago swamps have been extensively destroyed on Halmahera. Snared for food by local people and caught with dogs; species is also likely to be vulnerable to other introduced predators.
Bibliography. Andrew, P. (1992), Anon. (1995q), Collar & Andrew (1988), Collar *et al.* (1994), de Haan (1950), Heinrich (1932, 1956), Olson (1973b), Ripley (1977), Ripley & Beehler (1985), Stresemann (1931), White & Bruce (1986).

Genus *MEGACREX*



D'Albertis & Salvadori, 1879

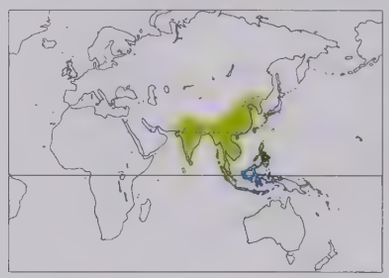
108. **New Guinea Flightless Rail**

Megacrex inepta

French: Râle géant **German**: Baumralle **Spanish**: Rascón Inepto
Other common names: Papuan Flightless/Grey-faced Rail

Taxonomy. *Megacrex inepta* D'Albertis and Salvadori, 1879, Fly River, New Guinea.
Very close to *Habroptila wallacii*; sometimes placed in *Habroptila*, or in *Amaurornis*; probably derived from latter. Two subspecies recognized.
Subspecies and Distribution.
M. i. pallida Rand, 1938 - NC New Guinea, from R Taritatu (Idenburg) to R Sepik.
M. i. inepta D'Albertis & Salvadori, 1879 - SC New Guinea, from R Setekwa and R Noord (Lorentz) to R Digul and R Fly.

Descriptive notes. 36-38 cm. Sexes alike. Large, powerful flightless rail, with long heavy legs and very short, decomposed tail; easily distinguished from sympatric rallids on structure, size and plumage. Runs strongly, and flicks wings upwards while moving around. Young bird has brownish black hairy plumes on crown and in lines on side of head and on throat; mantle browner than in adult. Race *pallida* has paler, more buffy sides of lower neck and body. VOICE. Harsh but shrill call "aaah-aaah", reminiscent of the squeal of a baby pig; also a short complaining whistle.
Habitat. Mangrove forests, wet thickets, swamp forest and riverine bamboo thickets in lowlands.
Food and Feeding. Nothing recorded.
Breeding. Undescribed; two downy young obtained at L Daviumbu, near R Fly in Sept (latter part of dry season). Downy chick is black on head, and brownish black on body, with upperparts darker than underparts.
Movements. None recorded.
Status and Conservation. Not globally threatened. Data Deficient. Very rarely seen, but regarded by local people as not uncommon near Kiunga (on upper R Fly). No obvious threats except perhaps from feral pigs, and possibly from casual hunting by local people while collecting sago; powerful enough to frighten dogs by kicking and stabbing before escaping into dense cover or up into trees. Initial populations probably small because of specialized habitat requirements.
Bibliography. Andrew, P. (1992), Beehler *et al.* (1986), Coates (1985), Collar *et al.* (1994), Diamond (1975), Olson (1973b), Rand & Gilliard (1967), Ripley (1964, 1977).



Genus *GALLICREX* Blyth, 1852

109. **Watercock**

Gallicrex cinerea

French: Râle à crête **German**: Wasserhahn **Spanish**: Gallineta Crestada

Taxonomy. *Fulica cinerea* Gmelin, 1789, China.
Monotypic.
Distribution. Pakistan, India, Maldives and Sri Lanka E to C & E China, Korea and Ryukyu Is, and S through Andamans, Nicobars and SE Asia to Sumatra and Philippines. Winters S to Greater and Lesser Sundas and Sulawesi; now annual visitor to S Japan, mostly during winter.

Descriptive notes. Male 42-43 cm, 300-650 g; female 36 cm, 200-434 g; wingspan 68-86 cm. Large moorhen-like rail with slimmer, long-necked appearance. Male black with upperpart feathers fringed grey and usually brown, giving scaled appearance; undertail-coverts barred black and buff; bill yellow, and iris, base of upper mandible, frontal shield, horn, legs and feet bright red. Female markedly smaller; darkish brown above with buff-brown scalloping, rufous buff below with fine wavy dark barring. Non-breeding male as female. Immature and juvenile like adult female, but juvenile more tawny overall and less barred below. VOICE. Noisy in breeding season, with 3 types of call, all produced fairly continuously and rhythmically with short silence between each series: 10-12 "kok" notes with head raised; then 10-12 deeper, faster, hollow metallic "utumb" notes with head lowered; and finally 5-6 "kluck" notes with head raised. Generally silent in winter.
Habitat. Reedy or grassy swamps, flooded pasture, rice fields, irrigated sugar cane, and rush-bordered channels, rivers, ponds and ditches; sometimes brackish swamps.
Food and Feeding. Feeds largely on seeds and shoots of "green crops", and wild and cultivated rice, but also takes worms, molluscs, aquatic insects and their larvae, and grasshoppers. Swims well and will cross open water. Skulking and largely crepuscular; also emerges to feed in overcast and rainy weather.
Breeding. India and Pakistan, mostly Jun-Sept (monsoon months); Sri Lanka, May, also Jan-Feb and possibly Jul-Aug; Maldives, Jun-Jul; Ryukyu Is, Aug; Philippines, May-Jul and Sept; Sumatra, Dec (female and eggs collected). Probably monogamous, and territorial when breeding. Nest a large concave or deep cup-shaped pad of sedges, rushes, rice blades or grass, built low down in reeds or rice, or on clump of coarse grass; stems and seedheads turned down to form platform on which more material added; sometimes domed over to form bower; occasionally builds on heap of vegetable rubbish. Usually 3-6 eggs (3-10); incubation period unknown, but c. 24 days with artificial incubation. Normally rears 2 broods.
Movements. Most birds from N China and Korea apparently migrate or disperse S for winter, but extent of movements unclear, and evidence somewhat conflicting, with species also reported to be resident even in NE China (Liaoning); absent from Hong Kong, and apparently from Korea, in winter. Regarded as largely a visitor to S part of range, with winter occurrences from Borneo, Java, Sumatra, Flores and Sulawesi; also May-Jul in Sumatra and breeding recorded; migrants present in Japan mainly Sept to mid-Jan (most Oct-Nov) with occasional spring records. In India and Pakistan, resident in well watered areas but disperses widely during monsoon with creation of marshy conditions in otherwise dry low-lying areas. Vagrant to Kamchatka, Christmas I (Indian Ocean) Dec-Jan, and possibly to Palau Is.
Status and Conservation. Not globally threatened. Formerly reckoned to be common over much of range. Currently regarded as common winter visitor Sumatra (perhaps breeding only exceptionally) but uncommon in rest of Greater Sundas; fairly common resident in Philippines. In Wallacea, where assumed to be winter visitor, only 4 records: Sulawesi in Dec-Feb, and Flores May. Uncommon resident in Yaeama Is (S Ryukyu Is); rare but annual visitor to main islands of Japan.

Genus *PORPHYRIO* Brisson, 1760

110. **Purple Swamphen**

Porphyrio porphyrio

French: Talève sultane **German**: Purpurhuhn **Spanish**: Calamón Común
Other common names: Purple Gallinule(!)

Taxonomy. *Fulica Porphyrio* Linnaeus, 1758, Asia, America (– lands bordering the western Mediterranean Sea).
Races *madagascariensis*, *pulverulentus* and *poliocephalus* (incorporating all remaining races except nominate) have at times been considered separate species; *melanotus* and *bellus* too might be separate species. Numerous other races described. Thirteen subspecies recognized.
Subspecies and Distribution.
P. p. porphyrio (Linnaeus, 1758) - E & S Spain, S France and Sardinia to Morocco, Algeria and Tunisia.
P. p. madagascariensis (Latham, 1801) - Egypt, sub-Saharan Africa and Madagascar.
P. p. caspius Hartert, 1917 - Caspian Sea, NW Iran and Turkey.
P. p. seistanicus Zarudny & Härms, 1911 - Iraq and S Iran to Afghanistan, Pakistan and NW India.
P. p. poliocephalus (Latham, 1801) - India and Sri Lanka through Bangladesh, Andamans, Nicobars and N Myanmar to SC China (Yunnan) and N Thailand.
P. p. viridis Begbie, 1834 - S Myanmar, S Thailand and Peninsular Malaysia through Indochina to S China.
P. p. indicus Horsfield, 1821 - Greater Sundas to Bali and Sulawesi.
P. p. pulverulentus Temminck, 1826 - Philippines.
P. p. pelewensis Hartlaub & Finsch, 1872 - Palau Is.
P. p. melanopterus Bonaparte, 1856 - Moluccas and Lesser Sundas to New Guinea.
P. p. bellus Gould, 1841 - SW Australia.
P. p. melanotus Temminck, 1820 - N & E Australia and Tasmania to New Zealand, Kermadec Is and Chatham Is; migrates to New Guinea.
P. p. samoensis Peale, 1848 - Admiralty Is S to New Caledonia and E to Samoa.

Descriptive notes. 38-50 cm; *madagascariensis* male 528-687 (636) g, female 480-737 (556) g; nominate male 720-1000 (869) g, female 520-870 (724) g; *melanotus* male 785-1310 (1089) g, female 679-1252 (881) g; wingspan 90-100 cm (nominate), 70-86 cm (*melanotus*, *bellus*). Very large, ponderous rail, much larger than all other congeners except flightless *P. mantelli*, with massive triangular red bill, red shield, red legs and long, slender toes; most races predominantly blue to violet on head and body, with contrastingly blackish or greenish back and upperwing-coverts. Female smaller, with smaller frontal shield. Immature similar to adult but duller; some juvenile body feathers often retained. Juvenile duller than adult; face, foreneck and breast washed grey and throat almost white (nominate, *madagascariensis*); wings as adult; bare parts duller than adult. Races separated on plumage and size, with six subspecies groups: (1) nominate *porphyrio* has purple back and wings; (2) *madagascariensis* has bronze-green or blue-green back and scapulars; (3) *poliocephalus* group has cerulean blue scapulars, upperwing-coverts, face, throat and breast, and dark blue back; size declines eastwards, with *caspius* largest, *seistanicus* smaller and *poliocephalus* smallest; (4) *indicus* group often has large shield, upperparts and upperwing-coverts black with green tinge (less green in *indicus*), and throat and breast turquoise green to cerulean blue; side of head blackish in *indicus*, cerulean blue in *viridis*; (5) *pulverulentus* has olive-chestnut mantle and scapulars, and whole body strongly tinged ashy grey; (6) *melanotus* group can have relatively small shield, and has short toes, black upperparts, and variably cobalt to violet throat and breast; *melanotus* has purple throat and breast, *bellus* cerulean blue in these regions, *samoensis* similar to *bellus* but smaller and often has greenish brown tinge to back; *melanopterus* very variable and differs from *melanotus* and *bellus* in having blue lesser upperwing-coverts and being smaller; *pelewensis* similar to *melanopterus* but has greener gloss on upperparts and more purple tinge to lesser upperwing-coverts and breast. Voice. Very vocal; repertoire rich and variable. Male has low, sonorous calls, sometimes ending with hoarse trumpet notes; female has shriller, softer calls. Notes include "chuck" or "n'yip" contact and rallying calls, nasal rallying calls, explosive trumpeting alarm call, crowing territorial calls, and harsh, grating threat calls. Song a powerful series of plaintive nasal rattles, with crescendo. Flight call a loud shrieking series of cackling notes. Also has various grunts, whistles and bell-like notes.
Habitat. Fresh or brackish, sheltered open waters, still or slow-flowing, fringed or overgrown by *Phragmites*, *Typha*, *Carex*, *Cyperus*, etc. Sometimes at saline, eutrophic or turbid wetlands. Inhabited wetlands often extensive but birds also found on small waters. Habitat normally permanent but in Africa also occupies, and breeds in, seasonal and temporary wetlands. Inhabits ponds, lakes, dams, marshes, swamps, rivers, floodplains, artesian and seismic bores, and sewage farms; also lakes in towns, and islands on R Nile. Extends into open habitats adjacent to wetlands, such as grassland, agricultural land, parks, gardens, roadside verges, hedgerows, forest margins and even chicken runs. Occurs from sea-level to c. 2300 m (New Zealand) and 2500 m (Africa).
Food and Feeding. Omnivorous, but primarily vegetarian, taking shoots, leaves, roots, stems, flowers and seeds of aquatic and semi-aquatic plants. Principal food items include *Typha* (especially leaf bases and pith), *Scirpus* (pith from stems), young rice plants, seeds of grasses, sedges, *Rumex*, *Polygonum*, etc., and vegetative parts (especially tubers) of water-lilies. Animal foods normally small proportion of diet, including molluscs, leeches, small crabs, insects and their larvae, spiders, fish and their eggs, frogs and their eggs, lizards, snakes, birds, their eggs and nestlings, small rodents, and carrion. Forages in cover, at edge of cover on muddy, sandy or hard shoreline, in shallow water and on floating vegetation. Swims relatively little, but will dabble near shallow margins like Mallard (*Anas platyrhynchos*); picks insects from water surface. Climbs freely to strip flowers and seeds from reeds, etc., and to take bird eggs and nestlings. Uses bill to cut, dig up or pull out plants, to move stones and gravel, to turn over matted vegetation, and to dismember food items, and foot to grasp and manipulate food (see page 126). Adaptable: will forage in pasture, scrub and mown fields; grazes clover and grass; also feeds in rice fields. Builds platforms for feeding and roosting. Feeds mainly in early morning and late evening; sometimes at night.
Breeding. Mediterranean, mainly Mar-Jun; India and Pakistan, mainly Jun-Sept (SW monsoon); sub-Saharan Africa, in rainy season (possibly two breeding seasons in areas with bimodal rainfall regime); Madagascar, Jan; Australia, all months, main breeding correlated with peak rainfall, temperature and increase in photoperiod; New Zealand, Aug-Feb (mainly Sept-Dec); Vanuatu, mainly Aug-Jan. Social structure and mating system complex (see page 130). Mainly permanently territorial. Monogamy apparently prevails in W Palearctic races and in *madagascariensis*, but elsewhere at least races *poliocephalus* and *melanotus* live in communal groups (the former in captivity). In *melanotus*, groups contain breeding males and females, and non-breeding helpers (offspring from previous matings); mate-sharing occurs and females lay in communal nest; all group members care for young. Nest in shallow water (occasionally up to 180 m from water), concealed in thick emergent vegetation; large, substantial structure of dead stems and leaves of water plants, with shallow cup, usually built on platform of beaten-down vegetation; normally just above water but sometimes floating; surrounding stems often pulled over to form canopy; 1-2 access ramps provided. Outside diameter of nest c. 30 cm, depth 10-20 cm; cavity diameter 19-30 cm, depth 3-10 cm; material often added during incubation. Both sexes build, sometimes with assistance from helpers. Eggs 3-5 (W Palearctic, *caspius*), 3-7 (*poliocephalus*), 2-6 (*madagascariensis*, *melanotus*); laid at daily intervals; in communal breeders all breeding females in group lay eggs in same nest, sometimes in double bowl; lays up to 3 replacement clutches after losses; incubation 23-27 days, by both sexes and helpers; hatching synchronous or asynchronous; chicks precocial and nidifugous; can leave nest soon after hatching but often remain on nest for first few days; fed and cared for by parents and helpers; black downy chick has white filoplumes on head, neck, mantle and wing; skin of forehead red and eyelids purple; iris slate; bill white with purple-red at nostril and base; legs and feet rosy-flesh; young begin feeding themselves at 10-14 days, but fed for 25-40 days; fledged at 60 days or more; independent at 6-8 weeks. Age of first breeding 1-2 years. May raise two broods per season in some regions.
Movements. No regular long distance migrations. Local seasonal movements, in response to changing habitat conditions, in many regions, including SW Europe, Sardinia, N and sub-Saharan Africa, Volga Delta (most move S in winter), Caspian (numbers increase in S in winter), Azerbaijan, India and Pakistan, and Australasia (may migrate regularly across Torres Strait); possibly prone to irruptive movements in some parts of Australia and New Zealand, but fluctuations in numbers may be partly associated with modifications to habitat. In Gambia, is only non-breeding dry season visitor. Local movements in Andalusian marshes (Spain) believed to be largely made on foot and at night. Some wandering reported, in Europe confused by escapes, but genuine vagrant to Germany, former Czechoslovakia, Austria, Hungary, former Yugoslavia, Lebanon, Israel, Kuwait and Cyprus; in Africa wandering also reported to Pemba I and to scattered desert localities. In Syria, recorded at Bahrat Homs, where unlikely to breed, but may breed in Euphrates Valley.
Status and Conservation. Not globally threatened. In 20th century, nominate race has suffered marked decrease in already restricted range, often because of wetland drainage and also through hunting and effects of pesticides; requires strict protection and habitat management. Races *caspius*, *seistanicus* and *poliocephalus* locally common in past; current status unclear but Azerbaijan breeding population of *caspius* at least 10,000-15,000 pairs. Status in Syria uncertain: recorded at Bahrat Homs, but unlikely to breed. Race *madagascariensis* locally common to uncommon in E, C & S Africa, and in Madagascar, where heavily hunted locally; has declined recently in Nigeria. Race *melanotus* widespread and locally common in Australia and New Zealand, where range has expanded due to construction of artificial lakes. Race *pulverulentus* uncommon and local; *pelewensis* rare and probably endangered. Vulnerable to wetland drainage and to frequent disturbance; numbers reduced locally throughout range by removal of marginal wetland vegetation and by drainage. Some artificially created habitat has been provided by forest clearance, swamp drainage and creation of impoundments; on Norfolk I and Lord Howe I (off E Australia), has become established only since vegetation clearance has produced suitable habitats. Sometimes considered a pest because may damage fruit, vegetables, grain crops and pastures, and sometimes raids chicken-houses for eggs. Several successful reintroductions in W Mediterranean in recent years.

111. **Takahe**

Porphyrio mantelli

French: Talève takahé **German**: Takahe **Spanish**: Calamón Takahe

Taxonomy. *Notornis Mantelli* Owen, 1848, Waingongoro, North Island, New Zealand.
Occasionally still placed in genus *Notornis* (see page 112). Nominate race of North I, New Zealand, recently extinct. One extant subspecies recognized.
Subspecies and Distribution.
P. m. hochstetteri (A. B. Meyer, 1883) - SW South I, New Zealand.
Race *hochstetteri* introduced to Tiritiri Matangi, Kapiti, Mana and Maud Is.
Descriptive notes. 63 cm; stands c. 50 cm tall; male 2250-3250 (2673) g, female 1850-2600 (2268) g. Largest living rallid; thickset, flightless species with reduced wings, massive bill and powerful legs and feet; plumage loose and has silken sheen. Female slightly smaller. Unmistakable: much larger and more robust than *Porphyrio porphyrio*. Immature like adult but slightly duller; bill pinkish with bluish cast; legs and feet dull red or pale brownish orange; iris attains adult colour by 5-6 months. Juvenile predominantly brownish grey on head, neck and upperparts; face and throat mottled white; upperparts

On following pages: 112. Allen's Gallinule (*Porphyrio alleni*); 113. American Purple Gallinule (*Porphyrio martinica*); 114. Azure Gallinule (*Porphyrio flavirostris*); 115. San Cristobal Moorhen (*Gallinula silvestris*); 116. Tristan Moorhen (*Gallinula nesiotis*); 117. Common Moorhen (*Gallinula chloropus*).

attain brownish tinge with wear; breast and upper flanks dull purplish blue; rear flanks to vent cream-buff; undertail-coverts white; wing feathers grow last and resemble those of adult; iris dark brown to grey; bill and developing frontal shield almost black, later fading to light brown or pinkish; legs and feet horn to dark purplish brown. Races differ in skeletal measurements, *hochstetteri* having shorter leg bones (nominate race known only from subfossils). VOICE. Contact call a single rising squawk "klowp". Alarm call a low, resonant "boomp" or percussive "oomp", repeated slowly. Also various clucking calls when feeding, and a loud screech or hiss when threatened, chased or caught. Contact call easily confused with that of *Gallirallus australis*, but generally deeper and more resonant.

Habitat. Alpine tussock grassland; also subalpine scrub and beech forest in winter, when snow covers grassland; before population decline may also have inhabited coastal sand ridges and open shrubland. Alpine grassland dominated by snow tussock grass (*Chionochloa*) c. 1 m high, with sedges (*Carex*, *Schoenus*), short grass (*Festuca*, *Poa*), herbs and shrubs. Forest dominated by beech *Nothofagus*, with understorey of shrubs, ferns and grass. In Fiordland National Park occurs in area of heavy snows and very high rainfall (2500-4800 mm per annum), commonly above tree-line at 1050-1520 m. Where introduced on islands, occurs in pastures of exotic grasses (*Bromus*, *Holcus*, *Dactylis*) and clovers (*Trifolium*). Frequents mountain lakes, rivers, streams and bogs; often by fast-flowing streams; some areas prone to flooding.

Food and Feeding. Eats predominantly leaf bases of *Chionochloa* tussocks and other alpine grass species; leaf bases of Cyperaceae, grass seeds and fern (*Hypolepis*) rhizomes taken seasonally, mainly in winter; rarely takes invertebrates and small reptiles. On islands eats leaf blades, leaf bases and seeds of many introduced grasses, also leaves and bases of clovers, all parts of chickweed (*Stellaria media*), and occasionally dead sticks, grass and flax stalks. Pulls tussock tillers out with bill, transferring them to foot to hold them parrot-fashion; strips seeds from seedheads by running partly open bill along stalk, sometimes first biting off stem and holding it in foot; digs up fern rhizomes with bill. Feeds selectively, taking plant bases richest in nitrogen, phosphorus, calcium, sodium, potassium and soluble sugars. Active throughout day; in winter to 22:00 hours. Energy requirement c. 2·0-2·2 kcal/g/day.

Breeding. Mainly Oct-Dec; eggs occasionally to mid-Feb and small young late Mar (probably from re-nesting after failure). Monogamous; pair-bond permanent, at least for 12 years and probably for life. Territorial within loose colonies; territory maintained while breeding, thereafter pairs remain in semi-communal and overlapping home ranges; holds same territory each year; territory size 2-60 ha. Breeds in family groups; juveniles sometimes ejected but first-year birds may assist with incubation and care of young; multiple male helpers reported in captivity. Nest built on well drained ground among tussocks; typically has 2 entrances connecting with runways; has latrine nearby. Nest a deep bowl of fine grass and tussock leaves, placed in saucer-like scrape in ground; both sexes build. Trial and/or brood nests often also built. Usually 2 eggs (1-3), with laying interval 48-72 hours; incubation 29-31 days, by both parents; hatching asynchronous; chicks precocial and nidifugous; usually leave nest soon after hatching; black downy chick has black-brown iris, bill white with black base and frontal shield, legs and feet pale pink, becoming purple-brown; down fades to black-brown (pale brown to whitish from face to breast) and replaced by grey second down at 4-5 weeks; body feathers develop at 5-8 weeks, tail at 14-18 weeks, wings at 9-20 weeks; young fed and brooded by both parents; dependent on adults for food for c. 4 months; post-juvenile moult occurs at c. 4 months; develop adult calls at c. 4·5 months; usually remain with parents for winter and disperse in following spring, some remaining for up to 2 years. Fostering recorded in captivity. Age of first breeding 2 years; sometimes 1 year. Egg fertility 70-80%; hatching success 67-76%; survival to 1 year 27-71%, dependent on weather and locality; usually only 1 young raised to independence; adult survival 73-88% per year. Second brood recorded only once.

Movements. Sedentary and flightless. Holds grassland territories until snow prevents feeding, when descends into forest or scrub, some birds wandering 5-10 km, possibly up to 30 km, from territories. Moves within territory when breeding, ascending in mid-Dec to higher altitude zones where preferred foods grow. Temporary immigration of adults recorded in 2 areas, 1972/73; known to move across and between valleys; young may move greater distances than adults, in search of territory or mate.

Status and Conservation. ENDANGERED. Formerly widespread on both North I and South I. Race *hochstetteri* thought extinct by 1930's but rediscovered W of Lake Te Anau in Murchison Mts in 1948, when population c. 260 pairs and range 750-800 km²; range then contracted, by 1966 total of 180-200 pairs occupying c. 600 km². In 1980 wild population c. 120 birds; in 1990, total of 60 pairs known; in 1992 only 41 pairs remained after hard weather and stoat predation; in 1994, c. 150 birds survived in c. 650 km² of Murchison and Stuart Mts in Fiordland. Introduced to 4 mainly predator-free nearshore islands, 1968-1992; has bred successfully on all 4, and island population now c. 40 birds. Main causes of recent decline: severe competition for food from introduced red deer (*Cervus elaphus*), which have modified habitat by overgrazing, eliminating most nutritious plants and preventing some grasses from seeding; and predation by introduced stoats (*Mustela erminea*), which take eggs and all ages of birds. Habitat also reduced by spread of forest in post-glacial Pleistocene-Holocene, leaving birds more vulnerable to hunting by Polynesian colonists, who arrived c. 1000 years ago. Probably once widespread in both forest and grassland down to sea-level; modern distribution probably in suboptimal habitat because of low hunting pressure. Removal of deer and fertilizing tussock lands allow vegetation to recover, while stoat numbers have been reduced by trapping. Captive breeding, begun in 1950's, initially had little success; since 1987, methods have improved, with 90% of viable eggs hatching and 74% of chicks surviving to maturity. Overall population continues to decline, and trends still uncertain, but recovery plans aim: to establish self-sustaining population of over 500 birds in Fiordland; to boost island populations; to introduce birds to other island or mainland sites; and to promote public awareness. Nominate race known only from subfossils.

112. Allen's Gallinule

Porphyrio alleni

French: Talève d'Allen **German**: Bronzesultanshuhn **Spanish**: Calamoncillo Africano

Taxonomy. *Porphyrio Alleni* Thomson, 1842, Idda, Niger River.
Sometimes placed in *Gallinula* or *Porphyrula*. Forms superspecies with *P. martinica*. Monotypic.

Distribution. Senegal and Gambia E to Ethiopia and Somalia and S to South Africa, excluding arid SW; also Madagascar, Comoro Is, and (probably introduced) Mauritius.

Descriptive notes. 22-26 cm; male 132-172 (154) g, female 112-145 (125) g; wingspan 48-52 cm. Superficially resembles *P. porphyrio* but much smaller, with less robust bill, blue-green frontal shield and no pale blue on face or throat. Similar to *P. martinica* but noticeably smaller and has black head, dark blue-violet neck, breast and flanks, red legs and feet, all red bill, slightly darker frontal shield, and dark central undertail-coverts, giving white undertail patch an inverted heart-shape. Sexes alike but female smaller; early in breeding season shield of male bright turquoise blue and that of female apple green, but after chicks hatch both adults have blue shield which becomes purplish to red-brown in non-breeding season; iris of breeding birds coral red, of non-breeding birds brown; leg colour duller red in non-breeding birds. Immature duller than non-breeding adult in plumage and bare parts colours. Juvenile has dark brown crown to hindneck, paler on sides of head and buff on neck and cheeks, cream chin and throat, dark brown upperparts with pale feather edges, buff underparts and undertail-coverts, and white belly; remiges as adult and outer upperwing-coverts have blue-green centres; legs and feet brown, iris grey-brown to orange, bill red-brown and shield grey to grey-brown; juvenile *P. martinica* lacks pale feather edges on upperparts. VOICE. Variety of harsh, often nasal, calls, including dry "keck" and drawn-out "kerk" (sometimes repeated); series of sharp "kik" notes ending in churring "kurr" notes; harsh quacking; high-pitched repeated "kli" call in flight; and sharp "click" of alarm.

Habitat. Freshwater marshes, reedbeds, inundated grassland and floodplains, especially with flooded *Oryza longistaminata* and *Cyperus fastigiatus*; papyrus swamps, rice fields, and thick vegetation such as sedges, reeds and rank grass beside lakes, rivers, ponds and temporary pools. Normally prefers wetlands with *Nymphaea*, *Nymphoides*, *Ottelia* and other floating-leaved vegetation. Occurs up to 1900 m in E Africa.

Food and Feeding. Flowers and seeds of reeds and sedges; seeds, stems and leaves of grasses and other marsh plants; unripe seedheads of water-lilies; fruits of thorn bush *Drepanocarpus lunatus*; also earthworms, molluscs, crustaceans, insects, spiders, fish eggs and small fish. Aggressive towards conspecifics when feeding, and sometimes kleptoparasitizes other species, e.g. robs African Pygmy-geese (*Nettapus auritus*) of water-lily seedheads. Feeds most actively in early morning and late afternoon but also in middle of day and on moonlit nights. Swims well: forages while swimming, taking insects and plant material from water; also forages while walking on floating vegetation, and occasionally in short grass bordering water. Turns over floating lily leaves with bill and gleans food from underside while holding leaf down with feet. Breaks off water-lily seedheads with bill and holds in foot while pulling apart with bill; also carries food in toes to bill. Climbs bushes to feed on fruits; climbs up to 2 m on reed stems, both to feed and to preen; said to construct platforms for feeding on flowers and seeds of reeds high above water.

Breeding. Sierra Leone, Sept, Nov; Nigeria, May-Oct; Ghana, Jun; Cameroon, Aug; Gabon, May; Ethiopia, Apr, Jun, Sept-Oct; Kenya and NE Tanzania, Apr-Oct; Zanzibar & Pemba Is, May-Aug; in E Africa prefers dry months following long rains; SE Zaire, probably begins Jan-Feb (second half of rains); Zambia, Dec-Apr; Malawi, Feb-Apr, Jun, Sept-Dec; Zimbabwe, mainly Dec-Apr, also May, Sept; Namibia, Apr; Botswana, Nov-Dec; South Africa (N Transvaal), Dec-Apr; Madagascar, Jan. Monogamous; occurs in pairs throughout year; territorial when breeding. Nest typically in reeds, grasses or tangled vegetation at edge of water; also in open marshes and rice fields; quite flimsy; loosely constructed of reed stems and blades, dry sedges and other plants, with deep or shallow cup; placed just above water; sometimes woven into surrounding vegetation, which may be bent down to form foundation and pulled over in dome. Eggs 3-8 (mean 4·4); incubation by both sexes c. 15 days, starting with 1st egg; hatching asynchronous; chicks precocial; chick has black down, browner on underparts, with silvery tips around face and chin; fed and cared for by both parents. No further details available.

Movements. Some birds resident year round in permanent wetlands, but with onset of rains in N tropics most migrate N (Nigeria, Cameroon and Chad), while most in S tropics move S to breed in rains. Mainly resident in Zaire but possible migrant birds reported Jun. Resident in some parts of E Africa, but seasonal occurrences also reported, e.g. in Kenya non-breeding birds present at Mombasa, Sept-Mar, and breeding birds present L Baringo, May-Jun and SW Tanzania only during Dec-Jan floods; wanders to desert areas, e.g. to L Turkana, N Kenya (Jun). Little evidence of movements in Malawi; some resident Zambia and Zimbabwe but many appear and breed during rains (Dec-Apr). Rains breeding visitor to NE Botswana (present Feb-May only), and to N Transvaal, South Africa, but also resident on permanent waters of N Botswana and NE Namibia. Vagrancy widely reported, with extralimital records from N Africa, 8 W European countries (peak occurrences Dec), Azores and possibly Madeira; from Ascension I and St Helena, 1600 km and 1900 km from African continent; Comoro Is; Rodrigues I, 1500 km E of Madagascar; also Gulf of Guinea islands. Stragglers also recorded from SW African region (SW Cape Province and SW Namibia).

Status and Conservation. Not globally threatened. Erratic nature of occurrence in very seasonal habitats makes populations difficult to assess, but may be locally very numerous in suitable breeding habitat during seasons of good rainfall, e.g. at least 10,000 pairs were thought to be present on the Nyl floodplain, N Transvaal, in early 1996, during an exceptionally wet season. However, the destruction and modification of wetlands, by drainage, damming and grazing, throughout the bird's range, and especially the loss of suitable seasonally flooded habitats, must have affected its numbers adversely.

113. American Purple Gallinule

Porphyrio martinica

French: Talève violacée **German**: Zwergsultanshuhn **Spanish**: Calamoncillo Americano
Other common names: Purple Gallinule(!)

Taxonomy. *Fulica martinica* Linnaeus, 1766, Martinique, West Indies.
Sometimes placed in *Gallinula* or *Porphyrula*. Forms superspecies with *P. alleni*. Monotypic.

Distribution. Interior E USA; Pacific coast from Nayarit and Atlantic coast from Maryland and Delaware, S through SE USA, Central America, West Indies and N & C South America S to S Peru and N Argentina. N populations winter S from Texas and Florida.

Descriptive notes. 27-36 cm; male 203-305 g, female 142-291 g; wingspan 50-55 cm. Similar to *P. alleni*, but noticeably larger with purple head, paler neck, breast and flanks, yellow legs, feet, and bill tip, slightly paler frontal shield, and entirely white undertail-coverts. Sexes alike, but female smaller. Bare parts duller outside breeding season. Immature similar to adult. Juvenile warm brown from crown to hindneck, pale buff-brown neck and sides of head, cream chin and throat; brown upperparts with bronze-green tinge on back, scapulars and upperwing-coverts; buff-brown underparts, palest on belly and vent; white undertail-coverts; outer upperwing-coverts similar to adult but less blue; legs and feet pale yellow or brownish, iris brown to pale orange, bill yellow-green with pale tip and brown-pink base, and shield brown or grey. Juvenile *P. alleni* has pale edges to upperpart feathers. Voice. Typical calls a sharp, high-pitched "kyik", sometimes with booming undertone; and loud "kur", often preceded by series of "cook" notes when commonly modified to "cu-kúr-cu". Also has wailing scream; rapid "ka-ka-ka"; gruff, repeated "kruk"; cackling "kek kek kek" in flight; low ticking; and low, reedy buzz.

Habitat. Occurs mainly in subtropical and tropical lowlands and coastal fringes, in lush wetlands, notably grassy marshes and overgrown swamps, and on pools, ponds, and channels of slow-moving water down to size of roadside ditches. Breeding habitat primarily fresh to intermediately saline wetlands, including deepwater marshes with water 25-100 cm deep, lakes, and impoundments (primarily coastal but also inland), with stable water levels and good interspersion of dense stands of floating, emergent and submerged vegetation; seldom uses areas of open water free of vegetation. Dependent on floating vegetation, and also submergents, for brood rearing, such vegetation providing food, cover and protection from aquatic predators. Rice fields also important nesting habitat. During movements, frequents wetlands at higher altitudes in E Andes of Colombia up to at least 3020 m, and recorded at 4080 m in Peru.

Food and Feeding. Predominantly plant material, including pondweed, sedges, willows, water-lilies, fruits, seeds of annual grasses and sedges and of floating and submerged vegetation, flowers of *Eichhornia crassipes*, and cultivated rice grains. Also eats insects, including Odonata adults and nymphs, Noctuidae (moth) larvae and pupae, Coleoptera, Hemiptera, Hymenoptera, Orthoptera (grasshoppers), and fly larvae and pupae (Corydalidae, Cyclorrhapha); worms, molluscs, spiders, frogs, and eggs and young of herons and jacanas; may occasionally scavenge. Walks on floating vegetation to feed; turns over lily pads to glean food from undersides, holding leaf down with foot; swims and dives easily. Climbs easily to feed in bushes and trees for up to 20 m from ground. Visits rice fields and fields of ripe grain in autumn, climbing stalks to feed on seedheads. Opportunistic, taking advantage of locally abundant foods. Usually remains close to cover, but feeds in open by day; when encouraged becomes tame, visits gardens and will pick up food dropped by humans.

Breeding. USA, May-Aug, in some habitats, e.g. rice fields, nesting delayed until plant density adequate; El Salvador, Jul-Aug; Panama, Mar-Nov; Colombia, May-Oct; Surinam, Jan, Mar-Jul; Argentina, Dec. Monogamous and territorial during breeding season; migrants arrive paired on breeding grounds or pair immediately on arrival. In Costa Rica, non-migratory birds live in extended family groups in which immatures and juveniles help with feeding and defending chicks, and with territory defence. Nest built on floating mats of vegetation, e.g. *Eichhornia* and *Alternanthera*, or in emergent vegetation, e.g. *Typha*, *Thalia* and *Zizaniopsis*; those in emergent vegetation normally near edge, where interface occurs with open water areas containing submergents such as *Ceratophyllum* and *Potamogeton*, or floating vegetation. Nest bulky, made from readily available plant materials, e.g. leaves of *Typha* or rice plants, usually obtained very close to nest-site. External diameter 16-28 cm, depth 6-20 cm; cup depth 2-9 cm; placed 20-60 cm above water. Partial canopy of growing vegetation often made; extensive ramp up to nest usually constructed; both sexes build. Eggs 6-10 (Florida), 3-12 (West Indies), 4-8 (Mexico), 3-7 (Costa Rica), 4-5 (Panama); laid at daily intervals; incubation 18-20 days, by both sexes; chicks precocial; black downy chicks have silver tips to down of head, neck and back, bill red with black tip, shield flesh; fed in nest for 2-4 days after hatching; fed and cared for by both parents; return to nest for brooding; separate brood nest sometimes constructed; chicks begin to feed themselves at 7-10 days; become self-feeding at c. 21 days; juvenile plumage attained, and young capable of flight, at 5-7 weeks. North American birds sometimes renest if first attempt fails; in Costa Rica pairs produce clutch every 2-4 months throughout year. Age of first breeding probably 1 year.

Movements. North American birds migrate S over Gulf of Mexico, Oct-Nov, a few remaining to Dec. Returning birds arrive in breeding areas in Georgia, Texas and Louisiana in mid-Apr. South American populations not migratory, except at S end of range, where birds move N into tropics for austral winter. Influx noted to coast of Brazil (Maranhão), Feb-Oct; present Rio Grande do Sul (SE Brazil) May-Sept. Well known for numerous instances of long distance vagrancy, both N and S of equator; migrants meeting cyclonic storms especially prone to being blown well beyond normal range. Recorded throughout much of USA, W to California, and into Canada, N to Labrador. Low pressure systems moving up coastal USA carry birds almost annually to Bermuda and New England, and sometimes beyond. Vagrant to S Greenland, Azores, Flores, Europe (Britain, Norway, Switzerland), and to islands in Atlantic and Pacific oceans: South Georgia, Tristan da Cunha (frequent), Galapagos, Falkland Is, Ascension I and St Helena. Quite regular in South Africa (W Cape), Apr-Aug, when birds are migrating N from Argentina, Uruguay and S Brazil, whence African vagrants may originate; also recorded off Liberian coast. S vagrants nearly all immatures.

Status and Conservation. Not globally threatened. Little information on current populations and population trends but, as wetland habitat quality and quantity are keys to population stability, populations are probably decreasing throughout range as result of freshwater wetland loss in USA and throughout South and Central America. In USA it is a game species but harvest is likely to be small because of low hunter interest and the fact that the birds migrate S prior to the late autumn hunting season in many states. In USA, conservation and management of freshwater wetlands along lower Atlantic and Gulf Coast states are critical for the species; there is also an urgent need to monitor population status, trends and harvest, and to provide information on annual productivity, recruitment and survival rates.

114. **Azure Gallinule**

Porphyrio flavirostris

French: Talève favorite **German**: Azursultanshuhn **Spanish**: Calamoncillo Celeste
Other common names: Little Gallinule

Taxonomy. *Fulica flavirostris* Gmelin, 1789, Cayenne.
Formerly listed as *P. parvus*, but this name preoccupied. Sometimes placed in *Gallinula* or *Porphyrula*. Monotypic.

Distribution. E Colombia through CS Venezuela to the Guianas and S to E Ecuador and N Peru E across NC Brazil; SE Peru, N Bolivia, W & C Brazil and C Paraguay to extreme N Argentina; also extreme SE Brazil.

Descriptive notes. 23-26 cm; male 92-111 g, female 92-107 g. Smallest *Porphyrio*, delicately proportioned and markedly different in appearance to congeners; plumage looks washed-out: crown and hindneck to back pale brownish olive with indistinct dusky streaks, lower back to tail dark brown, upperwing-coverts azure or greenish blue, remiges grey-blue, sides of head, neck and breast blue-grey, throat and underparts pure white; bill and frontal shield pale greenish yellow; legs and feet dull to bright yellow; iris reddish brown. Immature browner above, with contrasting dark rump and tail in flight, buffy sides of head, neck and breast; bill as adult but frontal shield and culmen green; legs and feet yellowish orange; iris amber-yellow. Voice. Usually rather quiet; sometimes utters a short trill.

Habitat. Freshwater marshes, especially those with fairly deep water and thick cover of marsh grass (e.g. *Paspalum* up to 1 m tall) or other emergent or floating vegetation; also rice paddies, wet savannas, swampy stream and river margins and marshy shores of lakes (including oxbow lakes), lagoons and permanent or seasonal ponds. Occurs alongside *P. martinica* but prefers shorter, smaller-leaved vegetation and avoids areas with bushes and *Heliconia*; often flushed from emergent grass 15-30 cm tall. Normally occurs in lowlands, up to 500 m, but recorded casually on savanna of Bogotá in E Andes at 2600 m.

Food and Feeding. Grass seeds, insects (including Hemiptera and Coleoptera) and spiders recorded. Forages in cover and on floating vegetation. Climbs on grass stalks to bend them to the water and eat seeds. Seldom swims.

Breeding. Surinam, May-Aug; E Amazonian Brazil, probably May-Jun: Ecuador, oviduct egg Jun; season may extend Mar-Aug, possibly Oct, and non-breeding season may be Sept-Dec. Monogamous; probably territorial when breeding. Nest an open cup of dead leaves or rushes, concealed in marsh vegetation. Eggs 4-5; both sexes incubate. No other information available.

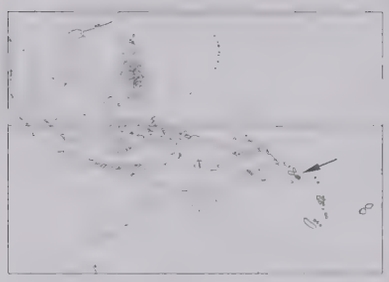
Movements. Highly seasonal in occurrence in parts of range. Present throughout year in much of Amazonia, but seasonal in the Guianas, almost all records Apr-Aug; also in SW Amazonia and Paraguay, mostly Oct-Jan. Near equator seasonality not so pronounced but still evident from specimen records: most specimens from E Amazonian Brazil are Feb-Aug, while specimens from W Amazonia peak in Jan and observations along upper Amazon (Iquitos and Leticia) indicate birds present only Jan-Jul. Occurrence may be timed to coincide with wet or high-water seasons; apparently present seasonally in areas at periphery of range. Arrival noted Tambopata Reserve, Madre de Dios (SE Peru), early Nov; possibly absent elsewhere in region Jun-Dec. Recorded from *llanos* of Venezuela only Aug-Dec. Apparently resident in Ecuador and S Colombia, but in C Colombia (W Meta) occurs only Mar-Jul, and migrants present Mar-May in savanna of Bogotá. Vagrancy or occurrence in atypical habitats also recorded: occurred at Escorial in Venezuelan Andes at 3000 m (Oct); twice in Bogotá city at 2600 m (Dec); on escarpment above forest in S Venezuela (Jan); and in Rio Grande do Sul, Brazil (Nov); also recorded Trinidad, where most occurrences since 1978; a specimen from New York, USA, (Dec) could be wild bird. After breeding in May-Jul, most of population in N South America may disperse S c. 1800 km to S periphery of Amazonia, returning N in Feb-Mar.

Status and Conservation. Not globally threatened. Formerly regarded as fairly common in some parts of its range, which has been conflictingly regarded as either fragmented or continuous. Apparently fairly common in the Guianas but uncommon in Colombia, E Peru and N Bolivia; probably more widespread in Amazonia than the relatively limited records indicate. Currently regarded as probably occurring regularly in summer in marshes of W São Paulo, SE Brazil, but likely to disappear as rivers become reservoirs.

Bibliography. Blake (1977), Boyle *et al.* (1987), Canevari *et al.* (1991), ffrench (1985), Fjeldså & Krabbe (1990), Haverschmidt (1968), Haverschmidt & Mees (1995), Hayes (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Nicéforo & Olivares (1965), Norton (1965), Parker (1982), de la Peña (1992), Remsen & Parker (1990), Sick (1985c, 1993), Snyder (1966), Tallman *et al.* (1977), Tostain *et al.* (1992), Willis & Oniki (1993).

Genus *GALLINULA* Brisson, 1760

115. **San Cristobal Moorhen**



Gallinula silvestris

French: Gallinule d'Édith **German**: Blaustirn-Pfuhlhuhn **Spanish**: Gallineta de San Cristóbal
Other common names: Mountain Rail

Taxonomy. *Edithornis silvestris* Mayr, 1933, San Cristobal Island.
Sometimes placed in genus *Pareudiastes*, with extinct Samoan Moorhen (*G. pacifica*), on basis of construction of bill, skull and tarsus, and plumage pattern. Monotypic.

Distribution. San Cristobal, Solomon Is.

Descriptive notes. 26·5 cm (1 male); 450 g. Male entirely plain: head, neck and breast dark bluish slate, almost blackish on chin and face; scapulars, wing-coverts and secondaries brown-black, tinged olive; rest of body dull brownish black; iris chocolate; legs, feet and bill bright scarlet; shield dark grey-blue; tail very short, with hair-like rectrices; secondaries soft and decomposed; bill strong and laterally compressed; legs and feet slender; flies very little, if at all. Voice. Unknown.

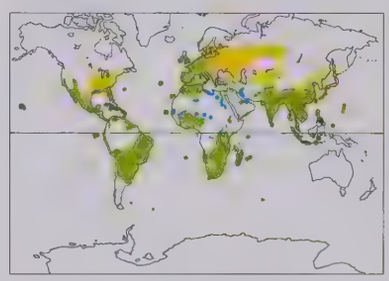
Habitat. Dense undergrowth of primeval mountain forest on steep slopes; type specimen obtained at altitude of 580 m, but mountains in the vicinity ascend to 1200 m; the area has many streams and creeks cutting deep into mountain slopes, but no standing water. Also reported as occurring in rocky valleys below 425 m.
Food and Feeding. No information: diet of extinct *G. pacificus*, of similar habitat, was apparently almost entirely animal matter.
Breeding. Unknown.
Movements. No information available.
Status and Conservation. CRITICALLY ENDANGERED. Known only from the holotype, collected in Dec 1929 in the central mountains of San Cristobal. Even then apparently rare, and hunted by local people with dogs. The only subsequent observations are of one seen by an expedition member in 1953, when it was reported apparently to be not uncommon in rocky valleys below Wuranakumau, on Naghasi ridge, and a report by local people of its presence in 1974; however, the forests where it was originally found have not been visited by ornithologists since 1950's. It is likely to have been affected by introduced mammalian predators, such as cats, which have wiped out most native terrestrial mammals on nearby Guadalcanal.
Bibliography. Cain & Galbraith (1956), Collar & Andrew (1988), Collar *et al.* (1994), Hay (1986), King (1978/79), Lees (1991), Mayr (1933), Olson (1973b, 1975b), Ripley (1977), Ripley & Beehler (1985).

116. Tristan Moorhen

Gallinula nesiotis

French: Gallinule de Tristan **German**: Tristanteichhuhn **Spanish**: Gallineta de Gough
Other common names: Gough Moorhen (*comeri*)

Taxonomy. *Gallinula nesiotis* P. L. Sclater, 1861, Tristan da Cunha.
In past, sometimes placed in genus *Porphyriornis*. Nominate race of Tristan da Cunha recently extinct. One extant subspecies recognized.
Subspecies and Distribution.
G. n. comeri (Allen, 1892) - Gough I, S Atlantic.
Race *comeri* introduced to Tristan da Cunha.



Descriptive notes. 25 cm; 3 adult *comeri* 505-530 (513) g. Sexes alike. Superficially resembles *G. chloropus* but smaller, much more strongly built, short-winged, and almost completely flightless but able to climb well and partially fly over obstacles; also differs in plumage, having black, not grey, neck and underparts, no white on flanks, and red legs heavily blotched with greenish yellow. Immature largely greyish brown, with dark sooty grey head, chestnut brown upperparts and sooty grey belly with cream feather tips; shield shiny red; bill dull, dark red with yellow-green tip. Juvenile predominantly brown, belly paler with cream feather tips; two dirty cream undertail bars; shield and bill dull green, bill with whitish tip; tibiae yellow; tarsi and feet green. Races differ only in skeletal measurements, *nesiotis* being slightly smaller and lighter. VOICE. Voice metallic and loud. Common call a harsh, staccato, high-pitched, far-carrying "koo-ik", often repeated, and taken up by surrounding birds; also loud, screaming series of "koo-ik" notes; and low-pitched, monotonous, whispered, repeated "ik" or "ook" given by pair members and audible at close range. Female gives harsh repeated call near nest.
Habitat. Race *comeri* occurs throughout Gough I in very dense vegetation of tussock grass and bushes in the shrub and tree-fern zones, generally below 500 m and mainly close to coast in boggy areas and along streams. On Tristan da Cunha, where introduced, inhabits rugged, luxuriant, inaccessible fern-bush (*Blechnum*), with dense *Phylica arborea* trees, at 300-900 m.
Food and Feeding. Gough I birds appear to feed as much on vegetable matter, seeds and carrion as on invertebrates. Generally remains in cover but feeds in open if undisturbed. Eats grass, and takes grass-heads with scythe-like motion of bill. Scavenges from carcasses of Soft-plumaged Petrels (*Pterodroma mollis*) and Broad-billed Prions (*Pachyptila vittata*) partly eaten by Brown Skuas (*Catharacta antarctica*); also feeds on garbage at meteorological station. Enters petrel burrows, apparently in search of food, and seen foraging in abandoned albatross nests, presumably for invertebrates; also scavenges around active albatross nests.
Breeding. On Gough lays Sept-Mar; on Tristan probably breeds Dec-Mar. Monogamous and territorial; pair-bond apparently permanent. Nest circular and cup-shaped; made of sticks; bowl diameter 14-20 cm; rim 10-15 cm above ground (in captivity 75 cm above ground); placed in grass (*Poa flabellata*) tussock, with access tunnel from edge of tussock to nest; both sexes build. Eggs 2-5 (up to 6 in captivity); incubation 21 days, by both sexes; downy chick black, with fringe of long silky hairs on throat, bill crimson at base, blue-grey towards tip, with white spot on top of upper mandible, legs and feet black; young fed by both parents; seen to be given fresh flesh from bird carcasses. Immature plumage retained into second year. 2 broods per season recorded, with c. 14 weeks between clutches; young of first brood help to feed second brood.
Movements. None. One at Cape Town in 1893 apparently an escape.
Status and Conservation. VULNERABLE. Numbers difficult to assess because of secretive nature. Race *comeri* common on Gough I, where total population probably 2000-3000 pairs; territory size c. 0·5 ha; no avian competitors, but egg predation by skuas recorded. Introduced to Tristan da Cunha in 1956, whence nominate race was extirpated by around 1900; current population c. 250 pairs. Both populations appear stable, and habitats unlikely to change significantly, but there is permanent risk of mammalian predators becoming established on the islands; however, chances of this happening have been minimized. Re-establishment on Tristan da Cunha successful despite large population of black rats (*Rattus rattus*); earlier extinction there was attributed to rat predation but possibly more due to combination of habitat destruction, predation by cats and pigs, and hunting with dogs. Captive stock exists in a few European zoos, and species breeds successfully in captivity, but hybridization with *G. chloropus* occurs and must be avoided.
Bibliography. Beintema (1972), Broekhuysen & Macnae (1949), Clancey (1981a), Collar & Andrew (1988), Collar & Stuart (1985), Collar *et al.* (1994), Cooper & Ryan (1994), Eber (1961), Elliott (1953, 1957), Holdgate (1957), Olson (1973a), Richardson (1984), Ripley (1977), Voisin (1979), Voous (1961b, 1962), Wace & Holdgate (1976), Watkins & Furness (1986), Wilson & Swales (1958).

117. Common Moorhen

Gallinula chloropus

French: Gallinule poule-d'eau **German**: Teichhuhn **Spanish**: Gallineta Común
Other common names: Common Gallinule

Taxonomy. *Fulica Chloropus* Linnaeus, 1758, England.
Sometimes considered conspecific with *G. tenebrosa*, or to form superspecies, but the two are sympatric in Wallacea. Many other races described; possible races *correiana* and *indica* included in nominate. Twelve subspecies recognized.
Subspecies and Distribution.
G. c. chloropus (Linnaeus, 1758) - Europe, North Africa, Azores, Canaries and Cape Verde Is E through W, C & S Asia to Japan, S to Sri Lanka and C Malaysia; N populations winter S to Mediterranean region, sub-Saharan Africa and S Asia.
G. c. meridionalis (C. L. Brehm, 1831) - sub-Saharan Africa and St Helena.
G. c. pyrrhorrhoa A. Newton, 1861 - Madagascar, Reunion, Mauritius and Comoros Is.
G. c. orientalis Horsfield, 1821 - Seychelles, Andamans, S Malaysia and Greater & W Lesser Sundas to Philippines and Palau Is.
G. c. guami Hartert, 1917 - Northern Mariana Is.
G. c. sandvicensis Streets, 1877 - Hawaiian Is.
G. c. cachinnans Bangs, 1915 - SE Canada and USA through Central America to W Panama, also Bermuda and Galapagos; N populations winter S to Panama and possibly beyond.
G. c. cerceris Bangs, 1910 - Greater & Lesser Antilles.
G. c. barbadensis Bond, 1954 - Barbados.
G. c. pauxilla Bangs, 1915 - E Panama, N & W Colombia, W Ecuador and coastal NW Peru.
G. c. garmani Allen, 1876 - Andes of Peru, Chile, Bolivia and NW Argentina.
G. c. galeata (Lichtenstein, 1818) - Trinidad and the Guianas S through Brazil to N Argentina and Uruguay.

Descriptive notes. 30-38 cm; male 249-493 (339) g, female 192-343 (271) g (*chloropus*), unsexed 173-335 (245) g (*meridionalis*); wingspan 50-55 cm. Medium-sized gallinule, plumage appearing essentially black at any distance, with prominent yellow-tipped red bill and red frontal shield, prominent white line along top of flanks, and white lateral undertail-coverts rendered obvious by constantly flicking of tail; legs and feet bright yellow-green to yellow, upper half of tibia orange. Sexes similar, but female smaller. Immature similar to juvenile, gradually attaining adult bare parts colours. Juvenile has crown, hindneck and upperparts brown to grey (depending on race), duller than in adult; underparts paler, becoming whitish on throat and belly; wings, white flank line, tail and undertail-coverts like adult; iris brownish, bill and shield greenish brown, olive-grey or pinkish; legs and feet olive-grey. Racial variation mostly clinal, mainly involving size, colour of upperparts and upperwing-coverts, and size and shape of shield: Old World birds have elliptical shield, widest in middle and with rounded top, New World birds mostly have truncated shield, top almost square and widest near top; races *meridionalis* and *orientalis* smaller with slaty blue-grey upperwing-coverts but without the olive wash; *orientalis* also has relatively large shield; *pyrrhorrhoa* has buff undertail-coverts; *guami* darker than nominate; *cachinnans* like nominate but has different shield shape and relatively long bill, tarsus and toes; *cerceris* has less brown on upperparts than *cachinnans*; *sandvicensis* has large frontal shield and red on front of tarsus; *pauxilla* smaller than *cachinnans*, with greyer brown upperparts; *garmani* larger, darker and more uniformly plumbeous; *galatea* also deep plumbeous above but smaller than *garmani*; *barbadensis* like *cerceris* but body plumage much brighter and head and neck paler. VOICE. Wide variety of clucking and chattering calls, sometimes repeated for long periods in American races, but not in Old World races. Most familiar calls are advertising call (crowing), a loud, explosive, single "krrrruk", and a similar "kurr-ik" and "kark". Anger or alarm indicated by loud "kik-kik" or "cuk", sometimes rapidly repeated; fighting birds emit short clicking chatter. Also has soft, musical, repeated "kook" call (murmur-call) used in various displays; loud "keh-keh"; "chuck" of distress; and familiar "kittick" of mild alarm.
Habitat. Exploits wide range of natural and man-made freshwater wetlands with fringing emergent vegetation; occurs on both still and moving water; tolerant of wide range of climatic conditions but vulnerable to freezing. Occurs on rivers, streams, canals, ditches, lakes, dams, pools, ponds, disused gravel pits, rice fields, swamps and marshes, and at seasonally flooded sites; avoids oligotrophic or saline situations, but inhabits brackish waters on Namibian coast and in Galapagos. Requires ready access to some open fresh water with adequate plant cover; occupies sites with small open water surfaces, such as ponds and pools only a few metres across; prefers waters sheltered by woodland or tall emergent plants; avoids very open sites, especially those exposed to wind and wave action. Occurs alongside *Fulica atra* at wetland margins but less prone to venture far out into open water. Normally occurs most commonly in lowlands, but reaches 1700 m in C Europe, 2400 m in Kashmir, 3000 m in Kenya and 4200 m in Argentina.
Food and Feeding. Omnivorous; proportions of plant and animal food vary. Plants include filamentous algae, moss, vegetative parts of *Lemna*, *Wolffia*, *Potamogeton*, *Juncus*, *Phragmites*, *Veronica*, *Hydrilla*, *Ceratophyllum* and grasses, seeds of *Typha*, *Sparganum*, *Potamogeton*, *Carex*, *Scirpus*, *Rumex*, *Polygonum*, *Nymphaea*, *Nuphar*, *Ranunculus*, *Ulmus*, *Zizaniopsis* and cereals, flowers of *Eichhornia*, berries of *Taxus*, *Rubus*, *Sorbus*, *Rosa*, *Crataegus*, *Rhamnus*, *Hedera*, *Sambucus* and *Hippophae*, and various orchard fruits. Animal foods include earthworms, molluscs, crustaceans, adult and larval insects (especially Ephemeroptera, Hemiptera, Trichoptera, Coleoptera, Lepidoptera and Diptera), spiders, small fish, tadpoles and occasionally eggs of birds; also takes carrion, rubbish (vegetable scraps), duck food and fish food. Feeds while swimming and while walking on floating vegetation, either in cover or in open; also feeds on land, grazing and gleaning over open grass or in arable farmland, usually near cover. In water, obtains food by dipping head, surface sifting, upending and rarely by diving. Gleans insects, seeds and fruits from ground and plants; often clambers over leaves and stems; climbs and perches well. May be opportunistic, feeding on most abundant food types. Kleptoparasitizes other birds, e.g. Great Crested Grebe (*Podiceps cristatus*). Normally diurnal but sometimes active on moonlit nights.
Breeding. Europe, Mar-Aug; N Africa, Apr-Aug; W Africa, Jun-Aug but all year S Ghana, except at peak of wet season; E Africa, all year, peaking in wet months; C Africa, Feb-Sept, Nov-Dec; S Africa all months, peaking Jan-Apr and Jun-Aug in Zimbabwe and Sept-Oct in W Cape; Madagascar, Oct-Mar; Indian Subcontinent, Mar-Sept; Philippines, Jul-Sept; Borneo, Apr; Lesser Sundas, May; Guam, Mar, Jun, Dec; North America, Apr-Jun (season 5-6 weeks longer in S than in N); Panama, mostly Dec-Jan; in Andes, Jul-Sept and in rainy season. Monogamous and territorial; territory may be perma-

nent; pair-bond sometimes maintained for several years. Polyandrous trios of 1 female and 2 males also occur; co-operative nesting of 2 or more females mated to 1 male also recorded; brood parasitism regularly occurs (see page 129). Nest saucer-shaped or more substantial, of twigs, reeds, rushes and sedges, with shallow to deep cup; on, or up to 1 m above, water; often built in emergent vegetation or on solid platform of branches or matted vegetation, in water; sometimes floating, less often in ground vegetation or low bush on bank, usually within few metres of water; occasionally in bushes and trees up to 8 m above ground. Floating nests often have entrance ramp. External diameter 24-30 cm, depth 10-20 cm; cup diameter 12-17 cm, depth 3-7 cm. Both sexes build, helped by other group members; material often added during incubation; also builds brood nests or platforms. Eggs 2-17, mostly 5-9 (W Palearctic), 3-9 (Africa), 7-9 (North America); laid at daily intervals; clutches larger than 13-14 probably from 2 females; up to 5 replacement clutches laid after egg loss; incubation 17-22 days, by both sexes; hatching usually synchronous for first clutches and asynchronous for replacements and later clutches, but asynchronous for all clutches in USA; black downy chick has bare skin of crown rose-red and blue, skin of throat yellow and of wing pink, iris grey-brown, bill orange with yellow tip, legs and feet black; chicks precocial and nidifugous; remain in nest for 1-2 days; swim well by 3rd day and dive at 8 days; fed and cared for by both parents, by immatures of previous broods and by other adults in group; brood division may occur; chicks use spur on alula to climb and grasp vegetation, and to enter brood nests; brooded frequently until c. 14 days old; become self-feeding at 21-25 days, but fed for up to 45 days; fledging 45-50 days, rarely 70 days; independent at 52-99 days (mean 72 days). May rear up to 3 (occasionally 4) broods per season; interval between broods 20-30 days; in South Africa, nested continuously in suitable conditions, although supplementary food was available. Age of first breeding 1 year.

Movements. In W Palearctic, resident or dispersive in S and extreme W, partially migratory to migratory elsewhere, extent of movement increasing further to N & E. Almost wholly summer visitor to former USSR and Finland, while relatively few remain in N Scandinavia, N Germany and Poland in winter. N European birds winter S to Iberia, Italy, Balkans and N Africa. Autumn movements mainly SW from N Europe and S-SE from C Europe; main S movements Sept-Dec, juveniles dispersing from Jul; return passage Mar-May. British and French populations resident but both receive winter migrants from NW Europe. Palearctic birds of unknown origins winter (Nov-Mar) in sub-Saharan Africa, in Senegal, Gambia, Mali, N Nigeria, C Chad and N Sudan. Winter range of emigrant Russian birds, and extent of dispersal by Near East birds, unknown. Passage noted Azerbaijan Mar-Apr and Oct-Nov. Numbers in India and Pakistan greatly augmented by winter visitors; passage noted Oct and Mar-May; occurs Japan Mar-Oct. Race *meridionalis* resident, with some local movements in response to changing conditions; wanders to temporary pools. In North America most of E population migratory, wintering along coast and S to Panama, West Indies and possibly South America; breeding migrants arrive Apr-Jun; some seasonal altitudinal movements occur in W populations (Arizona and Mew Mexico), and also some migration, extent of which unknown. Some seasonal movements noted in South America; winter migrants possibly occur Costa Rica, and Colombia Oct-Feb; presumed winter influx from S noted in Rio Grande do Sul, Brazil. Success in colonizing high proportion of suitable, often scattered, habitats, indicates effective prospecting on wing, largely at night and in lower airspace. Accidental to Iceland, Spitsbergen and São Tomé; *meridionalis* vagrant to NE Chad.

Status and Conservation. Not globally threatened. Most races at least locally common. Nominate generally common throughout range; has expanded range in N Europe since mid-19th century; common in NW Europe, where populations fluctuate markedly due to hard winters; overall increase in Fenno-Scandia and Britain; widespread in N Africa. Race *meridionalis* patchily distributed and uncommon to locally abundant in sub-Saharan Africa; increasing locally as result of man-made dams and ponds. Race *cachinnans* widespread and rare to locally abundant in North America. Race *sandvicensis* of Hawaii now restricted to a few hundred birds on 3 islands and is endangered; Mariana race *guami* also endangered, with only c. 300 birds remaining in greatly reduced wetland habitats. Locally uncommon to abundant throughout range in Central and South America. Readily exploits newly created habitats and is tenacious of occupied areas, not being displaced easily by changes or human disturbance; adapts well to situations at urban sites, where total acceptance of human presence is necessary in order to occupy suitable habitat of tree-lined ornamental waters and lawns. In North American rice fields, rice harvesting is harmful to nests and young broods. Estimated USA harvest averages 44,500 birds per year.

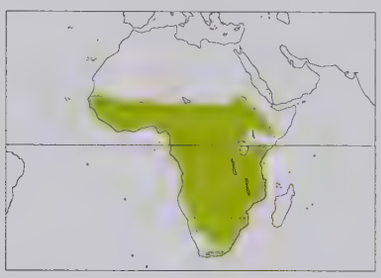
118. **Dusky Moorhen**

Gallinula tenebrosa

French: Gallinule sombre **German**: Papuateichhuhn **Spanish**: Gallineta Enlutada

Taxonomy. *Gallinula tenebrosa* Gould, 1846, South Australia.
Sometimes considered conspecific with *G. chloropus*, or to form superspecies, but the two are sympatric in Wallacea. Three subspecies recognized.
Subspecies and Distribution.
G. t. frontata Wallace, 1863 - SE Borneo and Sulawesi through S Moluccas and Lesser Sundas to W & SE New Guinea.
G. t. neumanni Hartert, 1930 - N New Guinea.
G. t. tenebrosa Gould, 1846 - Australia.



Descriptive notes. 35-40 cm (New Guinea birds 25-32 cm); nominate 336-720 (525) g, *neumanni* 290-370 (333) g; wingspan 55-65 cm. Darker and more uniform in plumage than Eurasian *G. c. chloropus*, but differs from marginally sympatric *G. c. orientalis* only in absence of prominent white line along top of flanks, only infrequently showing narrow or broken line; orange to red legs and feet with dark soles and joints. Separated from other sympatric congeners by dark plumage, white outer rectrices and lateral undertail-coverts, and bare part colours. Sexes similar. Non-breeding adult has bill dull red (most often in males) to olive-black, shrunken shield olive green or darker, red on tarsus and toes fades to olive green or yellow. Immature similar to adult but iris dark brown, bill, shield and tibia olive black or olive brown, and tarsus olive green. Juvenile duller than adult, browner on upperparts, paler on throat and underparts, with feathers of lower breast and belly extensively fringed white; bill and shrunken shield pale red, becoming dark olive brown; iris dark brown; legs and feet dark olive green or olive brown. Races separated on size and colour: *neumanni* smaller and darker; *frontata* slightly smaller than nominate, darker below, with front of tarsus and top of toes bright red (differences in leg and foot colour need further investigation). Voice. Territorial advertising call a raucous, crowing "kurk"; calls sometimes repeated or run together. Also various short, sharp alarm calls (including harsh squawks and shrieks) and a series of widely spaced staccato calls made by swimming or preening birds.
Habitat. Inhabits permanent or ephemeral wetlands, usually freshwater but sometimes brackish or saline: swamps, creeks, rivers, lagoons and estuaries. Also occupies artificial wetlands such as reservoirs, farm dams, and ornamental ponds and lakes in parks and gardens. Requires open water, which usually has fringing cover such as reeds, rushes and grass, and often has floating, emergent or aquatic vegetation; however, waters choked with water hyacinth (*Eichhornia*) are avoided. Occasionally frequents rubbish dumps and polluted water. Seldom found far from wetland edge, except when foraging in surrounding short vegetation. Uncommon on saline and ephemeral waters; rarely in mangroves.
Food and Feeding. Vegetable matter, including algae, and vegetative parts, seeds and fruits of plants of: Azollaceae, Hydrocharitaceae, Potomogetonaceae, Lemnaceae, Poaceae, Typhaceae, Polygonaceae, Portulacaceae, Solanaceae and Nymphaeaceae. Also worms, molluscs, arachnids, insects and their larvae (Odonata, Orthoptera, Hemiptera, Coleoptera, Lepidoptera and Hymenoptera), amphibians, fish, carrion, bread, and droppings of gulls and ducks. Diurnal; forages in open water and among floating vegetation, usually within 100 m of cover; also on adjacent land; often on grass and herbfields near water; rarely among tall terrestrial vegetation. Gleans and pecks on ground or low vegetation; while swimming gleans from surface and upends for 2-7 seconds, with tail and legs above water, taking food up to 30 cm below surface; does not dive. Sometimes chases insects; rarely stretches up on toes to take food; sometimes pins food item to ground with foot.
Breeding. Sulawesi, possibly Apr, downy young Mar; Seram, juvenile, May; New Guinea, small young May-Jun; Australia, Aug-Mar. Territorial when breeding. Simultaneously promiscuous, forming breeding groups of 2-7 apparently unrelated birds; individuals sometimes switch groups between seasons. Within group, all males copulate with all females. All group members defend territory, build nests, incubate, and care for young; older siblings sometimes help to care for young. Nest usually built up to 180 cm above water (occasionally on ground) in grass tussocks, reeds (especially *Typha, Phragmites*), rushes, bushes or trees; also on water-lilies, floating in clear water, and in stumps or hollow logs; recorded building inside metal drum and wire netting. In addition to egg-nest, may build 1-2 false nests, abandoned before completion; 1-2 brooding nests built after eggs hatch. Nest a bulky platform or shallow cup of reeds, rushes, twigs, bark, leaves and waterweed; external diameter 25-30 cm; bowl 15-20 cm wide, 6-8 cm deep. Eggs 5-18 (mean 8); large clutches probably from 2 or more females; laying irregular for first few days, then daily; in Australian study, one egg was laid per day by each female in group until clutch of 5-8 per female complete; incubation 19-24 days; hatching asynchronous, within 1-5 days; chick has black down, tipped silver on throat and neck, bill red with yellow base, skin of crown orange-brown or red, skin round eye bright blue, skin on leading edge of wing orange-yellow; chicks semi-precocial and nidifugous; leave nest after 3-4 days; fed intensively and brooded until c. 4 weeks old, then fed less frequently until c. 9 weeks old; begin to feed independently after 3-4 weeks; fully feathered at 1 month, brown with light grey streaks on cheeks; fly at 8 weeks; post-juvenile moult possibly occurs during autumn of first year, Australia. Most birds enter breeding groups when more than 20 months old. In Australian study, early nesting groups lost 13·4% eggs per group and fledged 1·97 young per female, while late nesting groups lost 38·5% eggs per group and fledged 0·5 young per female; Australian nest record cards show overall hatching success of 55·5%. Normally single-brooded; may lay twice per season in Australia.
Movements. In Australia sedentary, nomadic or dispersive, possibly partly migratory. Apparently occurs seasonally in some areas, and also shows seasonal fluctuations in numbers, but atlas reporting rates do not suggest large-scale seasonal pattern of movement. Appears at intermittent inland waters and isolated wetlands, and immatures disperse either in autumn or after wintering in flocks. Possibly moves to areas of high rainfall or surface water, to floodwaters or abundant food sources, and away from flooded areas where vegetation destroyed and from wetlands covered with *Eichhornia*. Unlike *G. ventralis*, does not undertake large-scale irruptive movements. Moves at night. Regarded as locally nomadic in New Guinea. Vagrant to New Zealand and Lord Howe I.
Status and Conservation. Not globally threatened. In Australia, nominate race widespread and common in E and inland range is expanding: small population recently established in N Western Australia and first breeding recorded recently in some parts of W Queensland and E South Australia. First bred on Flinders I 1935 and King I 1960's; has colonized N Tasmania since 1976. Favoured by construction of artificial wetlands, but habitat losses occur through wetland drainage. Race *frontata* formerly regarded as common over most of range; present overall status uncertain, but both this race and *neumanni* are currently widespread and locally common in lowlands of New Guinea. On the five islands where sympatry with *G. chloropus* is recorded, *G. chloropus* is apparently replacing present species on Sulawesi and Sumba, while present species has not been recorded from Borneo, Flores and Sumbawa since 19th century.

119. **Lesser Moorhen**

Gallinula angulata

French: Gallinule africaine **German**: Zwergteichhuhn **Spanish**: Gallineta Chica

Taxonomy. *Gallinula angulata* Sundevall, 1851, Lower Caffraria, (= Natal), South Africa.
Monotypic.
Distribution. Senegal and Gambia E to Ethiopia, and S to N & E Namibia, Botswana and E South Africa.

Descriptive notes. 22-23 cm; male 145-164 (155) g, female 92-137 (109) g, 1 unsexed 149 g. Like small version of *G. chloropus*, but paler overall, appearing mainly grey in flight with darker wings; bright yellow bill, scarlet culmen, scarlet pointed frontal shield (rounded in *G. chloropus*); legs and feet yellow-green, sometimes green, orange, flesh or pinkish red, with no red "garter". Female has paler, browner upperparts, light grey face with black only round base of bill, silvery grey throat, and paler grey underparts, especially on belly; frontal shield smaller, duller and orange next to feathers. Immature has crown, upperwing-coverts and upperparts olive brown, greyer on mantle; scapulars and tertials edged pale buff; sides of head and neck buffy brown; chin to lower breast and belly creamy white, shading to light grey on flanks; undertail-coverts white at sides, black in centre; bill brownish yellow with dusky base to culmen; legs and feet greyish green to dull yellow-green; may breed in this plumage. Voice. Calls resemble those of *G. chloropus* and include: rapid series of clucking notes; series of subdued chuckling or pumping notes; and sharp clicking and squeaky calls. Alarm a sharp "tik" or "tek".
Habitat. Permanent and temporary freshwater wetlands, such as papyrus swamps, reedbeds, marshes with rushes and open water, ponds with water-lilies, floodplains and pans with emergent grass or sedge cover and often floating plants; rank fringing vegetation on ponds, dams, rivers and forest streams; rice fields, flooded farmland, sewage ponds and seasonally inundated grassland. Occurs at "coastal lagoons" in Ghana. Normally occupies different habitat to that utilized by *G. chloropus*, preferring temporary waters with abundant cover of emergent vegetation as opposed to permanent waters with fringing vegetation, but both species sometimes occur together. In E Africa occurs up to 2000 m.
Food and Feeding. Molluscs, insects (especially beetles), vegetable matter including seeds and flowers of reeds; also (in captivity) termites. Forages while swimming or while walking at edge of water, on floating vegetation such as lily pads, or on open mud. Usually shy, remaining in cover while foraging. Not aggressive when feeding.
Breeding. Senegal and Gambia, breeding condition Aug; Sierra Leone, Nov; Nigeria, Jul-Sept; Ghana, Jun; Gabon, Feb; Chad, Aug; Sudan, Aug; Somalia, May; Zaire, high plateau of SE, Jan-Mar, at lower altitudes possibly Apr-May; Angola, Jan, Mar; Kenya and NE Tanzania, Mar, May-Jun; Tanzania Dec-Mar; Zambia and Malawi, Jan-Mar; Zimbabwe, Dec-Apr; Namibia, Feb-Mar, probably Sept; Botswana, Feb; South Africa, Dec-Apr. Monogamous; territorial when breeding. Nest smaller and more compact than that of *G. chloropus*; pad of grass or sedges with shallow cup; placed on or up to 5 cm above water (recorded water depth 20-100 cm) in emergent grasses or sedges up to 1·5 m tall, with surrounding stems often bent down over nest and bound together to form canopy; entrance ramp of grass and sedge stems sometimes built from water to lip of cup. External diameter 15-20 cm; thickness 6-10 cm; depth of cup 2·5-5 cm. Nests usually well separated but in Nigeria 4 pairs nested in radius of 20 m. Eggs 3-9 (mean 5); incubation 19-20 days, probably by both sexes, starting before clutch complete; black downy chick has black bill with white tip and pink base, frontal shield and base of culmen pale red-brown, pale purple next to forehead, eye dark brown, legs and feet bluish grey; fledging 35-38 days. No information on parental care.
Movements. Some birds resident year round in permanently suitable habitats, but many are rains migrants. In W Africa some resident in wet S areas but in dry N areas numbers increase during rains, when birds breed, and decrease as seasonal habitats dry out. Occurs Senegal and Gambia mainly in wet season; seasonal movements in Ivory Coast; almost all records in Nigeria Mar-Sept; occurs Ghana mainly Jun-Sept; resident in Chad except in Sahel zone, where purely a rains migrant. Probable migrants found Cameroon, Nov, and Zaire (Kivu) May-Jun; migrants arrive Gabon, Nov-Dec. Present all year near Entebbe, Uganda. Occurs Kenya and NE Tanzania most months but commonest Apr-Jul; night migrants attracted to lights, E Kenya, Dec-Jan. Largely rainy season visitor in S Africa: 88% of specimens from SE Zaire to South Africa taken Dec-Apr (38% in Jan). In Zambia, largely absent Jun-Nov; night migrant found Apr. In Zimbabwe and Botswana breeds in semi-arid areas at pans and other temporary waters which disappear in dry season; occurs Botswana Oct-Jun, mainly Dec-Apr. In South Africa, occurs Transvaal Dec-May; probable migrant found Natal Feb.

On following pages: 120. Spot-flanked Gallinule (*Gallinula melanops*); 121. Black-tailed Native-hen (*Gallinula ventralis*); 122. Tasmanian Native-hen (*Gallinula mortierii*); 123. Red-knobbed Coot (*Fulica cristata*); 124. Common Coot (*Fulica atra*); 125. Hawaiian Coot (*Fulica alai*); 126. American Coot (*Fulica americana*); 127. Caribbean Coot (*Fulica caribaea*); 128. White-winged Coot (*Fulica leucoptera*); 129. Andean Coot (*Fulica ardesiaca*); 130. Red-gartered Coot (*Fulica armillata*); 131. Red-fronted Coot (*Fulica rufifrons*); 132. Giant Coot (*Fulica gigantea*); 133. Horned Coot (*Fulica cornuta*).

Status and Conservation. Not globally threatened. Widespread and locally common over much of range but, as with *Porphyrio alleni*, erratic nature of its occurrence in seasonal habitats makes numbers difficult to assess. Sometimes locally very numerous in suitable breeding habitat during seasons of good rainfall, e.g. at least 50,000 pairs thought to be present on the Nyl floodplain, N Transvaal, in early 1996, during an exceptionally wet season; concentrations of over 1000 seen on Kafue Flats, Zambia, at end of rainy season. In Ivory Coast, outnumbers *G. chloropus* in Korhogo marshes; numerous in S Cameroon; frequent in Nigeria, except SE; locally abundant during rains in Kenya, Zambia and Zimbabwe. Much habitat loss must have occurred in recent years as a result of the draining, damming and grazing of its wetland habitats, but overall effect of this is unclear.

(1980), Brosset & Érard (1986), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Hopkinson & Masterson (1984), Irwin (1981), Jackson & Sclater (1938), Lewis & Pomeroy (1989), Lippens & Wille (1976), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Penry (1994), Pinto (1983), Sclater (1906), Serle (1939b), Short *et al.* (1990), Snow (1978), Tarboton, Kemp & Kemp (1987), Urban *et al.* (1986), Verheyen (1953), White (1945).

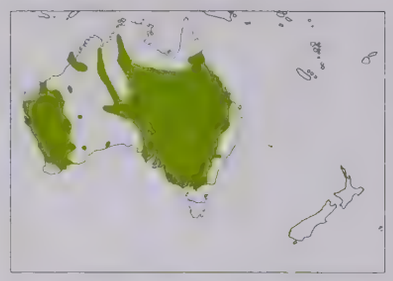
120. **Spot-flanked Gallinule**

Gallinula melanops

French: Gallinule à face noire **German**: Maskenpfuhlhuhn **Spanish**: Gallineta Pintada
Other common names: Little Waterhen

Taxonomy. *Rallus melanops* Vieillot, 1819, Paraguay.
Sometimes placed in *Porphyriops*. Three subspecies recognized.
Subspecies and Distribution.
G. m. bogotensis (Chapman, 1914) - E Andes of Colombia.
G. m. melanops (Vieillot, 1819) - E Bolivia and Paraguay, E & S Brazil to extreme NE Argentina and Uruguay.
G. m. crassirostris (J. E. Gray, 1829) - Chile and Argentina, except extreme S.

Descriptive notes. 22-30 cm; 1 unsexed 154 g. Distinctive gallinule, in shape resembling more a large *Porzana* crake than *Gallinula*; black face, grey and olive body, flanks heavily spotted white, prominent white undertail-coverts; iris red, bill stout and lime green, frontal shield green to pale bluish green, legs and feet greenish. Unique in genus in having lobed toes. On water appears flat-backed with scarcely raised rear end. Sexes alike. Shield may become duller in non-breeding season. Immature not described. Juvenile uniform olive brown, paler below and with rather faint flank spots. Races separated on colour of axillaries, white in *bogotensis*, barred in others; and size, *crassirostris* smaller than nominate, with thicker bill (variable). Voice. Common call is hollow cackling, resembling sudden burst of hysterical laughter, the notes beginning loud and long and becoming brief and hurried as they die away. Calls mainly in evening.
Habitat. Ponds, ditches, marshes, lagoons, and lake margins with often extensive floating-leaved vegetation; also wet savannas, and said to frequent dense reeds and rushes along rivers. Occurs in temperate zones; inhabits lowlands of Argentina up to 750 m; in E Andes of Colombia, occurs at 2000-3000 m.
Food and Feeding. Food not described. Feeds mostly by swimming, picking food from floating vegetation or sometimes from water; seldom walks on marsh vegetation or on land. Normally conspicuous and easily seen.
Breeding. Colombia, Feb and Jun, but also breeds in other seasons; Chile, Oct-Nov (spring); SE Brazil, season prolonged, feathered young seen with adults from mid-Oct to Mar; Argentina, Oct-Jan. Nest built among reeds or on damp ground, slightly above water rather than floating; built of dry rushes, which are also used to form half-dome. Eggs 4-8; downy young described as blackish brown. No other information.
Movements. None recorded, but at Cape San Antonio, E Argentina, birds were first seen in Sept and were gone by late May. Regarded as resident in SE Brazil.
Status and Conservation. Not globally threatened. Locally common in SE Brazil, widespread in SW Brazil, Paraguay, E Bolivia and lowlands of N & C Argentina, and thought to be spreading southwards. Race *bogotensis* has small range in Colombia, but is apparently locally common, e.g. at Parque La Florida, near Bogotá.



Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Contreras *et al.* (1990), Fjeldså & Krabbe (1990), Forrester (1993), Hayes (1995), Hellmayr & Conover (1942), Hilty & Brown (1986), Johnson (1965b), Klimaitis & Moschione (1987), Meyer de Schauensee (1982), Narosky & Yzurieta (1987), Olrog (1984), de la Peña (1992), Pinto (1964), Remsen & Traylor (1989), Sick (1985c, 1993), Varty *et al.* (1986), Weller (1967).

121. **Black-tailed Native-hen**

Gallinula ventralis

French: Gallinule aborigène **German**: Rotfuß-Pfuhlhuhn **Spanish**: Gallineta Patirroja

Taxonomy. *Gallinula ventralis* Gould, 1837, Swan River, West Australia.
In past sometimes placed in genus *Tribonyx*; although most appropriately retained in *Gallinula*, may merit separate subgenus along with *G. mortierii* on basis of morphological features. Monotypic.
Distribution. Australia.
Descriptive notes. 30-38 cm; male 250-530 (412) g, female 322-405 (364) g; wingspan 55-66 cm. Large, thickset rail with vertically fanned black tail, black undertail-coverts, long wings, orange-yellow iris, nimble gait and somewhat bantam-like shape; gregarious; swims readily, with buoyant carriage and erect tail; these characters, and preference for foraging in groups in drier habitats, distinguish from all sympatric rallids. *G. mortierii* is much larger, flightless and appears much shorter-winged; has red iris, olive-yellow bill and grey or grey-olive legs and feet. Sexes similar, but female slightly smaller, and slightly duller and paler overall; dark band round base of bill reduced or absent and white spots on sides of belly smaller. Immature very similar to adult, but some retain smaller juvenile white flank spots; bare part colours identical to adult. Juvenile resembles adult female but has smaller white flank spots; in worn plumage is paler, with off-white lores, face, chin and throat, and paler underparts contrasting more with blackish vent and undertail-coverts; bill greenish yellow with dusky tip; iris blackish; legs and feet brownish pink. Voice. Virtually unknown. Usually silent, but both sexes have sharp "kak" of alarm and rapid, harsh, metallic cackle.

Habitat. Opportunistic, especially during influxes. Normally occurs in low rainfall areas at permanent or ephemeral terrestrial wetlands, including shallow lakes, swamps, pools, floodplains and flats of rivers and creeks, and inundated depressions; favours fresh or brackish waters but often on shallow and more saline drying ephemeral wetlands; rarely in dry *Banksia* woodland, and at mangroves and tidal pools. Habitat often characterized by dense clumps of lignum, canegrass, or scrub; sometimes sparsely wooded. Also occurs at artificial wetlands, e.g. dams, margins of reservoirs, sewage ponds; in pasture, crops or fallow lands. May occur in urban areas, e.g. streets, gardens, parks, golf courses and racecourses; and in unusual situations such as arid country, sandhills, undulating hills and valleys, coastal flats, and among samphire and coastal shrubs. May occur far from water.
Food and Feeding. Takes seeds, plant material and invertebrates (especially insects). Plant food includes grain, seeds of *Polygonum*, *Triticum* and *Hordeum*, young vegetables and cereal crops, fodder crops, fresh green growth of annuals, aquatic plants, and drying apricots; invertebrate food includes molluscs, and adult and larval insects (Orthoptera, Coleoptera, Lepidoptera, and Hymenoptera in form of ants). Diurnal; forages gregariously or in pairs; feeds at grassy or muddy wetland margins, on open ground near wetlands, in pastures and crops, and in scrub and sand dunes; sometimes feeds with domestic fowl and at piggeries. Gleans from ground, alternately running and stopping in order to disturb insects. Also feeds from surface of water and submerges head and shoulders.
Breeding. E & S Australia, usually Aug-Dec, but timing influenced by rainfall, especially after drought, when may breed any month; in SW, Jun-Nov; in SE breeds after large influxes, continuously through winter and summer; breeds opportunistically, often soon after arrival following heavy rain, or as water dries up after flooding; laying time correlated with peak rainfall + 2-3 months. Social organization unclear; on existing evidence, appears monogamous, and territorial when breeding; often nests in colonies. Nest usually well concealed low in dense vegetation, such as clumps of grass, reeds, bushes, and herbage; also on tree stump, in tree fork or branches, on debris on log in water, in shallow depression in ground, in wooden box in tree, and under wire fence enclosure. Nest cup-shaped, of any available vegetation, including lignum, reeds, twigs, leaves, grass and bark; often with partial roof of woven stems; sometimes with approach ramp of broken reeds; external diameter 26 cm, depth 10 cm; height above ground 0-80 cm. Usually 5-7 eggs (4-12); larger clutches possibly from 2 females; laying probably synchronous in large colonies where arrival virtually simultaneous; incubation probably begins before clutch complete, period unknown; hatching asynchronous but probably within 24-48 hours; chicks precocial and nidifugous; black downy chick has greenish sheen, colour fading to black-brown on body, bill black with large white egg-tooth, pink basal third of upper mandible and narrow white or grey central saddle, iris blackish, legs and feet grey-black; chicks remain in nest for unknown time after hatching; timing of chick development not recorded, and no information on parental care; date of post-juvenile moult presumably depends on hatching date, recorded Jan-Apr, but birds with fresh plumage and no moult collected May and Jul.
Movements. May make regular seasonal movements: reported as regular visitor in extreme SW, and reporting rates in N increase in summer; however in some areas present at most times of year. Dispersive and highly irruptive; since 1833 irruptions have occurred on average once every 2·7 years. Irruptions probably associated with favourable breeding conditions in N allowing build-up of numbers, followed by harsh conditions such as drought and decreasing food supplies which force birds to leave interior. Irruptions sometimes characterized by sudden appearance and disappearance of large numbers of birds over period of as little as 12 hours. Movements often linked with rain: often appears after rain and after cyclonic disturbances; also claimed to appear before rain actually falls; possibly moves in response to cloud banks. May move into flooded areas and areas with lush green growth, and away from areas subjected to drying-out, drought or hot weather. During irruptions possibly disperses in all directions, but in Queensland may move towards coast. Possibly moves back to normal range after rainfall. May move at night, and can fly long distances. Vagrant to Tasmania (3 records) and New Zealand (4 records); these and mainland vagrant occurrences often coincide with irruptions.
Status and Conservation. Not globally threatened. Generally widespread inland S of 20° S and W of Great Dividing Range, with scattered records from coastal and sub-coastal regions. Australian Atlas records no breeding N of 22° S. Locally common; wide fluctuations in numbers recorded, large concentrations of 10,000-20,000 birds recorded during irruptions. Annual indices of relative abundance, obtained in 1983-1989 and covering wetlands in c. 12% of land area in E Australia, were between 2222 and 25,424 (61-100% of total numbers were counted). Irruptions more frequent 50-100 years ago; lower frequency in recent years possibly because of reduced extent of breeding grounds following drainage of swamps and control of flooding on inland rivers. During irruptions, causes damage to crops and vegetable gardens by trampling and eating plants, and may pollute water supplies. Artificial habitats are often used, especially during irruptions.

122. **Tasmanian Native-hen**

Gallinula mortierii

French: Gallinule de Tasmanie **German**: Grünfuß-Pfuhlhuhn **Spanish**: Gallineta Tasmania

Taxonomy. *Tribonyx mortierii* Du Bus de Gisignies, 1840, Tasmania.
Although most appropriately retained in *Gallinula*, may merit separate subgenus along with *G. ventralis* on basis of morphological features. Monotypic.
Distribution. Tasmania.
Introduced to Maria I (off E Tasmania).
Descriptive notes. 42-51 cm; male (mean) 1334 g, female (mean) 1251 g. Large, thickset, flightless rail, rather bantam-like, with long, narrow tail, and stout bill and legs; conspicuous, active, noisy, demonstrative and aggressive; walks with short wings partly drooped and tail constantly jerked up and down or carried erect; runs very swiftly with tail erect, opening wings to balance. *G. ventralis* much smaller and longer-winged, with dark area round base of bill, white spots on sides of belly sometimes covering rear flanks, no pale tips to upperwing-coverts, orange-yellow iris, pale green bill with red base to lower mandible, and pinkish red legs and feet. Sexes alike. Immature like adult except for narrower juvenile remiges. Juvenile duller and paler overall; as plumage becomes worn, white patch

develops on lores and buff tips show from back to uppertail-coverts; feathers of breast and belly have whitish tips; bare parts as in adult, but bill initially dusky. Voice. Characteristic aggressive call of pairs is loud, rasping, antiphonal "see-saw". Also various grunts, a repeated click call, sharp and harsh alarm calls, and screaming calls when chased or attacked. Noisy early in morning and in evening; also calls at night.

Habitat. Open pasture, grassland, crops (newly sown cereals or legumes) and other cleared land round permanent or seasonal freshwater wetlands which include marshes, lakes, dams, creeks, rivers and streams; rarely round saline wetlands. Grassland may be lightly timbered or infested with alien weeds; usually frequents wetland areas with abundant cover of rushes, reeds, sedges, tussocks, bracken or willows for shelter and nesting. Occasionally enters adjacent woodland, or penetrates forest along tracks and in clearings. Occurs throughout agricultural areas, especially where farming less intense; absent from heath dominated by button-grass in SW. Requires short-grazed pasture all year for foraging; currently dependent on swards maintained by introduced species (rabbits, sheep and cattle); swards formerly maintained by grazing marsupials and by fire. Always breeds near water.

Food and Feeding. Mostly seeds and leaves of: Poaceae, Cyperaceae, Restionaceae, Juncaceae, Polygonaceae, Portulaceae, Caryophyllaceae, Brassicaceae, Rosaceae, Fabaceae, Geraniaceae, Thymelaceae, Apiaceae, Epacridaceae, Primulaceae, Convolvulaceae, Boraginaceae, Scrophulariaceae, Plantaginaceae, Rubiaceae, Asteraceae and Hydrocharitaceae; also cereal crops; diet varies with availability of plant species. Also takes a few insects (Orthoptera, Coleoptera, Diptera and Lepidoptera); in captivity eats meat and fish. Herbage eaten most in winter and spring, seeds and insects in summer. Young chicks given worms, insects and tadpoles as well as plant material; by 14 days of age, diet as adult. Diurnal; forages on ground in pastures and paddocks; also on exposed mud. Gleans and pecks at ground and seedheads; grasps herbage and pulls seeds off with tip of bill; in orchards takes fruit from ground or low branches, sometimes hopping onto branches; chases flying moths. A secondary grazer, requiring primary grazers to maintain suitable habitat.

Breeding. Jul-Jan, usually Aug-Nov; determined by rainfall, as dependent on fresh young plant growth. Monogamous or polygamous, usually polyandrous; permanently territorial in groups of 2-17 birds consisting of 2-5 breeding adults, plus young usually up to 2 years old. Breeding unit usually adult pair, or trio of 2 males (often brothers) and 1 female; rarely has 2 females (sisters). Adults normally associate for life. All males perform copulations. Sex-ratio biased towards males. Adults share all territorial and breeding duties; young of previous year sometimes help with breeding duties; first-brood young sometimes feed and brood second-brood chicks. Nest a bulky woven cup of grass, reeds or herbage, well concealed in tall, thick vegetation such as rushes, reeds, sedges, tussocks, ferns, prickly bushes, occasionally thistles. Built 10-120 cm above ground or over water, almost always on edge of stream, dam, lagoon or pond; sometimes under overhang or in hole in creek bank; concealed overhead with woven stems; entrance leads towards water. Also constructs 1-7 brood nests after eggs hatch; usually in exposed location and often untidier and bulkier than egg-nests. Usually 5-8 eggs (3-9), laid at daily intervals; incubation 19-25 days (usually 22); eggs normally hatch within 48 hours; downy chick black (fading to dark brown), bill black with large white egg-tooth, pink base to upper mandible, and narrow lavender saddle, iris black, legs and feet grey-black; chicks semi-precocial and nidifugous; leave nest 1-2 days after hatching; become self-feeding after 1-2 weeks but fed for 8 weeks; tended closely for 3-4 weeks and then less frequently until 6 weeks old; usually remain with parents until 9-15 months; post-juvenile moult occurs before first winter. Able to breed in first year. Hatching success 89%; survival of young to 4 months 46% in adult pairs and 61% in trios; survival higher in adult groups than first-year groups. Often rears 2 broods per season, sometimes 3.

Movements. Sedentary, but some groups recorded as disappearing in summer. Many young disperse from natal area at end of first year, but on Maria I 20-30% of young were still in natal territories at end of 2nd year. Movements of up to 15 km recorded; once 40 km.

Status and Conservation. Not globally threatened. Distribution has not changed substantially in recent past, although has expanded into newly opened land. Introduced to Maria I in 1969. Has benefited from introduction of rabbits as well as clearance of wooded land for grazing and crops, and construction of artificial wetlands. Road construction may provide corridors for range expansion. Very numerous, despite some local declines. Drastic decline near Geeveston, S Tasmania, in 1989, thought to be result of disease. Decline reported in Midlands after introduction of myxomatosis and consequent reduction of rabbits; recent spread of rabbit calicivirus on Australian mainland, if extending to Tasmania, could have similar effect. Not protected: traditionally regarded as agricultural pest: claimed to trample, graze and foul pasture and crops; most claims unsubstantiated, but species may reduce sprouting oats by up to 8%. Declared vermin in 1950, and thousands were killed in 1955-1958; still controlled by shooting and round-ups. Attacked by feral cats and dogs. Killed by road traffic; appears particularly susceptible on elevated sections of roads. Formerly occurred on mainland Australia (SE Queensland to Victoria and SE South Australia); thought to have become extinct 20,000-12,000 years ago during a period of severe aridity; however recent finding of remains only 4700 years old suggests that final disappearance coincided roughly with arrival of dingo (*Canis familiaris dingo*). In Tasmania survives predation by cats as well as native species such as Tasmanian devil (*Sarcophilus harrisi*).

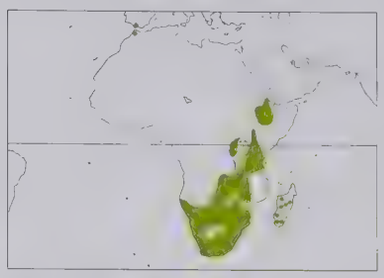
Genus *FULICA* Linnaeus, 1758



123. **Red-knobbed Coot**

Fulica cristata

French: Foulque à crête **German**: Kammbläßhuhn **Spanish**: Focha Moruna
Other common names: Crested Coot

Taxonomy. *Fulica cristata* Gmelin, 1789, Madagascar.
Forms superspecies with *F. atra*, *F. alai*, *F. americana*, *F. caribaea*, *F. leucoptera* and *F. ardesiaca*. Monotypic.

Distribution. S Spain and N Morocco; Ethiopia, Eritrea, Kenya and Uganda S through Rwanda, Burundi, E Zaire and Tanzania, W to Angola and S to South Africa; also Madagascar.

Descriptive notes. 35-42 cm; male 770-910 g, female 455-790 g, unsexed 363-1236 (737) g; wingspan 75-85 cm. Differs from *F. atra* in overall slightly darker appearance, no white tips to secondaries, rounded projection of loral feathering between bill and shield, red knobs at top of frontal shield. Sexes alike, but female smaller. Non-breeding adult has small knobs (often very hard to see), red-brown iris, duskier tinge at sides of bill, and dull slate legs and feet. Immature like adult but feathers of chin, throat, breast and underparts fringed white; upperparts often have dusky olive tinge. Juvenile has crown and upperparts dark brown with olive tinge, sides of head, neck and flanks dark olive brown mottled off-white, lores, chin and throat white, and underparts pale ash grey; iris grey-brown to dark brown; bill dull grey; legs and feet dark grey. Voice. Vocabulary wide. Commonest calls: sharp, shrill "kik" or "krik"; low, reedy "kek"; shrill, trilled "krrt"; double clucking note; and deep, "koop" or "kup". Also has hollow "hoo"; deep, nasal, frog-like croak; drawn-out "ker"; "coo-dooc"; metallic ringing "croo-oo-k" or snorting "tcholf" of alarm; and high-pitched, nasal, repeated "hue" group alarm call.

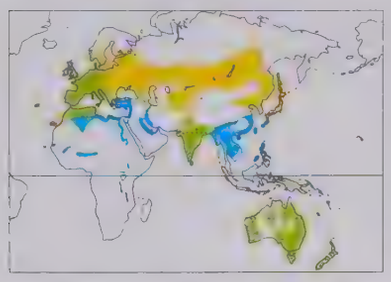
Habitat. Chiefly frequents open fresh water of lakes, lagoons, ponds, permanent and temporary dams and vleis, and floodplains. Also occurs in swamps with reeds and papyrus, and at sewage ponds; sometimes found on rivers and tidal lagoons but generally prefers still water. When breeding, frequents waters with fringing or emergent vegetation, but at other times may occur on completely open waters; requires submerged aquatic vegetation for food. Habitat very similar to that of *F. atra*, which it replaces over most of range. Occurs up to 3000 m in E Africa.

Food and Feeding. Omnivorous; takes mainly aquatic vegetation, especially non-rooting submerged or floating plants and including filamentous algae (Chlorophyceae), water plants such as *Marsilia*, *Aeschynomene fluitans* (stems, flowers, fruits and aerial roots), *Polygonum limbatum* (stems, leaves and fruits), *Najas pectinata* (stems and leaves), *Potamogeton pectinatus*, *Ruppia maritima* and *Eichhornia crassipes*, grass (e.g. leaves of *Panicum repens*) and seeds. Also eats molluscs (Gastropoda), crustaceans and arthropods (including insects), and occasionally carrion (e.g. ducks washed up on shore). Feeding techniques similar to those of *F. atra*, with emphasis on aquatic modes such as diving down and pulling up underwater vegetation; diving ability better developed than in *F. atra*; S of Sahara feeds mostly in water. Also feeds from surface, either while swimming or when standing in shallow water. Feeds much less often on land than does *F. atra*, but grazes short grass near water, especially when food scarce (bill has shearing edge adapted to grazing). On Kafue Flats, Zambia, grazes where vegetation trampled by lechwe (*Kobus leche*); in Natal, overgrazes green crops planted near dams.

Breeding. Spain and N Africa, May; Morocco, Feb-Sept; Ethiopia, Apr-Jul, Sept-Dec; Kenya and NE Tanzania, all months; W Kenya and Uganda, all months except Feb; Zambia, Apr-Jul; Malawi, Jun-Jul; Zimbabwe, Jan-Sept; South Africa, all months; Madagascar, Dec-May. Gregarious outside breeding season but monogamous and territorial when breeding; some birds apparently also paired in winter flocks. Nest a bulky platform of leaves and stems of water plants; usually with ramp at one side; in shallow water, or floating and anchored to vegetation, built either in open water or within emergent vegetation, with no attempt at concealment. Both sexes build, occasionally with help of immatures; building renewed if platform settles or water rises; material also added during incubation. Builds many "false nests", used as resting platforms. Normally 5-7 eggs (3-11), laid at daily intervals; 2 females known to have laid in 1 nest; incubation 18-25 days, by both sexes; hatching asynchronous; downy chick ashy or grey-black, paler below, with golden yellow down on neck, bare skin of crown pink and blue, down of mantle and back with white tips, iris brown, bill red with narrow white subterminal band, legs and feet pale grey-green with pink tinge; chicks precocial; leave nest after 1 day; able to dive soon after hatching, suggesting capability for independent feeding at early age; fed and cared for by both parents, sometimes with help of immatures from earlier brood, particularly when food and nesting habitat abnormally abundant; broods often divided between parents; fledging 55-60 days. In South Africa, 42% of nests produced fledged young. Often only 1 brood, unless conditions very favourable; possibly double-brooded in Morocco.

Movements. Mainly sedentary; also nomadic and opportunistic. Local movements evident from degree of winter flocking, e.g. in Morocco, and from fluctuations in numbers on permanent waters throughout range. Erratic winter wandering beyond normal range reported in past from Morocco and Spain; in 19th century, when range extended to Algeria and Tunisia, wandered in winter to Portugal, S France, Sardinia, Sicily, Italy, and Malta. Flocks in Africa often sedentary on suitable waters but birds may move considerable distances outside breeding season, e.g. up to 1070 km in South Africa. At Barberspan, South Africa, factors influencing fluctuations include rainfall, water level and availability of favourite food; ringing recoveries show mean distance travelled from Barberspan 270 km, 70% recovered within 300 km; longest distances travelled Jan-Apr, when population drops during rainy season. Birds ringed Rondevlei, South Africa, disperse up to 400 km; birds ringed in Ngorongoro Crater, Tanzania, recovered at Eldoret and Naivasha, Kenya. On Kafue Flats, Zambia, present Feb-Oct, most Mar-Jun. Wanders to S Somalia.

Status and Conservation. Not globally threatened. Range has decreased in both Europe and N Africa; now close to extinction in Europe; reasons for decline not clear. Locally common to abundant in sub-Saharan Africa, including Ethiopia, E Africa (L Victoria, L Naivasha and many highland dams and lakes), Zimbabwe, Namibia and Botswana; sometimes up to 27,000 birds at Barberspan and over 30,000 at de Hoop Vlei, South Africa; formerly common on Kafue Flats, Zambia. Uncommon in Angola, occurring mainly on coastal plain, and in Mozambique. In some areas, especially in South Africa and Zimbabwe, has benefited from the proliferation of farm dams and other artificial water bodies, especially as can breed on very small waters.



Bibliography. Benson & Benson (1975), Cramp & Simmons (1980), Dean (1980), Dean & Skead (1979b), Douthwaite (1978), Dowsett & Forbes-Watson (1993), Étchécopar & Hüe (1964), Fernández-Palacios (1994), Fernández-Palacios & Raya (1991), Forsman (1991), Ginn *et al.* (1989), Hockey, Underhill & Neatherway (1989), Jackson & Sclater (1938), Keijl *et al.* (1993), Langrand (1990), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Milon *et al.* (1973), Pinto (1983), Sánchez (1992), Short *et al.* (1990), Skead (1980), Snow (1978), Stewart & Bally (1985), Tarboton, Kemp & Kemp (1987), Urban *et al.* (1986), Watson *et al.* (1970), Winterbottom (1966), Wood (1975).

124. **Common Coot**

Fulica atra

French: Foulque macroule **German**: Bläßhuhn **Spanish**: Focha Común
Other common names: (Eurasian/Black) Coot

Taxonomy. *Fulica atra* Linnaeus, 1758, Sweden.
Forms superspecies with *F. cristata*, *F. alai*, *F. americana*, *F. caribaea*, *F. leucoptera* and *F. ardesiaca*. Four subspecies recognized.
Subspecies and Distribution.
F. a. atra Linnaeus, 1758 - Europe, N Africa, Azores and Canaries E through C Asia to Japan and S to Indian Subcontinent and Sri Lanka; winters S to W & NE Africa, SE Asia and Philippines.
F. a. lugubris S. Müller, 1847 - E Java (formerly?) and NW New Guinea.
F. a. novaeguinea Rand, 1940 - C New Guinea.
F. a. australis Gould, 1845 - Australia, Tasmania and New Zealand.

Descriptive notes. 36-39 cm; nominate male 610-1200 (902) g, female 610-1150 (770) g; race *australis* male 481-660 (568) g, female 476-609 (552) g, unsexed 305-725 (511) g; wingspan 70-80 cm in nominate, 56-64 cm in *australis*. Distinguished from *F. cristata* by greater contrast between black head and neck and somewhat paler body, white tips to secondaries (nominate and *lugubris*), lack of red knobs at top of frontal shield, and pointed projection of loral feathering between bill and shield. Differs from *F. americana* in colours of bill, shield, legs and feet, dark undertail-coverts, and less contrast between dark head and paler body. Sexes alike, female averages smaller. Immature like adult but upperparts more washed with olive brown and feathers of throat, cheeks and underparts with broader white tips, giving variably mottled appearance; attains adult bare part colours between autumn and spring. Juvenile has crown, hindneck and upperparts dark brown to dark olive brown, rest of head and neck mixed dark grey and white (whitest on throat), flanks olive brown, breast whitish and belly to vent white with grey suffusion; iris dark grey to pale brown; bill dusky grey, pink towards tip in *australis*; legs and feet grey. Races separated on: amount of white on tips of secondaries, much reduced or absent in *novaeguinea* and *australis*; size, nominate larger than *lugubris*; and underpart colour, darker in *novaeguinea* than *australis*; *novaeguinea* has deeper black head and neck. VOICE. Combat call of male a sharp, explosive "pssi", of female a short, croaking "ai"; alarm call of male a sharp variant of combat call, of female a rapid sequence of "ai-oeu" sounds. Typical contact call a single, short "kow", "kowk", "kup", or sharper "kick"; sometimes 2 notes combined, e.g. "kick-kowp"; male also has mechanical "p" or "ta" calls and female a high, short, falsetto "oeu". Calls often metallic, resonant, querulous or explosive, particularly sharp and high when birds agitated. Often noisy.
Habitat. Mainly large, still or slow-moving waters. Inhabits lakes, pools, ponds, reservoirs, barrages, gravel pits, canals, drainage channels, dykes, rivers, creeks, oxbow lakes, open marshes, floodlands and lagoons; also lakes and pools in towns, and salt-pans and clay-pans. Exploits temporary pools and seasonal marshes for breeding. Prefers fairly shallow waters with room to dive and with muddy bottom well furnished with marginal, emergent, floating or submerged vegetation; requires some open water but when breeding not normally far from banks or from emergent or floating vegetation. In winter will resort to quiet estuarine or inshore sea waters, and often occurs on open water of lakes and reservoirs. Avoids small pools and streams; sometimes occurs on fast rivers where suitable vegetation flourishes. Makes little use of cover, either in water or on land. Normally occurs in lowlands, but up to 1000 m in Europe, 2000 m in Tadjikistan and Iran, 2500 m in Kashmir; occurs up to 3500 m in New Guinea, where resident at montane lakes.
Food and Feeding. Omnivorous, but primarily vegetarian. Eats mainly vegetative parts and seeds of aquatic and sometimes terrestrial plants, including algae (*Chara*, *Vaucheria*, *Cladophora*, *Spirogyra*, *Ectocarpus* and *Nostoc*), vegetative parts of *Potamogeton*, *Ruppia*, *Zannichella*, *Elodea*, *Zostera*, *Vallisnaria*, *Lemna*, *Ceratophyllum*, *Ranunculus*, *Polygonum*, *Myriophyllum*, *Najas*, *Scirpus*, *Typha*, *Phragmites*, *Phalaris*, *Sparganium* and grasses; also seeds of *Ruppia*, *Sparganium*, *Potamogeton*, *Carex*, *Nymphaea*, grasses and cereals. Takes plant debris drifting on water surface. Animal food eaten includes worms, leeches, molluscs, shrimps, adult and larval insects (especially Diptera, Trichoptera, Odonata, Lepidoptera, Coleoptera and Hemiptera), spiders, fish, fish eggs, frogs, birds and their eggs, and small mammals. Takes fish food and duck food. Employs diverse foraging methods (see page 126), including scraping algae from hard substrates, gleaning, dabbling, upending, diving and grazing. Feeds in flocks on land, grazing near water, especially when wind causes high waves. Kleptoparasitizes conspecifics as well as swans and ducks. Large food items are shaken to break them up, or may be chopped up by bill on ground. Diurnal, but often active at night on moonlit nights or on floodlit waters.
Breeding. Europe, Feb-Sept, mostly Mar-Jul; Azerbaijan, Apr-Jun; N Africa, Mar-Jun; Kashmir and N India, May-Sept; S India, Nov-Dec; Australia, mainly Aug-Feb, also other months; New Zealand, Sept-Feb. Gregarious, but monogamous, territorial and pugnacious when breeding. Some birds territorial all year where climate and food availability permit; pair-bonds may sometimes be retained in flocking and migratory populations. Nest almost always in shallow water, normally in emergent vegetation but sometimes in open; normally resting on bottom or trampled foundation of vegetation, occasionally floating; artificial platforms, rafts, tree stumps, tree forks, or islands sometimes used. Receding water level can leave nest some way from water. Nest bulky, of dead and live stems and leaves, sometimes also twigs, bark and roots; external diameter 25-55 cm, height 8-35 cm; cup diameter 16-30 cm, depth 6-13 cm; nest may be built up if water level rises. Both sexes build; brood platforms for family also built by male. Usually 6-10 eggs (1-14), larger clutches may be laid by 2 females; eggs laid daily, sometimes at intervals of 1-2 days; up to 3 replacements laid after egg loss; incubation 21-26 days; by both parents; hatching asynchronous; black downy chick has orange to yellow tips to down of neck and side of head, wings and mantle, and red tips on lores and around shield, iris hazel to grey-brown, bare skin of crown red and blue, bill and shield red, bill white distally and black at tip, legs and feet slate grey; chicks precocial and nidifugous; brooded on nest for 3-4 days; fed and cared for by both parents, which may divide brood temporarily or permanently; older young help feed chicks of later broods; young begin to dive at 3-5 weeks; become self-feeding at 30 days; fledging 55-60 days; fed by parents for up to 2 months; independent at 6-8 weeks; fly at 8-11 weeks; remain in parental territory for up to 14 weeks, possibly helping in territory defence. Age of first breeding 1 year (usually older). May have 2 broods per season.
Movements. Present all year in warm and temperate regions, although not necessarily resident, but mainly migratory in N Eurasia under influence of continental climate. In W Palearctic, N populations winter from North Sea, Baltic, EC Europe, Black and Caspian Seas, Iraq and Arabia S to Senegal, Mali, N Nigeria, S Niger, WC Chad, desert oases in Morocco and S Algeria, and N Sudan (along R Nile). Movement through continental Europe on broad front, W to S, and coastal movement via Baltic brings birds from as far E as Moscow into North Sea area; S movements occur Sept-Nov and return passage Mar-May. Crosses Sahara on broad front, reaching W African wintering areas Nov and departing Mar-Apr. Birds wintering Black and Caspian Seas S to Iraq are presumably from former USSR; movements noted Azerbaijan Sept-Dec and Feb-Apr. Moult migrations occur; little studied but some involve non-breeding adults, while moulting concentrations occur Jun-Sept in Denmark, Bavaria, Bodensee, Black Sea, and probably much more widely. Further E in Asia, N populations winter on Indian Subcontinent, with N passage observed in Afghanistan and Pakistan, Feb-May; also in SE Asia S to Thailand, Cambodia, Vietnam and Philippines (recorded Nov-Mar); and E to S Japan and Ryukyu Is, stragglers reaching Northern Mariana Is. Dispersive in Australia, where large changes in abundance occur, possibly in response to weather conditions and changes in water levels, as birds move to flooded areas, breed and then depart; such patterns may not be seasonal, but seasonal changes occur in some areas; in New Zealand, numbers may fluctuate seasonally. Probably often crosses Bass Strait and Tasman Sea; also crosses other oceans, and recorded occasionally on Norfolk I, Lord Howe I and Macquarie I. Birds seen irregularly in New Guinea lowlands may be vagrants from Australia. Accidental in Alaska, Labrador, Newfoundland, Greenland, Iceland, Spitsbergen and Faeroes.
Status and Conservation. Not globally threatened. Nominate race has expanded range in Europe since late 19th century; marked population fluctuations in many areas due to hard winters, but has probably increased generally, aided by eutrophication, new man-made habitats, and adaptation to urban environments. In 1970's, populations of 40,000-100,000 pairs estimated for several European countries, while Jan counts for NW Europe totalled 438,000-646,000 birds, and European sector of former USSR held over 580,000 pairs in summer and 804,000 birds in winter; area of Mediterranean and Black Seas held 1,035,000-1,296,000 birds in 1969-1971 winters. Has bred in Iceland, but only very sporadically. Declining in Azerbaijan due to hunting and oil pollution. Locally common breeder in N Africa. Formerly abundant in winter, India and Pakistan; present status not clear. Uncommon and local New Guinea; increasing Japan; occurs only rarely in Borneo, Bali and Java; formerly bred in Java but no recent records. Widespread in Australia and New Zealand; locally common in Australia, counts in Victoria in 1991/92 totalling 110,000 and 131,000 birds, with populations stable. Displaced by wetland drainage but rapidly colonizes suitable artificial habitats such as dams, while in arid areas artificial wetlands act as refuges.

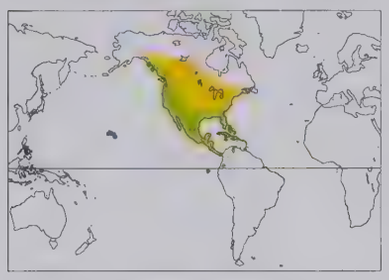
125. Hawaiian Coot

Fulica alai

French: Foulque des Hawaï **German**: Hawaiiblässhuhn **Spanish**: Focha Hawaiana

Taxonomy. *Fulica alai* Peale, 1848, Hawaiian Islands.
Sometimes regarded as a race of *F. americana*. Forms superspecies with *F. cristata*, *F. atra*, *F. americana*, *F. caribaea*, *F. leucoptera* and *F. ardesiaca*. Monotypic.
Distribution. Hawaiian Is.



Descriptive notes. 39 cm. Differs from *F. americana* in shorter wing, pale grey or bluish legs and feet, and more swollen frontal shield which extends back to crown; bill and shield white in most birds, but colour varies from bluish white to yellow to dark blood red; in c. 15% of birds shield is red and bill has broken, reddish brown to black, subterminal ring (as in *F. americana*); white undertail-coverts often not visible in swimming birds; leading edge of wing white at bend, but outermost primary has no white. Sexes alike. Immature has white throat and breast, dark bill and small frontal shield. VOICE. Chicken-like "keck-keck" calls and other clucks and creaks.
Habitat. All types of wetland, including fresh and saltwater ponds, estuaries and marshes, irrigation ditches and flooded agricultural lands.
Food and Feeding. Limited information available. Mainly vegetarian; food apparently similar to that of *F. americana*.
Breeding. Breeds throughout year, mostly Apr-Aug. Monogamous; territorial when breeding. Nest floating, usually built among robust emergent aquatic vegetation near open water and anchored to surrounding vegetation; sometimes in open water, anchored to dense algal mats, or on mats of *Bacopa* or *Paspalum*; twice recorded nesting on islands, near water. Nest platform substantial, made from buoyant stems of nearby emergent plants, particularly *Scirpus*; broader base of nests built in open water probably serves to improve stability and reduce effects of wave action. Average nesting density 1·6-12·5 nests/ha. Eggs 1-10 (mean 4·9), laid at daily intervals; replacements laid after clutch loss; incubation 23-27 days, by both parents; hatching asynchronous; black downy chick has reddish orange bristles on head; chicks precocial; details of care and development presumably similar to those for *F. americana*. Nesting success high (over 90%); hatching success averages 80%; chick mortality high. 2 broods per year occasional.
Movements. No information; apparently wanders between islands.
Status and Conservation. VULNERABLE. Resident on all main Hawaiian Is from Niihau eastward, except Lanai, with stragglers reaching as far W as Kure Atoll in NW Hawaiian Is. Suitable water bodies are scattered and very limited in area, and species has suffered from wetland destruction as result of drainage for cultivation and other development. Also, herbicides used to clear canals and drainage ditches serving sugar cane plantations may have poisoned coots directly or indirectly. When nesting, species also vulnerable to introduced predators such as dogs, cats and mongooses. Population probably fluctuates between 2000 and 4000 birds, 80% of which probably occur on Kauai, Oahu and Maui. Hunting prohibited in 1939 and species is fully protected. Management recommendations include: habitat management to promote optimum conditions, i.e. 50:50 ratio of open water and sparse emergent cover, and water depth of c. 30 cm; a better study of seasonality of breeding; more detailed studies of food requirements and breeding success; and a study of local movements.
Bibliography. Berger (1972), Byrd *et al.* (1985), Collar *et al.* (1994), Engilis & Pratt (1993), King (1978/79), Munro (1960), Pratt (1987, 1993), Pratt *et al.* (1987), Schwartz & Schwartz (1952), Stephens (1974), Udvardy (1960).

126. **American Coot**

Fulica americana

French: Foulque d'Amérique **German**: Amerikanisches Bläßhuhn **Spanish**: Focha Americana

Taxonomy. *Fulica americana* Gmelin, 1789, North America.
Sometimes considered to include *F. alai*, *F. caribaea* and *F. ardesiaca* as races; forms superspecies with these, and with *F. cristata*, *F. atra* and *F. leucoptera*. Proposed race *grenadensis* included in nominate. Two subspecies recognized.
Subspecies and Distribution.
F. a. americana Gmelin, 1789 - SE Alaska E to Nova Scotia, and S to West Indies, Nicaragua and Costa Rica; winters to W to Hawaii and S to Panama.
F. a. columbiana Chapman, 1914 - Colombia and N Ecuador.

Descriptive notes. 34-43 cm; male 576-848 (742) g, female 427-628 (560) g; wingspan 60-70 cm. Differs from American congeners in having white bill with broken subterminal chestnut or maroon ring, rather small white frontal shield with dark chestnut or red-brown horny callus at top (in breeding birds sometimes covering entire shield), yellow to orange legs and feet, red tibiae and pale blue-grey toe lobes. Differs from *F. atra* in white undertail-coverts, and greater contrast between blackish head and breast and paler mantle and flanks; secondaries have small white tips. Sexes alike, but female smaller. Immature similar to adult; legs and feet become green, and tibiae red, by spring; tarsal colour then progresses through yellow-green and yellow to become orange-red after 4 years. Juvenile dark olive-brown on crown and upperparts, pale ash grey on sides of head and body, flanks and underparts; bill and shield uniform ivory-grey with small, pale red callus, most birds attaining adult colours at c. 4 months; legs and feet blue-grey or grey-green. Race *columbiana* has longer tarsus and toes, heavier and longer bill with yellow base, larger, higher, more rounded frontal shield, darker plumage (especially on underparts) and less white on underwing-coverts and tips of secondaries. Voice. Loquacious; has variety of cackling and clucking notes, often repeated. Alarm call of male "puhlk" and of female "poonk"; under stress male also gives plaintive, crowing "puhk-cowah" or "pow-ur" and female a simpler "cooah"; aggressive male gives explosive "hic".
Habitat. Reed-fringed lakes and ponds, open marshes and sluggish rivers; also estuaries and bays. Nominate race has maximum nesting densities on well flooded, semi-permanent and persistent wetlands with good interspersion of emergent vegetation and open water; nests usually found where foundations (e.g. mats of algae) are available; uses seasonal wetlands when water levels high. Race *columbianus* has peak abundance in areas with mosaics of low *Bidens* and *Limnobium*, and open water with much submerged vegetation outside fringing reeds. Prefers fresh water but sometimes forced in winter to shift temporarily to salt water and salt-marshes on sheltered coasts or estuaries; in winter uses man-made wetlands including brackish impoundments, crayfish and catfish ponds, and coal mine sediment ponds; *Hydrilla* cover may be an important component of wintering habitat in S USA. Occupies similar niche in Nearctic to that of *F. atra* in W Palearctic. In Colombia occurs up to 1000 m and in E Andes at 2100-3250 m.
Food and Feeding. Principally aquatic vegetation, mostly submerged plants, especially *Chara* and other algae, *Potamogeton*, *Lemna*, *Myriophyllum* and *Scirpus*, but also grass, sprouting grain and waste grain. Also takes aquatic insects and molluscs (especially Trichoptera and Diptera larvae, Coleoptera and Gastropoda), more frequently during breeding season; aquatic invertebrates may constitute large proportion of diet of young chicks. Feeds from surface, immerses head and neck, dives in shallow water; sometimes upends; also grazes on land or floating matted vegetation; sometimes scavenges. Sometimes feeds in association with Canvasbacks (*Aythya valisineria*), taking rootstocks of *Potamogeton* disturbed by the diving ducks; associations with other waterfowl species also recorded. Kleptoparasitism by some duck species on coots also recorded (see page 127).
Breeding. North America, Apr-Jul (peak Apr-May), winter breeding reported in Florida; Colombia, laying peaks Jun-Jul but also lays Sept, building reported Mar; usually begins nesting within 10-14 days of arrival on breeding grounds. Gregarious, but monogamous, territorial and pugnacious when breeding; both sexes assist in territory defence. Nest a large floating pile of aquatic vegetation, usually in, and anchored to, residual emergent vegetation, preferably of *Typha* or *Scirpus* although *Carex*, *Scholochloa* or *Salix* sometimes used; nests late in season sometimes in new-growth emergents; nest usually built within 1-5 m of open water, sometimes in open, and resting on mass of old matted reeds. Both sexes build. Eggs 6-15 (3-5 in *columbiana*), laid at daily intervals; some females are intraspecific brood parasites, laying eggs in other nests before producing their own clutches; incubation by both sexes, 22-27 days, starting with 3rd-6th egg; hatching asynchronous; black downy chick greyer on underside, with blue and orange to red skin on top of head, dense yellow to red bristles round neck and red bill shading to pink distally and with black to whitish tip; chicks precocial, leave nest soon after hatching; return to nest or brood platforms for frequent brooding; cared for by both parents; fed for first 2 weeks; gradually become independent over next 3-10 weeks; juvenile plumage acquired from c. 3 weeks of age; fledging 60-70 days. Nest parasitism by Ruddy Duck (*Oxyura jamaicensis*) occurs rarely. Age of first breeding 1 year; breeding performance increases with age, especially between 1 and 2 years of age. Nest success usually over 80%; hatching success 80-100%; renesting may occur up to 4 times after clutch or brood loss. Two sequential broods occasionally raised in S parts of breeding range; elsewhere, 2nd clutch may be laid while 1st still being incubated.
Movements. Mainly migratory, especially in North America E of Rocky Mts. Many apparently migrate to larger N wetlands for post-breeding moult. Winters in Pacific and Atlantic coastal states N to British Columbia and Maryland; most winter in S USA and Mexico. Birds ringed in Alberta winter mainly in California and W Mexico; those from Saskatchewan and Manitoba mainly E Mexico to Louisiana, some reaching Caribbean islands. All populations mix in Gulf states in winter. Birds nesting more to S move furthest S in winter, e.g. 32% of recoveries of those ringed in Iowa found in Cuba. Winters throughout Central America S to Panama and possibly Colombia; small numbers reach larger Hawaiian islands in winter. Migrates at night, singly or in loose flocks, probably on broad front; birds often hit powerlines. Males and non-breeders congregate in late summer and move S ahead of females and juveniles. Autumn passage late Aug to Dec; peaks in Mississippi flyway late Oct; wintering birds present Louisiana and Mexico Oct-Mar, Costa Rica Oct-Apr, and Panama Oct to late Apr. Spring migration occurs late Feb through to mid-May; males and older birds migrate first; birds arrive on N breeding grounds from late Mar. Many cases of birds wandering N of breeding range in summer and autumn, as far as Newfoundland, Labrador, Franklin and S Greenland; vagrant to Iceland. Numbers increase in Colombia Oct-Apr, but origins of birds involved not clear.
Status and Conservation. Not globally threatened. In North America considered abundant and is a game species; annual harvest over last 3-4 decades averaged c. 8000 birds in Canada and 880,000 in USA, and has declined in recent years in both countries. North American populations have increased since breeding-ground surveys began in 1950's, although reliability of estimates unknown. Major population management requirements include: evaluation of breeding-ground and wintering-ground surveys; establishment of surveys in Mexico; updated estimates of survival and recovery rates; and assessment of possible bias in harvest surveys. Traditionally, wetland habitats have not been managed for coots but the birds appear to benefit from many waterfowl management activities; however, wetland loss has reduced potential breeding population in areas such as Iowa and Minnesota. Species's ability to pioneer new habitats enables it to take advantage of wetland restoration efforts. Sometimes regarded as an urban and agricultural pest in winter, e.g. on golf courses and in rice fields. Locally common in Panama in winter. Race *columbiana* is locally common in Colombia.

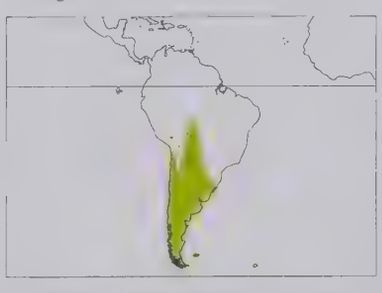
127. **Caribbean Coot**

Fulica caribaea

French: Foulque à cachet blanc **German**: Karibenbläßhuhn **Spanish**: Focha Caribeña

Taxonomy. *Fulica caribaea* Ridgway, 1884, St John, Virgin Islands.
Sometimes regarded as conspecific with *F. americana*. Forms superspecies with *F. cristata*, *F. atra*, *F. alai*, *F. americana*, *F. leucoptera* and *F. ardesiaca*. Monotypic.
Distribution. S Bahamas (N Caicos) through Greater Antilles (except I of Pines) and Lesser Antilles (S to Grenada and Barbados) to Trinidad, Curaçao and NW Venezuela. Records of birds from North American localities all refer to *F. americana*.



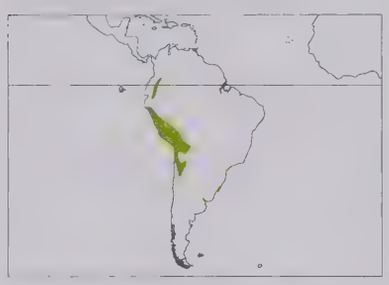
Descriptive notes. 33-38 cm. Differs from *F. americana* in having frontal shield entirely white, sometimes tinged yellow, broader, oval or elliptical; bill entirely white or with reddish brown spot near tip of both mandibles; extent of white on outer web of outermost primary and tips of secondaries very variable in both species and apparently not a distinguishing character. Undertail-coverts white; legs and feet dull olive to yellowish. Sexes alike, but female averages smaller. Immature and juvenile presumably similar to those of *F. americana*. Voice. Similar to that of *F. americana*: a variety of cackling and clucking notes.
Habitat. Freshwater lakes, ponds and marshes; also less frequently in coastal brackish lagoons. Lowlands, up to 500 m in Venezuela.
Food and Feeding. No information: presumably similar to *F. americana*.
Breeding. Poorly known; details presumably similar to *F. americana*. Virgin Is, May-Jun and Sept-Oct; season elsewhere not recorded. Eggs 4-7.
Movements. None recorded.
Status and Conservation. Not globally threatened. Formerly regarded as locally uncommon to rare throughout range; current status not clear. Much research required.
Bibliography. Anon. (1983a), Benito-Espinal & Hautcastel (1988), Biaggi (1983), Blake (1977), Bond (1985), Clark (1985), Herklots (1961), Kautesk (1985), Meyer de Schauensee (1982), Meyer de Schauensee & Phelps (1978), Raffaele (1989), Ripley (1977), Ripley & Beehler (1985), Roberson & Baptista (1988), Stockton (1978), Sykes (1975).

128. **White-winged Coot**

Fulica leucoptera

French: Foulque leucoptère **German**: Weißflügel-Bläßhuhn **Spanish**: Focha Aliblanca

Taxonomy. *Fulica leucoptera* Vieillot, 1817, Paraguay.
Forms superspecies with *F. cristata*, *F. atra*, *F. alai*, *F. americana*, *F. caribaea* and *F. ardesiaca*. Monotypic.
Distribution. Chile, E & SE Bolivia, Paraguay and extreme SE Brazil S through Argentina to Tierra del Fuego.



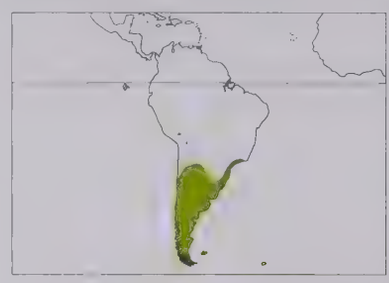
Descriptive notes. 35-43 cm; 5 females 400-500 and 607 g. Darker than *F. americana* on body; distinguished from congeners by yellow to greenish yellow bill, occasionally with a dark spot near tip, and small pale yellow to orange-yellow shield, rounded at top giving round-headed appearance; legs and feet pale sea green to yellow-green, with grey to blackish toes and joints. Some birds have predominantly bluish pink or pinkish grey bill, others have pink to light reddish shield; colour variations in Brazilian birds could be age-related. White undertail-coverts very conspicuous as bird swims away with raised tail; white line formed by broad white tips to secondaries conspicuous in flight. Sexes alike. Immature has grey-brown upperparts and paler underparts, whitish from chin to breast; brown iris, dusky olivaceous bill, greenish grey legs and feet. Juvenile dark drab grey, with white head and neck mottled dusky. Voice. Vocal, with variety of loud, hollow cackling calls and clucking notes; some calls resemble peals of laughter. Aggressive male has explosive "huc" note.

Habitat. Freshwater lagoons, river backwaters, ponds and marshes; prefers grassy or vegetation-free shores, waters with many submerged plants, or *Lemna* duckweed-covered waters. Upland breeding sites usually barren, with no fringing reeds but with much floating *Myriophyllum*. Occasionally occurs on sea, close to shore. Sometimes occurs alongside *F. armillata*.
Food and Feeding. Eats mostly aquatic weeds. Chiefly a surface feeder, but dives occasionally; pecks at surface and upends frequently. Also grazes on land some distance from marsh edges. Sometimes pulls seeds from bent-over grass-heads. Gregarious; normally seen in large flocks.
Breeding. Lowlands of C Argentina, mainly Apr-Nov; uplands, Nov-Jan; season very prolonged in Rio Grande do Sul, Brazil, where species nests throughout spring and summer. Monogamous; territorial when breeding. Nest a floating platform of rushes, green grass or other aquatic plants, often among emergent vegetation but also floating offshore on beds of aquatic plants; slight canopy sometimes built over nest. May nest alongside *F. armillata*. Eggs 10-12 (3 also recorded); black downy chick has partly naked pink and blue crown, orange tips to down of head and dense yellow bristles around neck, blood red bill with black tip, and greenish brown legs and feet; both parents feed young. No other information available.
Movements. Present all year in Rio Grande do Sul but makes considerable local movements, with most or all birds absent from some breeding areas in autumn or winter.
Status and Conservation. Not globally threatened. Formerly regarded as widespread, and common to locally abundant; recorded in flocks of thousands on large marshy lagoons of Argentine *pampas*. At present reckoned to be generally common.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Clark (1986), Contreras *et al.* (1990), Fjeldså (1983a), Fjeldså & Krabbe (1990), Friedmann (1927), Hayes (1995), Heimsath *et al.* (1993), Hellmayr & Conover (1942), Johnson (1965b), Klimaitis & Moschione (1987), Meyer de Schauensee (1982), Mosso & Beltzer (1993), Narosky & Yzurieta (1987), Olrog (1984), de la Peña (1992), Pinto (1964), Remsen & Traylor (1989), Remsen *et al.* (1985), Sick (1985c, 1993), Weller (1967), Woods (1988)

129. **Andean Coot**
Fulica ardesiaca

French: Foulque ardoisée **German**: Andenbläßhuhn **Spanish**: Focha Andina
Other common names: Slate-coloured Coot

Taxonomy. *Fulica ardesiaca* Tschudi, 1843, Lake Junín, Peru.
Chestnut- and white-fronted birds formerly treated as separate species, *F. americana peruviana* and *F. ardesiaca*, and later lumped as *F. americana ardesiaca*. Forms superspecies with *F. cristata*, *F. atra*, *F. alai*, *F. americana*, *F. caribaea* and *F. leucoptera*. Two subspecies recognized.
Subspecies and Distribution.
F. a. atrura Fjeldså, 1983 - S Colombia, Ecuador and coastal Peru.
F. a. ardesiaca Tschudi, 1843 - interior Peru, C & W Bolivia, N Chile and NW Argentina.

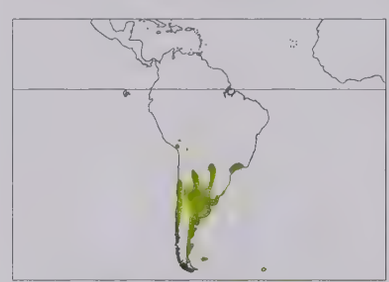


Descriptive notes. 40-43 cm. Stocky coot with large, rounded frontal shield giving round head shape; secondaries usually have white tips; undertail-coverts white to almost black; iris red to reddish yellow. Two colour morphs: red-fronted, with more solid, deep chestnut frontal shield, chrome yellow bill becoming pale yellow to green (sometimes white) near tip, and green legs and feet; and pale-fronted, with white bill, white or orange-yellow frontal shield, and slaty legs and feet. Other variants also exist: bill may be flesh-coloured, shield variably pale to primrose yellow, and legs and feet sometimes grey or lavender. Smaller than *F. armillata*; larger than *F. americana* with sometimes paler slate-coloured body plumage contrasting more with blackish head and neck. Sexes alike. Immature not described. Juvenile dark drab grey with paler underparts and mainly white face; iris dark brown; bill dark greyish horn with paler tip; legs and feet greyish horn with darker joints. Races separated on colour of undertail-coverts: all white in nominate, and with black inner webs to almost completely black in *atrura*. Voice. Usual call a low "churr" or harder "hrrp", often repeated. Females give low chitter.
Habitat. Ponds, lakes, rivers and marshes. Mostly in fairly large lakes with extensive shallows having dense submerged vegetation, fringed by reeds, but also breeds in barren lakes lacking reeds. Except furthest S, there is a tendency for red-fronted birds to dominate in well vegetated lakes and white-fronted birds to dominate in barren high altitude lakes with *Chara* as principal submerged plant. Nominate race occurs from 2100 to 4700 m; *atrura* occurring in coastal Peru and tablelands of Ecuador and Colombia, found at 2200-3600 m in Colombia.
Food and Feeding. Mainly aquatic vegetation, especially *Chara*, but also *Myriophyllum* and *Elodea*. Feeds in areas of shallow water with dense submerged or floating vegetation; generally gregarious and sometimes in mixed flocks. Dives for food at depths of 2-5 m; also feeds by walking on floating vegetation and on beaches.
Breeding. Poorly known; breeding behaviour apparently close to that of *F. americana*. Colombia, Feb; N Chile, Nov-Jan; Peru, Apr and Jun-Nov; Bolivia, adults feeding small chicks, Aug; laying peaks in dry season (Jul-Aug) but may nest in any season. Generally gregarious; monogamous, territorial and pugnacious when breeding. Mixed pairs of red-fronted and white-fronted birds often occur but there may be a tendency for assortative mating. Nest placed among reeds, or open to view in floating water weeds. Clutch size most frequently 4-5; black downy chick has red and blue skin on crown, short orange bristles on throat, and red bill with dark subterminal bar and orange tip. Second clutches likely to occur, as juveniles seen feeding downy chicks.
Movements. Seasonal population movements occur, not properly described.
Status and Conservation. Not globally threatened. No precise data available, but species is locally common to abundant, sometimes assembling in thousands.
Bibliography. Blake (1977), Canevari *et al.* (1991), Fjeldså (1982, 1983a, 1983c), Fjeldså & Krabbe (1990), Gill (1964), Harris (1981), Hellmayr & Conover (1942), Hilty & Brown (1986), Hughes (1980), Johnson (1965b, 1972), Koepcke (1970), Meyer de Schauensee (1982), Morrison (1939a, 1939b), Olrog (1984), Parker *et al.* (1982), de la Peña (1992), Remsen & Traylor (1989), Rocha & Peñaranda (1995).

130. **Red-gartered Coot**
Fulica armillata

French: Foulque à jarretières **German**: Gelbschnabel-Bläßhuhn **Spanish**: Focha de Ligas

Taxonomy. *Fulica armillata* Vieillot, 1817, Paraguay.
Monotypic.
Distribution. C & S Chile, and SE Brazil and Uruguay S through Argentina to Tierra del Fuego; possibly also Paraguay and Falkland Is.



Descriptive notes. 43-51 cm. Large coot, with white undertail-coverts and no white on secondaries; pointed frontal shield, giving somewhat angular profile, and distinct red mark along base of culmen, separating yellow of bill and shield. Colours of bill and shield may vary: shield may be paler yellow than bill; bill sometimes reddish. Legs and feet orange-yellow to yellow, with pale red "garter" above ankle joint; iris usually reddish but can be yellow. Sexes alike. Immature has horn-coloured bill but soon acquires yellow shield; legs and feet olive; in second or third year birds have duller, more olive, legs and feet than adult. Juvenile dull drab grey-brown with white head and neck, mottled dusky from crown to hindneck. Voice. Alarm call of male a short, whistled "huit"; also an explosive "pit" and repeated "wuw" of aggression; repeated soft "cuit" when near female. Female has "yec" of alarm and loud, repeated "terr".
Habitat. Lakes, large ponds, rivers, marshes and deep, clear roadside ditches; rarely seen on small pools but occasionally feeds in protected waters associated with lakes. Sometimes occurs alongside *F. leucoptera* and *F. rufifrons*. On Patagonian uplands breeds mainly on exposed shallow lakes with extensive carpets of floating *Myriophyllum*. Occurs mainly in lowlands, but ascends to 1200 m on barren plateaux of inland Patagonia, up to 1000 m on lakes of S Andes, and breeds at 2100 m in L Volcán, Jujuy (NW Argentina). In winter, can form large agglomerations on sheltered marine bays.
Food and Feeding. Eats primarily aquatic plants. A skilled diver, obtaining most of food in open, fairly deep water; also upends. Occasionally raids water weeds pulled about by Rosy-billed Pochards (*Netta peposaca*) and Black-headed Ducks (*Heteronetta atricapilla*).
Breeding. Chile, Oct-Nov with replacement clutches until Jan; Brazil, Nov, large young Feb; Argentina, two peaks, mid-Sept and mid-Oct (latter possibly due to renesting). Normally gregarious, but monogamous, strongly territorial and pugnacious when breeding. Nest a loosely built platform of dried rushes with rim built up; usually in tules of moderate density near open water; sometimes floating; nest area usually free of floating vegetation. May nest alongside *F. leucoptera*. Eggs 2-8 (mean 5·3); after chicks hatch, nest built up to serve as brood site, or brood nests or platforms often constructed; black downy chick has partly naked pink and blue crown, small orange bristles on throat, black bill with orange band and red shield; young fed by both parents; able do dive quite early in life. Replacement clutches laid after egg loss. Nest parasitism by *Heteronetta atricapilla* recorded once.
Movements. Apparently normally sedentary; in Rio Grande do Sul present all year but given to considerable movement and local concentration; has strayed to Tristan da Cunha.
Status and Conservation. Not globally threatened. Formerly regarded as abundant, and still regarded as common, but very few data available. Concentration of c. 10,400 birds counted in coastal inlet at Puerto Natales, Aug 1992, in company of small numbers of *F. leucoptera*. No recent record from Paraguay.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Clark (1986), Contreras *et al.* (1990), Fjeldså & Krabbe (1990), Forrester (1993), Heimsath *et al.* (1993), Hellmayr & Conover (1942), Johnson (1965b), Klimaitis & Moschione (1987), Meyer de Schauensee (1982), Narosky & Yzurieta (1987), Navas (1956, 1960, 1970), Olrog (1984), de la Peña (1992), Pinto (1964), Sick (1985c, 1993), Weller (1967), Woods (1988).

131. **Red-fronted Coot**
Fulica rufifrons

French: Foulque à front rouge **German**: Rotstirn-Bläßhuhn **Spanish**: Focha Frentirroja

Taxonomy. *Tulica* [sic] *rufifrons* Philippi and Landbeck, 1861, Chile.
Monotypic.
Distribution. Coastal S Peru; extreme SE Brazil; coastal C Chile E to S Paraguay, NE Argentina and Uruguay, and S to N Tierra del Fuego; also Falkland Is (formerly?). Erroneous records from N Argentina based on confusion with *F. armillata*.

Descriptive notes. 38-43 cm; 1 male 685 g, 1 female 550 g. Unlike other coots, lacks greatly enlarged lobes on feet. Dark slate grey, blacker on head and neck; prominent white undertail-coverts form inverted heart shape; characteristic profile with almost straight line from bill tip to knob-like top of elongated frontal shield; bill yellow, ridge and frontal shield dark chestnut-red; legs and feet olive. Sexes alike. Juvenile rather uniform grey-brown, with diagnostic pointed shield and white undertail-coverts (inverted heart-shaped); some white spots on throat; bill blackish. Voice. A long, chattering series of calls, described as "togo togo togo..., cu cu cu..., puhúh puhúh puhúh...", etc. Alarm note "tuc".
Habitat. Semi-open marshes and reedy lakes, especially with much floating duckweed and waterferns and often with very shallow water; usually found among vegetation, rarely venturing far from cover. Inhabits lowlands up to 800 m; casual up to 2100 m in NW Argentina.
Food and Feeding. Primarily a surface feeder, pecking at *Azolla* and duckweed mats, but also dives skilfully and grazes in upland areas adjacent to water when marshes dry up seasonally. Generally in loose flocks, sometimes with *F. armillata*.
Breeding. In Chile lays Sept-Oct; Argentina, May-Nov; Peru, Sept-Jan. Monogamous. Nest of plant material; rather small for the genus; generally well hidden and low in water; species very adaptable in nest-site selection. Eggs 2-9 (mean 5·6); late clutches smaller than early ones; downy chick black, crown partly naked pink and blue, throat with some broad, flat, orange bristles, bill red with 2-3 black bands; after chicks hatch, nest often relined with more delicate material, and serves as brood platform for at least 4 days. Nest success high (83%) at Cape San Antonio, E Argentina, and second broods common, but deserted readily, mostly as result of human intrusion, even when clutch well incubated. Present species is apparently main host of parasitic Black-headed Duck (*Heteronetta atricapilla*); few desertions associated with parasitism.
Movements. No regular movements recorded, but records of casual birds and occasional influxes indicate some wandering or dispersal. Apparently a migrant at São Paulo, Brazil; at Cape San Antonio,

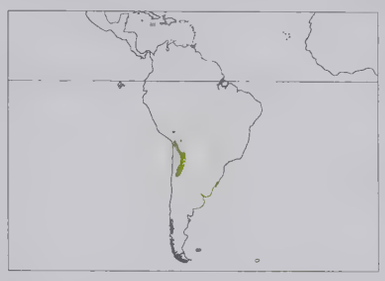
Argentina, most birds left during winter when marshes dried up, the birds remaining being mostly immatures.
Status and Conservation. Not globally threatened. Not uncommon over most of range, and abundant in *pampas* marshes, but scarce in Rio Grande do Sul. Population apparently stable. Not recorded in Falkland Is since 1924, where may perhaps never have been more than vagrant.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Clark (1986), Contreras *et al.* (1990), Fjeldså & Krabbe (1990), Friedmann (1927), Hayes (1995), Hellmayr & Conover (1942), Johnson (1965b), Klimaitis & Moschione (1987), Meyer de Schauensee (1982), Narosky & Yzurieta (1987), Navas (1956), Olrog (1984), Parker *et al.* (1982), de la Peña (1992), Pinto (1964), Pulido (1991), Tallman *et al.* (1978), Sick (1985c, 1993), Weller (1967), Woods (1988).

132. Giant Coot

Fulica gigantea

French: Foulque géante **German**: Riesenbläßhuhn **Spanish**: Focha Gigante

Taxonomy. *Fulcia* [sic] *gigantea* Eydoux and Souleyet, 1841, Peru.
Monotypic.
Distribution. S Peru through W Bolivia to N Chile and NW Argentina.



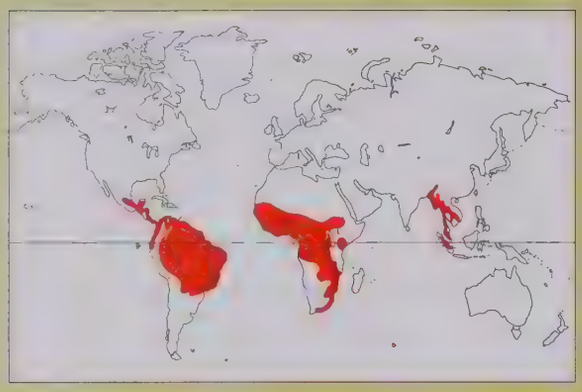
Descriptive notes. 48-59 cm; c. 2000-2500 g. Adult deep slaty, inclining to black on head and neck; variable white streaking on lateral undertail-coverts; very heavy-bodied with relatively small head, concave forehead and high knobs formed by enlarged orbital rims; also distinguished from all other coots by deep red legs and feet; bill deep red, ridge white, sides and shield yellow. Sexes alike. Adult normally too heavy to fly but immature smaller, not much larger than *F. ardesiaca*, and can fly readily. Immature has dark grey breast and belly, duller bill and pale greyish red legs and feet. Juvenile dull dark grey, foreneck and side of head below eye white, bare parts dusky. Voice. Male gives alternating gobbling or laughing "houehouhouhouhoou" and low, growling "hrr" or "horr" sounds; sometimes utters only growls. Female has low, crackling "chee-jrrrh", low squeaking or cracking sounds sometimes becoming a soft chittering, and soft "hi-hirr hirrr hirrr..." when with male.
Habitat. Ponds and lakes in barren highlands of Andean *puna* zone; most numerous on lakes with extensive weedy shallows. Occurs on lakes with emergent vegetation but always stays outside cover. Probably requires wide shallows with abundant weeds for nesting, thus restricting the number of good breeding sites. Occurs chiefly at 3600-5000 m, but up to 6540 m.
Food and Feeding. Vegetarian: takes much aquatic vegetation, especially *Myriophyllum*, *Potamogeton*, *Zanichellia*, *Ruppia*; also some filamentous algae; feeds on grass on shore; unlike sympatric *F. ardesiaca* does not eat *Chara*. Feeds from surface of water with sideways throwing movement; occasionally upends like dabbling duck; also dives occasionally.
Breeding. Breeds at any season but laying peaks in local winter, Jun-Jul, often with second clutch Nov-Feb. Monogamous and permanently territorial. Nest enormous, of aquatic vegetation, forming raft up to 3 m long and projecting 50 cm above water. Nest has high rim and deep cup; maintained and enlarged over several years, the original structure having compacted into peat in centre; pairs probably hold same platform for life. Nests in water c. 1 m deep with dense water weeds rising to surface, sometimes on miry clay; small new nests usually float but large old ones rest on bottom. Both adults build; fresh weed constantly added to rim while young on raft. Eggs 3-7 (mean 4·4); both parents incubate; downy chick c. 40 g at hatching, sooty black, browner on underparts with few orange bristles on throat, pink skin of crown hardly visible, bill pink with yellow tip and magenta base separated by black bands; young fed until 2 months old; in captive juvenile, plumage complete after 67 days, fully fledged at 4 months, post-juvenile moult occurred some time later. Because of frequent strong, cold winds, chicks spend much time in nest, feeding on fresh nest material from rim. Adults often feed chicks in nest, offering weed fragments and invertebrates such as amphipods; captive young ate plants (*Elodea*, *Oxalis*), small fish, tadpoles and a small frog; immatures from previous broods often feed young. Many eggs taken by people at some sites, but survival of young high: pre-fledging mortality estimated at 36%.
Movements. Immatures disperse widely by flying at night but adults normally attached to territory and nest for life; when small breeding ponds freeze, may walk to larger ice-free lakes. Although normally confined to high altitudes, straggles to lower elevations, occasionally to Pacific coast.
Status and Conservation. Not globally threatened. Scarce through most of range, but large populations exist in some areas, including c. 12,000 in Lauca National Park, N Chile. Populations seem to have exploded in Chile and Peru, as consequence of control on use of fire-arms.
Bibliography. Blake (1977), Canevari *et al.* (1991), Chebez (1994), Fjeldså (1981), Fjeldså & Krabbe (1990), Harris (1981), Hellmayr & Conover (1942), Hughes (1980), Johnson (1964c, 1965b), Koepcke (1970), McFarlane (1975), Meyer de Schauensee (1982), Narosky & Yzurieta (1987), Olrog (1984), Parker *et al.* (1982), de la Peña (1992), Pulido (1991), Remsen & Traylor (1989), Roe & Rees (1979).

133. Horned Coot

Fulica cornuta

French: Foulque cornue **German**: Rüsselbläßhuhn **Spanish**: Focha Cornuda

Taxonomy. *Fulica cornuta* Bonaparte, 1853, Potosí, Bolivia.
Monotypic.
Distribution. N Chile, SW Bolivia and NW Argentina.



Descriptive notes. 46-53 cm; 1 male 2100 g, 2 females 1600 and 1900 g, 2 juveniles 1360 and 1500 g. Adult slate grey, darkest on head and neck; undertail-coverts black with two white stripes; bill greenish yellow with dull orange base and black ridge; long, extensible and erectile black proboscis which normally rests on ridge of bill, and has two black tufts at base; legs and feet olive with dark joints. Shape and size like *F. gigantea*, but differs strikingly in bare part colours and forecrown structure. Sexes alike. Juvenile greyer, with extensively white chin and throat; bill black, tinged greenish; proboscis reduced or absent. Voice. Apparently similar to that of *F. gigantea*, although only a low grunting series of 3-5 syllables, and loud sharp grunts, are described.
Habitat. Barren Andean high altitude lakes, both freshwater and brackish, with dense submerged aquatic plants. Occurs chiefly at 3000-5200 m in desert *puna*.
Food and Feeding. Poorly known. Eats mainly aquatic plants, especially *Myriophyllum*, *Potamogeton* and *Ruppia*; also grass and some seeds.
Breeding. Breeds mainly Oct-Feb, although nest building recorded as early as Sept. Monogamous; may breed in colonies of up to 80 pairs. Nest enormous, resembling that of *F. gigantea* but usually built on conical mound of up to 1·5 t of stones, up to 4 m in basal diameter and built up from lake bed to height of c. 60 cm, ending just below water surface in platform c. 1 m² on which nest of water weed is placed. Both adults build; fresh material (usually *Ruppia* or *Myriophyllum*) constantly added to rim while nest in use; nest often used over many years, and also serves as nest-site for other waterbirds after coots have bred. Eggs 3-5; downy chick black with feathered crown, bill light grey with yellow base and tip, legs black; young fed by both parents; when adults bring fresh material to nest, seed pods are torn off and given to young. Chick mortality estimated at 25%.
Movements. May fly from one feeding ground to another. Local populations fluctuate greatly between periods of drought and inundation; altitudinal movements or displacements, some over long distances, may occur in harsh weather, especially in winter when food becomes locally unavailable as some lakes freeze, and at such times birds recorded as low as 2000 m. Moves at night.
Status and Conservation. VULNERABLE. Probably in decline. Normally occurs at low densities: 1-10 nesting pairs at some sites with up to 70-80 at a few; concentrations of over 100 birds (up to 780) reported occasionally; 2800 birds reported on Laguna Pelada, Bolivia, in Nov 1989. Total numbers not known; Chilean population estimated at 620 birds; 180-200 birds and 70-80 nests counted at Laguna Meñique in Nov 1993, with 30-40 birds at adjacent Laguna Miscanti; little known about population trends and no definite evidence of recent decline. Lakes at which species occurs, although remote, remain vulnerable to contamination and effects of trampling by cattle, while from some, water is pumped to coastal cities and towns and to mines. Also suffers from hunting and egg-harvesting. Predation by Andean Gull (*Larus serranus*) reported as an occasional threat. Some lakes at which species occurs have been protected, including the important Laguna Pelada. Officially considered "vulnerable" in Chile, where census work, surveillance and other studies are being carried out.
Bibliography. Class AVES

Order GRUIFORMES

Suborder HELIORNITHES

Family HELIORNITHIDAE (FINFOOTS)

- Medium-sized largely aquatic birds, with brightly coloured lobed toes.
- 26-59 cm.

- Pantropical.
- Thickly vegetated margins of rivers, lakes and swamps.
- 3 genera, 3 species, 6 taxa.
- 1 species threatened; none extinct since 1600.

Systematics

Rather few bird families are as poorly known and infrequently observed as the Heliornithidae, or finfoots. These birds have long been included within the Gruiformes on the classical taxonomic basis of the skeletal and musculature arrangements, but where they should be placed within this diverse order of birds is open to question. There is no fossil evidence of any of the Heliornithidae to provide any guidance, although the wide geographical distribution of this small family across three continents suggests an ancient lineage. On the grounds of superficial similarities to some rails, as well as similar Mallophaga, or feather lice, the family has usually been considered as close to the Rallidae, but, as with the even greater resemblance to the grebes (Podicipedidae), such similarities may well be misleading.

The limited DNA-DNA hybridization work carried out so far indicates that, of those species examined, the closest relative of the Sungrebe (*Heliornis fulica*) might be the Limpkin (*Aramus guarauna*); however, in that particular study no material was available for either of the other members of Heliornithidae, the African Finfoot (*Podica senegalensis*) and the Masked Finfoot (*Heliopais personata*), and such comparisons would clearly be highly desirable. A close relationship with the Limpkin has apparently never been suggested on the basis of an examination of morphological characters.

The three species are placed in three separate genera, but these are not considered equidistant from one another. The Masked Finfoot and most African Finfoots are much larger than the Sungrebe, and both of these Old World genera have stiffened rectrices, quite markedly so in the case of the African Finfoot. The differences between the hatchlings are considerably greater still: those of the African Finfoot and Masked Finfoot are down-covered and nidifugous, while the newly-hatched chicks of the Sungrebe are thoroughly altricial, in being blind, naked and helpless. On the basis of this considerable degree of difference among them, the recognition of two distinct subfamilies was proposed: Podicinae, containing the African and Masked Finfoots; and Heliornithinae, containing the Sungrebe alone.

Morphological Aspects

The three finfoot genera share a number of features that are clearly related to their way of life. They range in body length from the 26 cm of a female Sungrebe to the 59 cm of a large male African Finfoot. All birds have a long neck, slender body, pale underside, sharp pointed bill, brightly coloured lobed feet, sharp claws and a long broad tail.

The lobed feet, like those of coots (*Fulica*) and grebes, are clearly adapted to a largely aquatic way of life. They enable a powerful degree of propulsion through the water, yet do not encumber the bird on land, where the long body is carried relatively erect. Reports of finfoots' movements when on solid ground emphasize their nimbleness and the fact that they can, and do, run fast. They can also clamber into trees and move around in them in a moderately agile manner that a fully webbed foot would make impossible.

The legs and feet are brightly coloured, with striking differences between the species. The African Finfoot has bright orange or salmon red legs and feet, with bright yellow claws; the Masked Finfoot has bright pea green ones; and the Sungrebe has yellow and black banded and striped feet and legs respectively. There are no obvious behavioural reasons for this conspicuousness: for example, no courtship or other behaviour has been reported which particularly displays the feet. The latter trail behind the bird when it flies, but are obscured by the tail, and, in any case, the birds do not usually fly in company. Yellow and black striping is a classic warning colour combination in nature, for instance in wasps, snakes and caterpillars, and such colours might conceivably deter some underwater predators, such as large South American fish, although this explanation seems less applicable to the bright foot colours of the Old World finfoots.

The African Finfoot has markedly stiffened retrices with conspicuous pale shafts, and the bird often swims with the tail spread flat on the surface of the water. The function of the stiffening is not clear: presumably it does not influence the bird's flight, but it may well enable it to manoeuvre better in or on the water. It appears to be helpful to birds when they are clambering out of the water, on land or among tree branches. It is not clear why, if this stiffening is beneficial to the African Finfoot for this or any other purpose, the Masked Finfoot manages with less stiffening, and the Sungrebe with none at all. It may be that these other two species clamber and climb less, but the observations to support or refute such a suggestion are lacking.

A second possible adaptation for climbing is also found in the African Finfoot, which has a well developed claw on its wing, on the end of an independently mobile first digit that is 12-18

mm in length. This claw might be helpful when the bird is clambering among vegetation, apparently with half-open wings, rather as the young Hoatzin (*Opisthocomus hoazin*) does with its two claws. The claw on the wing of the African Finfoot is present in adults as well as in young. Both the claw and the digit are easily overlooked in a fresh specimen, and, because they shrivel when the bird is dead and dry, they are almost undetectable in dried museum skins. With far fewer specimens collected, it is not clear whether there is ever any trace of this claw and digit in the Masked Finfoot or in the Sungrebe.

The similarity between the African Finfoot, in particular, and the male Torrent Duck (*Merganetta armata*) of South America is striking, and has been commented on. It obviously has no genetic basis, but may well reflect adaptation to similar aspects of the birds' ways of life. Both birds have bright red bills and legs, elongated bodies, stiffened tail feathers, white and dark lines from either side of the eye going down the side of the neck, and a carpal spur or claw which is used in scrambling on rocks or in trees. All three finfoots have the white longitudinal neck stripes, which presumably help with the birds' concealment by breaking up the outline of head and eye.

Finfoots are to a fair extent at home in four domains, in and on the water, in the air, on the ground, and in trees and bushes. Like darters (Anhingidae), they swim with exaggerated backward and forward movements of the head and neck, presumably in time with each propulsive foot stroke. They will sometimes swim low in the water, and when alarmed may have only the head and neck above the surface. They rarely dive, for food or when disturbed, but they may lower themselves further in the water, and generally swim away to cover at the water's edge. If pressed, a bird often patters over the surface, beating its wings. Finfoots do not take to the air very readily, although they clearly are capable of long aerial journeys (see Movements). They generally fly low, with steady, fast wingbeats and with the long tail spread. They do not usually fly to a perch, but land on water and climb up to the resting place.

The African Finfoot shows a great deal of variation in size, and birds from South Africa may weigh twice as much as those from West Africa. The reasons for this cline in size are totally unknown, and the other two genera do not show any consistent variation in size over similarly large geographical ranges. The African Finfoot also exhibits considerable variation in its plumage, independent of the variation in size. One race, *camerunensis*, is much darker than the nominate race, to the extent that in some individuals the whole body, both above and below, may be largely black. The races mostly intergrade, and birds with intermediate characteristics are found. Within all four races, some birds are more blotched or barred below than others, particularly towards the rear, while some have more, and others less, white spotting on the back, which in turn may be browner or greyer. The causes and possible significance of this variation are quite unknown, and, again, the other two species do not exhibit variability of this sort: a Sungrebe looks much the same, wherever it comes from.

The greater amount of geographical variation in size in the African Finfoot than in the other two species is also reflected in the much greater degree of sexual dimorphism in the African species, where males are considerably larger than females, sometimes as much as 25%. This sexual size difference caused confusion in the past, in attempts to delineate the geographical races of this species on the basis of very small numbers of birds collected. Not enough is known of the mating systems of the three species to say whether these differences in the extent of sexual dimorphism are related to greater male competition for mates or for territory in the African Finfoot.

Habitat

Over their enormous range, finfoots are found in a wide variety of habitats where the two essential components, water and cover, are present together. Such habitats range from coastal creeks up to some wetlands about 2000 m above sea-level. In many places,

Though seemingly rare, the African Finfoot is widely distributed over the whole continent from sub-Saharan regions southwards, and it occurs wherever undisturbed perennial streams and other bodies of water offer well vegetated banks. In coloration strikingly similar to the Torrent Duck (Merganetta armata) *of South America, its behaviour is really more similar to that of darters (Anhingidae). The body lies flat in the water, the head is relatively small, the neck slender and the broad tail with its stiffened rectrices is often spread as the bird swims with strong to-and-fro movements of neck and head. The adult breeding male is colourful with bright red bill and reddish orange feet, while the female is similar but with more muted plumage. This juvenile bird recalls an adult female, but can be separated by the buff on the neck and breast, but most readily by the dark bill.*

[*Podica senegalensis petersii*, Kwazulu, Natal, South Africa. Photo: Nigel J. Dennis/ NHPA]

In common with the other finfoots, the New World Sungrebe frequents mainly slow-moving waters, usually in forested country. Apart from water it has two other essential requirements: dense riparian vegetation and freedom from disturbance. Finfoots are shy birds that often pass undetected, and the paucity of information about them is typified by the fact that it is not yet known whether they spend more time on water or on land. Clearly, the lobed feet equip them well for movement on both elements. When disturbed on water, they invariably clamber ashore to hide among vegetation. In addition, although most of their food is taken from the surface of the water, they are also known to forage on land.

[*Heliornis fulica*, La Encrucijada, Mexico. Photo: A. de Sostoa & X. Ferrer]

finfoots inhabit mangrove swamps by the shore, while at the other extreme they are found from mountain streams downwards. They may frequent quite fast-flowing streams, but in general they are most often in still or relatively slow-moving water, in streams, rivers, ponds, lakes and estuaries. On large water bodies, they are always to be found relatively close to the shore, in places where there is thick vegetation along the water's edge, particularly overhanging and emergent vegetation.

The finfoots also inhabit areas of humid and flooded rain forest, papyrus swamps, and reedbeds with shrubs, trees and creepers. Many of the tropical wetlands they inhabit experience unpredictable or seasonal changes in rainfall, and in water flow and water levels, and the birds are clearly able to cope with such variations.

It is not clear what factors determine which habitats are acceptable to the birds. Food supply and avoidance of disturbance are likely to be significant. Clearly, vegetation cover appears to be important, for reasons that are not understood: why should finfoots be so particularly keen on cover? Absolutely nothing is known of their natural predators, except for one report of a chick disappearing under the water with a sudden splash! Not being particularly proficient divers, finfoots out in open water are likely to be vulnerable to birds of prey, while both birds roosting and nests along the water's edge may be at risk from terrestrial predators. The activities of human beings nowadays are likely to be reducing the amount of suitable habitat available to the birds (see Status and Conservation).

General Habits

Finfoots are relatively unsocial birds. They are usually encountered singly, but sometimes in pairs, with or without accompanying young. As far as is known, they do not gather into any larger aggregations for any purpose. The indications are that they are territorial, individuals driving away others that may come into their own stretch of water. A male Sungrebe holds a year round territory of about 200 m of stream banks, driving out and fighting with intruding birds.

Finfoots are almost invariably described as being elusive, shy, wary and skulking. It is not at all clear why this family, in particular, should be so determined to avoid human beings and presumably many other animals too. The birds certainly never make themselves at all conspicuous, and this, of course, is why they are so often overlooked. Many experienced ornithologists in Africa count on the fingers of one hand the number of their sightings of African Finfoots in decades of birdwatching. It is only when the birds are on or beside the water on streams, rivers or lakes that the vegetation may be open enough for them to be observed at all. Their habit of seeking cover on land when in any way disturbed means that the great majority of observations are of birds on the water. It is not known where, in fact, they spend most of their time. They obviously swim very well, but there are no data on what proportion of their day they spend in the water; what is known is that, when on the water, they stay close to the banks and the concealment that the edge vegetation provides. They also use the alternative strategy of freezing motionless and semi-submerged if surprised when away from cover.

Like many other birds, finfoots are reported to be most active early in the morning and late in the afternoon, and to be relatively inactive in the middle of the day. Sungrebes watched in Mexico spent from about 09:00 hours until about 16:00 hours either floating on the water or, more often, perched on a low branch above the water, essentially resting; while on the perch, they preened sometimes, or occasionally dropped into the water below to catch an insect that was drifting by.

At dusk, the finfoot clambers up, rather than flying up, into a higher concealed roosting place in thick vegetation, from which, if disturbed, it can drop down into the safety of the water. Otherwise, the bird will remain inactive roosting there for the night.

Voice

Parallel to the finfoots' apparent determination to remain inconspicuous, they are not noted as being highly vocal. The sounds

they make have been rather poorly described, although they do seem to be remarkably diverse.

The African Finfoot is reported to produce occasionally, and particularly during the breeding season, a repeated low booming sound, either loud or soft. It is likely that the bird's indigenous local name of "Mumbooma" in the Upper Zambezi region is onomatopoeic. This species apparently also utters a number of explosive or staccato croaks, barks or chatters.

The Masked Finfoot utters a bubbling call, fairly high-pitched, apparently like the sound of air being blown through a tube into water. It may be that this sound has given rise to the local Burmese name of "Ye-balon".

Sungrebes produce a characteristic territorial call, which M. Álvarez del Toro described phonetically as "eeyooo, eeyoo, eeyoo-eeyaaa, eeyaa, rather similar to the calls of some grebes". The sound is made more when a bird is advertising territorial ownership, and particularly before and after territorial disputes. Male and female utter soft clucking sounds during their mutual courtship displays, and when relieving one another at the nest.

Apart from these few, mostly rather anecdotal, descriptions, there are reports of squawking or growling noises being made by captured birds held in the hand or in traps, but in such circumstances the noises made are unlikely to be of any great significance.

Food and Feeding

The members of Heliornithidae are catholic feeders, consuming many of the range of small animals that can be found and caught along riverbanks or the margins of other water bodies. There are no quantitative data on their diets, and it is regrettable that the collectors of most museum specimens did not manage to supply information on the gut contents of their quarry. With so few data available, no meaningful dietary differences between the species have been noted.

Insects are the most frequent component of their diets, particularly the adults and aquatic larval stages of midges, mayflies and dragonflies; in addition, of other insect foods, there are records of their eating grasshoppers, flies, beetles, a butterfly and a mantis egg case. Mollusc food is common, in the form of many small snails, of which the opercula are easily recognizable in the stomach. There are records of worms, spiders and millipedes, and of crustaceans such as shrimps, prawns and crabs. Some vertebrate prey is taken, particularly tadpoles and frogs, with one record of a snake, and indications of small fish having been consumed. Vegetable matter is also eaten, including seeds as well as leaves, but in apparently small amounts. Nothing is known of the birds' preferences, and it seems quite likely that they eat virtually whatever animal matter they encounter and can catch.

The food is obtained in a number of different ways. Significant amounts are simply found drifting on the water surface, and can be picked off by the swimming bird. Such food may also be detected by a bird perched nearby, which then drops down onto the water to secure it.

Swimming finfoots are sometimes seen picking insects off rocks or off the leaves or stems of riverside vegetation, sometimes jumping clear of the water in order to do so. One was observed taking fairly large pieces of leaf in the same way, and another was seen jumping up off the water surface to catch a flying insect. Unlike coots and grebes, finfoots do not feed by diving and bringing up material from below.

Finfoots also feed on land, but the extent to which they do so is unknown, because they are so rarely observed there. The ground does not generally constitute such a convenient collecting system for insect casualties as does a moving water surface; on the other hand, there are many underwater competitors, such as fish, that are quick to seize any insects that end up in the water.

Breeding

Although data are scanty, and there is clearly some variation, it appears that all three species generally breed at times of, or soon after, high water levels, which often means during the summer rainy season. Thus, the African Finfoot in southern Africa usually nests between September and December, whereas in East Africa it is more likely to nest in the period March to June. There are no reliable data on the nesting season of the Masked Finfoot, although it is reported to take place during the rains. The Sungrebe

Thinly distributed over a vast area extending from Bangladesh eastwards through to Cambodia and Vietnam, the Masked Finfoot frequents varied habitats including swamps and mangroves. Like the other Heliornithidae, it is essentially a secretive species which keeps well hidden in thick riparian vegetation, although this individual has allowed itself to be caught by the camera as it forages on a more open stretch of mangrove shoreline. Data on its food requirements are scanty, but items are known to include aquatic insects, molluscs, fish, frogs and some vegetable matter.

[*Heliopais personata*, Krabi, Thailand. Photo: Jerry Warne]

nests in spring to early summer in Mexico in the north of its range.

The birds are apparently territorial when nesting, and probably for much of the year. They remain in a stretch of water several hundred metres long, which they defend.

There are changes in appearance related to the breeding season in one sex or the other in all three species. Thus, a breeding male Masked Finfoot develops a small fleshy knob above the base of his bill; this is present only in the breeding season, and is almost undetectable at other times. The male African Finfoot when ready to breed acquires a greyness over his white chin, throat and foreneck. On the other hand, in the Sungrebe it is the female that changes in the breeding season: her bill becomes scarlet, her eyelids turn from brown to red, and her cheeks and the sides of her neck acquire a rusty cinnamon patch.

The nest is a fairly untidy construction of sticks, twigs and reeds, in the form of a shallow bowl, lined with dead leaves. It is usually situated over water, often among thick overhanging vegetation. Favoured nesting sites, for all three species, are the masses of tangled dead vegetation remaining caught in low riverside branches or fallen trees after flood waters have subsided and left their flotsam behind them; on top of these, the finfoot constructs its nest using additional material that it has collected.

The nesting behaviour of the Masked Finfoot has not been observed, so almost nothing is known of the breeding of this species. Courtship has been observed in the African Finfoot; it takes place on the water, with one bird, probably the male, swimming repeatedly out from cover, raising and opening its wings on each side alternately; meanwhile its mate, from a position in cover, makes a snapping sound, probably with its bill, and makes forays out to escort the first bird back into cover. In Sungrebe courtship, as in their aggressive displays, the two birds swim in counter circles, with their necks stretched out low over the water and their wings half raised; copulation takes place when the two birds meet as their circles decrease in size.

Usually two, but sometimes three, eggs constitute the clutch in the African Finfoot and the Sungrebe. By contrast, the Masked Finfoot is reputed to lay 5-7 eggs.

In the Sungrebe, both male and female take part in nest building, and both sexes also share incubation duties, with the male taking the middle of the day shift from about 09:00-10:00 hours until 16:00-18:00 hours, and the female sitting on the nest for the remainder of the daylight hours and overnight. Observations of African Finfoots at the nest indicate that only the female incubates, although the male is fairly often nearby; it is not known whether earlier on he plays a part in nest construction. In the face of disturbance, the female will sit tightly, before eventually slipping off the nest and dropping quietly into the water. When returning, she swims back nearby, then clambers quietly up the branches to her nest.

The incubation period of the African Finfoot is unknown, except that it lasts at least 12 days. The downy young are able to leave the nest and swim strongly only a couple of days after hatching, although whether they usually leave the nest quite as early as that is not known. It is likely that both parents help to care for them.

The Sungrebe is reported to have an astonishingly short incubation period of only 10-11 days, which rivals even the short incubation periods of the small passerines. Whereas the young African Finfoot is precocial, the newly-hatched Sungrebe is highly altricial and completely helpless. It is blind, with the eyelids tightly joined. It is almost naked, with pale pink skin but with a little short sparse down only along the future feather tracts. Its bill and feet are short and poorly formed.

More astonishing still, the male is able to transport these helpless offspring, even in flight. M. Álvarez del Toro, who observed a nesting pair in Mexico, discovered that the male has a shallow pocket under each wing into which the two young can fit. The pocket is formed by a pleat of skin, and made more secure by the feathers on the side of the body just below. The heads of the chicks could be seen from below as the bird flew. Álvarez del Toro collected the bird in order to examine it and confirm the unlikely discovery. Subsequently, he found it confirmed also by a report published by Prince Maximilian of Wied 138 years earlier but apparently ignored, forgotten or not believed.

This adaptation is unique among birds: in no other species is there any mechanism whereby altricial young can be transported. Of course, the precocial young of some swans and grebes may hitch rides on their swimming parents' backs, and a male jacana can transport his chicks about holding them between his wings and body (see page 286), but neither of these cases applies when the adults are in flight. There are also occasional reports of young galliforms dropping from a flying adult, but it is likely that these are chicks which were not disentangled from a parent's legs or feathers in time before the parent took off, and no systematic transport system or adaptation has been suggested.

The transport system of the Sungrebe raises numerous further questions. How do the chicks get into the pocket? Are they put in by the male? Does he feed them in there? Do they stay inside, or get in and out? Why does the female not have similar pockets? And indeed, why do other species not have similar adaptations? The African and Masked Finfoots both have downy precocial young. If the Masked Finfoot's clutch actually does regularly consist of 5-7 eggs, transporting a whole clutch in this way might be impracticable. No such pockets have been reported in the African or Masked Finfoot, but again these features are not detectable in dried skins. Even if they are present in fresh material, unless they were particularly searched for they would probably be overlooked, as the African Finfoot's first digit and claw so often has been.

Movements

All the signs are that all three species of finfoots are largely static and resident. There is no evidence of any regular migration. However, a fair amount of travelling obviously does take place, with all species widely distributed and occurring on a variety of changing water bodies. Colonization of new areas of aquatic habitat, such as newly created lakes, takes place reasonably soon, which implies that there are birds which are moving around in search of habitat in which to settle. Without gene interchange as a result of such travel, each species would very likely have given rise to many more localized variations than is the case. It is only the African Finfoot which exhibits any noticeable regional variation.

Occasionally, individual birds crop up outside the species' normal ranges. For example, Sungrebes turn up from time to time in Trinidad, and Masked Finfoots have occurred in west Java, where they are not known to breed. It is extraordinary that a bird which is not normally prepared to venture more than a few metres away from the protection of the vegetated water's edge will sometimes undertake flights out to sea.

Relationship with Man

Finfoots must be amongst those bird families that have had least impact on the lves of men over the centuries. Their wetland haunts are on the whole not very densely populated by human beings, and the birds' avoidance of people is so strong that they very rarely come into any sort of contact. Finfoot population densities are apparently so low that they are nowhere a significant item in the hunting bags or diet of humans, although the flesh of the Masked Finfoot was described as "delicious" by W. Davison, and both the birds themselves and their eggs are said to be relished in places by the local people. Again, their diet, consisting mainly of small aquatic invertebrates, does not bring them in any way into conflict or competition for food resources that people value. The birds apparently do not feature significantly in local legends.

As far as is known, there is no finfoot in captivity anywhere in the world. Certainly, no zoo that contributes to the International Species Inventory System (ISIS) records their presence in their collections, and zoo literature does not report the keeping of them. It is likely that the birds' reclusiveness deters zoos and bird collections from trying to get hold of birds that would prob-

ably do their best not to be seen by the public, quite apart from the difficulties of finding and capturing birds, and then of inducing them to change their diet to one that could be suitably provided for in captivity.

The name *Heliornis* is derived from the Greek *helios* meaning "sun" and *ornis* meaning "bird", reflecting the original vernacular name "Sunbird". It is not at all clear why this name should have been applied to a bird which so particularly haunts shaded thick cover and water, both of which are antitheses of the sun. Other names are related to the sun theme, notably *Heliopais* meaning "sun-child", or are descriptive. Thus, *Podica* means "belonging to the foot" and draws attention to the lobed feet, as, of course, does the common name "finfoot". The species name *personata* means "wearing a mask", in reference to the black front of the face of the Masked Finfoot. The Sungrebe's species name, *fulica*, is Latin for "coot", as coots too have lobed feet. The French term *Grébifoulques* for the Heliornithidae means "Grebe-coots".

Status and Conservation

The three members of the Heliornithidae are the kind of species that are likely in the long term to be casualties of the further spread of human activities over the coming decades. Although the available evidence suggests that they are nowhere deliberately persecuted or even systematically hunted, they are nonetheless vulnerable for several reasons.

First, and primarily, the birds' wetland habitats are themselves almost everywhere under threat, from a wide range of hostile factors. Tropical wetland areas, with abundant water and sun, are highly productive, and so are often converted by mankind for his own agricultural needs, such as rice production. Many mangrove swamps are cleared for timber. Many wetlands are completely lost through drainage for urban development or mining. Others may be destroyed by water abstraction and its diversion elsewhere, so that their water supply is lost.

Second, the water supply may be modified, as a result of silt run-off in the catchment areas, or through seepage of fertilizers or other chemicals into the water system. In either case, the riverine micro-habitat is likely to be changed, and the invertebrate fauna on which the finfoots depend may well become insufficient to maintain them.

Third, finfoots do not need just water, but also cover and freedom from disturbance as well. An increase in human activity along a waterway, or the clearing of some of the waterside vegetation, can render the habitat undesirable or apparently uninhabitable to finfoots.

Due to their secretive habits, finfoots are observed too infrequently for their status to be evaluated satisfactorily. However, they are increasingly threatened as their wetland habitats suffer relentless exploitation by man. Nowhere is this threat more patent than in South-east Asia, the home of the Masked Finfoot, where native forests, including mangroves, are disappearing fast. This species is currently classed as Vulnerable, and undoubtedly requires a concerted research effort.

[*Heliopais personata*, Krabi, Thailand. Photo: Jerry Warne]

Fourth, despite their wide distribution, because they are at or near the top of their food chain finfoots occur only at low population densities almost throughout their range. Therefore, even if highly effective conservation measures are in place for protecting a particular area and its ecological integrity, that area will still hold only relatively few individuals of species such as finfoots. Destructive activities outside protected areas result in fragmentation of the population. Small populations are always at greater risk than larger ones, for stochastic reasons as well as inbreeding.

And fifth, the terrain in between areas of adequate safe habitat are becoming less habitable to any finfoots that may be travelling in search of mates or of new areas to colonize.

The Masked Finfoot is the finfoot most at risk. It is the only member of the family currently classed as a globally threatened species, and has been classified by BirdLife International (ICBP) as Vulnerable. Its total population is estimated to number fewer than 10,000 birds, and is considered likely to decline by more than 20% over the next 10 years; it is suffering from severe fragmentation of its wetland habitat. The Masked Finfoot has a smaller geographical range than the other two species, and South-east Asia is one of the most densely populated regions of the whole world. That high and growing human population is exploiting lowland forest and mangrove swamps at a disturbing and often unsustainable rate, is spreading its successful aquacultural practices in the region, and is producing increased traffic and development along the waterways of the region. There are threats to 94% of the wetlands of international importance in South-east Asia.

Although the African Finfoot was included in the South African Red Data Book, with indeterminate category, the species, and indeed even the race *petersii* of South Africa, occurs predominantly further north and west. Nothing is known of its population size or of trends in the rest of Africa, but the habitat the birds need is definitely being reduced and will continue to shrink. Also, there are many dam projects which alter local wetland ecology, and the amount of disturbance and waterside clearance will continue to increase, so the long-term outlook for the species is not encouraging. Nonetheless, human population pressures on the African Finfoot are not as great as those confronting the Masked.

The Sungrebe's large range is generally less densely populated by humans than are the ranges of the other two finfoots. Nevertheless, the same pressures apply, with large-scale drainage of wetlands to claim them for human agriculture, industry or settlement. Water supplies are being lost through deforestation of catchment areas, being diverted for irrigation, or being disrupted by dams for hydro-electric power. Domestic and industrial pollution from urban centres, and pesticide and fertilizer pollution from agricultural areas, are both damaging wetlands. And, as elsewhere, human beings are increasingly penetrating the wetland habitats where Sungrebes try to live undisturbed.

It may be that their protective shyness could in the end be the downfall of the finfoots. At present, their timidity means that they can not inhabit areas with more than minimal human activity and disturbance. That may not necessarily always be the case, however, as several species regularly characterized as being shy have ultimately been found able to adapt to an environment dominated by people. It would be interesting to discover whether finfoots could ever adapt themselves to living alongside humans. Properly organized attempts at captive breeding, by means of artificial incubation and rearing, might prove valuable, if this meant that the wild populations could be provided with the safety net of viable captive populations, which might be available in appropriate cases for restocking or reintroductions. Field studies too, although undoubtedly offering a major challenge, would surely prove worthwhile, as such a great deal remains to be learnt about the finfoot family.

General Bibliography

Genus *PODICA* Lesson, 1831

1. African Finfoot

Podica senegalensis

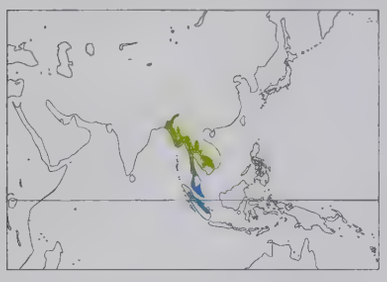
French: Grébifoulque d'Afrique **German**: Binsenralle **Spanish**: Avesol Africano
Other common names: Peters's Finfoot (*petersii*)

Taxonomy. *Heliornis senegalensis* Vieillot, 1817, Senegal.
Suggested subdivision of family into two subfamilies places present species in Podicinae alongside *Heliopais personata*. A cline in size, increasing towards south and east of range. Race *camerunensis* may apparently intermix with *senegalensis* in S Cameroon. Birds from Loango coast (extreme NW Angola) formerly awarded separate race *albipectus*, being intermediate in size and range, but not reliably separable. Four subspecies currently recognized.
Subspecies and Distribution.
P. s. senegalensis (Vieillot, 1817) - Senegal E mainly through forested belt of W Africa to E Zaire, Uganda, NW Tanzania and Ethiopia.
P. s. somereni Chapin, 1954 - Kenya and NE Tanzania.
P. s. camerunensis Sjöstedt, 1893 - S Cameroon, Gabon, Congo and N Zaire.
P. s petersii Hartlaub, 1852 - Angola E to SE Zaire, Zambia and Mozambique, and S to E South Africa.
Descriptive notes. 35-59 cm; 340-880 g. Retrices stiffened markedly; small bony knob on carpal joint; first digit carries sharp claw; legs and feet bright salmon red to orange. Extensive grey colouring on male's chin, throat and foreneck gives way to white outside breeding season. Female resembles non-breeding male, but smaller and browner, with more extensive white on head and neck. Immature similar to female, but generally warmer brown above, unmarked with white; buff breast and flanks, latter with faint spotting. Generally an extraordinarily variable species, with considerable difference between individuals even within races, especially in amount of white spotting on back, blotching and barring below, and overall tone of plumage coloration; race *camerunensis* small like nominate race,

but variably darker, without spots or neck stripes; *petersii* resembles nominate race, but larger; *somereni* resembles *camerunensis*, but larger and not quite so dark.
Habitat. Permanent streams, rivers, pools and lakes, with well vegetated banks, particularly with reeds and overhanging tree branches; also occurs among mangroves and flooded rain forest. Typically found in forest zone, but also in wooded savannas. Occasionally observed further out in the open. Occurs from sea-level up to c. 1800 m.
Food and Feeding. A variety of invertebrates, particularly larvae and adults of mayflies, dragonflies, beetles, grasshoppers; spiders, millipedes; crustaceans, small snails, frogs, small fish; occasionally vegetation. Feeds both on water and on land; swimming bird often picks insects off surface; will take prey off rocks and vegetation up to 50 cm above water surface.
Breeding. Season varies with location, corresponding with high water levels; Sept in Sierra Leone; chicks in Nov-Dec in Liberia, in Oct in Nigeria; birds in breeding condition Apr-Jul in Zaire; laying Apr-May in Kenya, Oct and Jan-Feb in Zambia, and Sept-Dec and Apr in Zimbabwe. Pairs territorial. Nest is an untidy flat structure of reeds and twigs, lined with a few leaves; often placed over water, 1-3 m up, on mass of flood debris on overhanging or fallen branch. Usually 2 eggs, sometimes 3; incubated by female only, although male often nearby; incubation period reputedly short; downy chicks white below grading to dark above, with red legs; chicks leave nest within very few days.
Movements. Resident, but colonizes new locations regularly; in South Africa, and probably elsewhere, some wandering takes place, perhaps involving immatures looking for a suitable territory in which to install themselves. No evidence of migration.
Status and Conservation. Not globally threatened. Widespread, but never at high population densities; usually considered to be scarce because is so elusive and so rarely observed. Not uncommon in suitable habitat in Ghana and Nigeria, and probably also in Gambia and Sierra Leone; relatively abundant in Gabon; generally uncommon in E Africa; considered to be threatened in South Africa, and is absent from a number of areas with apparently suitable habitat. Undisturbed patches of forested

rivers are declining throughout the species' range; as species is so difficult to observe, any population declines might easily pass unnoticed.

Bibliography. Beddard (1890), Benson & Benson (1975), Benson & Schuz (1967), Brooke (1984a), Carver & Carver (1979), Chapin (1954b), Chubb (1908), Dennis & Tarboton (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Érard & Benson (1975), Gerhart (1980), Ginn (1977a, 1977b), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Hosken (1966), Johnson (1964b), Jubb (1982), Krienke (1943), Lawson (1966), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Mitchell (1977), Percy (1963), Pinto (1983), Pitman (1962), Rutgers & Norris (1970), Sassoon (1974), Schepers & Marteijn (1993), Short *et al.* (1990), Skead (1962), Snow (1978), Urban *et al.* (1986), Vernon (1983b), Whateley (1982), White (1965).



Genus *HELIOPAIS* Sharpe, 1893

2. Masked Finfoot

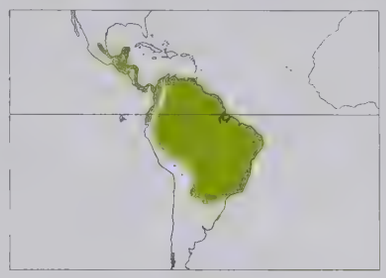
Heliopais personata

French: Grébifoulque d'Asie **German**: Maskenbinsenralle **Spanish**: Avesol Asiático
Other common names: Asian Finfoot

Taxonomy. *Podica personata* G. R. Gray, 1849, Malacca.
Suggested subdivision of family into two subfamilies places present species in Podicinae alongside *Podica senegalensis*. Monotypic.
Distribution. Bangladesh and NE India (Assam) through Myanmar and Thailand to Cambodia and Vietnam; status uncertain in Malaysia and Sumatra, but recently recorded all year round in NW Sumatra.

Descriptive notes. 43-55 cm. Retrices somewhat stiffened, but not as much as in *Podica senegalensis*, and tail appears broad and rounded in flight; slight barring on pale underside; legs and feet green. Small fleshy knob above base of bill present only in male, and only in breeding season. Female somewhat smaller than male; has white patch on chin, throat and forehead. Juvenile resembles female, but lacks black on crown.
Habitat. Fairly varied: well vegetated wetlands, including swamps and overgrown ponds, lake edges, streams, slow-moving forest waterways; flooded forest, including swamp forest; tidal creeks; often among mangroves. Especially found among overhanging vegetation at water's edge. Recent sightings on former tin mining pools and ornamental lakes might suggest some possible degree of adaptability to man-modified sites, or simply reflect rapid disappearance of suitable habitat.
Food and Feeding. Very few data available. Reported to feed on aquatic insects, molluscs, frogs, crustaceans, small fish and some vegetable matter. Food is gathered on water and on land. One bird reported to forage by stirring shallow lake bottom detritus with its feet.
Breeding. Very poorly known. Breeding season reputed to be during rains. Nest is a thick pad of small sticks, hidden amongst vegetation up to 2-3 m above water. Clutch reported to comprise 5-7 eggs; downy chicks dark above, pale below; chicks apparently nidifugous; roles of sexes and further breeding details unknown.
Movements. Little known. Thought to be essentially sedentary throughout most, if not all, of range, but scarcity of records impedes clear view of movement patterns, e.g. in Thailand usually considered resident, but may merely be uncommon passage migrant and winter visitor. Status uncertain in Peninsular Malaysia and Sumatra, where breeding not recorded, and species traditionally classed as possible winter visitor; recently, evidence suggests possible breeding in Malaysia; in NW Sumatra, species recently found to occur all year round in area of swamp forest, so breeding may also be likely. Occasional vagrant to Java.
Status and Conservation. VULNERABLE. World population estimated at fewer than 10,000 birds. Considered to be threatened because of small and declining population, which is severely fragmented. Extensive distribution probably masks low population densities almost everywhere in its range, and species may have restricted breeding range. Main threats include disturbance and development along rivers, as well as rapid loss of lowland forest and mangrove swamps throughout most of range. Protected species in Malaysia.

Bibliography. Ali & Ripley (1980), Chong (1994), Collar & Andrew (1988), Collar *et al.* (1994), Deignan (1945), Harvey (1990), Hawkins & Silvius (1986), Hopwood (1921), King *et al.* (1975), Komolphalin (1993), Lekagul & Round (1991), MacKinnon & Phillipps (1993), van Marle & Voous (1988), Medway & Wells (1976), Milton (1985), Mundkur *et al.* (1995), Perennou *et al.* (1994), Robson (1992), Round (1988), Scott (1989), Smythies (1986), Ticehurst (1929), Wells (1990).



Genus *HELIORNIS* Bonnaterre, 1791

3. Sungrebe

Heliornis fulica

French: Grébifoulque d'Amérique **German**: Zwergbinsenralle **Spanish**: Avesol Americano
Other common names: American Finfoot

Taxonomy. *Colymbus fulica* Boddaert, 1783, Cayenne.
Suggested subdivision of family into two subfamilies places present species alone in Heliornithinae. DNA analysis suggests possible link between present species and Aramidae. Monotypic.
Distribution. SE Mexico S through Central America and throughout most of N South America mainly E of the Andes, as far S as Bolivia and NE Argentina.

Descriptive notes. 26-33 cm; 120-150 g. Unmistakable. Smallest member of Heliornithidae; lacks the stiffened retrices of *Podica* and *Heliopais*; white tip to tail conspicuous in flight; feet conspicuously banded, legs striped, yellow and black. Male has bill dark above, pale horn below. Female slightly smaller than male, with cinnamon patch on cheeks and side of neck, scarlet eyelids and red upper mandible. Outside breeding season, most of these features lacking and female resembles male; bill retains same colour pattern, but duller. Juvenile similar to non-breeding adult, but generally duller.
Habitat. Forest streams and rivers, especially quiet backwaters; also freshwater lakes and ponds. Typically found along margins of water with thick and overhanging vegetation.
Food and Feeding. Little known. Mostly takes aquatic insects (adults and larvae), including dragonflies; ants, beetles and spiders that have fallen into the water; also crustaceans, amphibians and small fish; some seeds. Normally feeds from water surface, but also known to forage on land.
Breeding. Males reported to be more territorial during spring breeding season in N of range; elsewhere probably related to rains; laying Jun-Jul in Panama, female in breeding condition in Jan in Colombia. Nest is platform of twigs in tangle of vegetation 1-2 m above water. Usually 2 eggs, sometimes 3; incubation by both sexes, for period reported as only lasting 10-11 days; chicks altricial, carried by male in special skin pockets beneath wings (see page 214).
Movements. Local resident. No indication of migration, but birds may turn up as accidentals outside normal range.
Status and Conservation. Not globally threatened. Like other members of family, rarely observed so numbers unknown. Wide distribution, with apparently low population density. Suitable undisturbed habitat is disappearing in much of range in the face of human activity and development. Uncommon to fairly common in Mexico; uncommon and local in Panama, Colombia and French Guiana. In Brazil, species can survive in dammed water-holes beside highways; at night, birds sometimes caught in nets by fishermen.

Bibliography. Álvarez del Toro (1970, 1971), Anon. Class AVES

Order GRUIFORMES

Suborder RHYNOCHETI

Family RHYNOCHETIDAE (KAGU)

- Medium-sized flightless birds, with long crest feathers, and distinctively banded wings.
- 55 cm.

- New Caledonia.
- Forests and certain types of shrubland.
- 1 genus, 1 species, 1 taxon.
- 1 species threatened; none extinct since 1600.

Systematics

The Kagu (*Rhynochetos jubatus*) is the only extant species in a monotypic family, Rhynochetidae, within the order Gruiformes. Another, larger species, *Rhynochetos orarius*, has been described from sub-fossils found in Holocene deposits on the coast of New Caledonia, which date back some 2000-4000 years. The distinction between the two forms is based almost entirely on a slight size difference, and this raises doubts as to whether or not it really is a separate species.

The Kagu was first placed with the Ardeidae because of similarities in plumage coloration with herons and egrets; the Kagu's powder-downs are also characteristic of members of the Ardeidae. Since 1862, it has been placed with the Gruiformes because of greater similarities in internal anatomy, agility of movement on land, the coloration of the chicks and eggs, and the change in coloration between the chick and the adult (see Morphological Aspects). Amongst the Gruiformes, the Eurypygidae of South America and the Mesitornithidae of Madagascar have been cited as probable near relatives of the Kagu, and these associations have been considered to suggest a close link between the Kagu and the original fauna of Gondwanaland. Another gruiform family recently suggested to be related to Rhynochetidae is the extinct Messelornithidae of Europe and Northern America.

Over the years, systematists have found that the determination of the Kagu's closest affinities within the Gruiformes is problematic, and to date this still remains a matter for speculation. The species has features that are not shared with other Gruiformes, and, in some cases, with other birds: the unique rolled corns that cover the nasal openings, and were used to give the species its genus name, *Rhynochetos*, from the Greek *rhis* meaning "nose", and *chetos* meaning "corn"; a unique blood composition, with one third of the red blood cells and three times the haemoglobin content of those found in all other birds so far analysed; and large eyes. DNA hybridization evidence has so far been unable to establish clear relationships. Karyotype comparisons suggest that the Kagu is close to the Gruidae, which are hypothesized to be representative of the ancestral Gruiformes, which, if correct, would imply that, as a family, Rhynochetidae does not appear to have evolved recently. In the long term, further genetic comparisons should help to provide a clearer picture of the Kagu's relationships to the other families within the order Gruiformes.

Morphological Aspects

Kagus are flightless, with an appearance of something between a small heron and a rail. An obvious feature is their ash grey and white plumage, somewhat unusual for ground-living forest birds, which tend to be cryptically coloured. The long crest feathers, which extend to the lower back, are a distinguishing characteristic, but are often difficult to detect unless displayed. Adults vary considerably in weight between about 700 and 1100 g, depending on seasonal and individual size variation, as no sexual size dimorphism is known.

A striking feature of the Kagu, and usually concealed, is the patterning on the upper side of the primary wing feathers. A dominant background of alternating lateral black and white bands radiates out from the feather bases. Appearing to overlie the bands is a finer pattern of brown, black and grey coloured "stripes" extending across the primaries, mainly between black bands two and three (counting from the feather tips). An initial investigation of wild birds showed that the striped pattern tended to be much more extensive on females, so this could provide a simple method to sex quite a high percentage of birds. No other sexual dimorphism is evident.

Although the wings do not appear reduced in size, and total wingspan amounts to roughly 77·5 cm, the musculature necessary for sustained flight is lacking. Birds use the wings to assist their movement, when they are forced to flee from danger, over steep descents, or when they are climbing in difficult terrain. At these times, the birds often flap their wings, but they can also glide during airborne descents. The wings are also important for behavioural displays, in which the strikingly patterned primaries are particularly evident (see General Habits).

The large, dark red eyes and longish orange-red legs and bill are prominent features associated with the Kagu's lifestyle. The eyes are positioned in such a way as to give the Kagu excellent binocular vision, which should aid in the capture of small soil and litter fauna, particularly in the reduced light of the forest understorey. The longish bill measures about 60 mm; it is narrow, pointed and strong, and is often used for shallow digging in soil and humus to capture prey (see Food and Feeding). The rolled corns, or flaps, covering the nasal openings would seem to be designed to keep particles from entering them during probing activities.

Considerable agility in movement, aided by the longish, strong legs and relatively compact build, enables birds to travel

The Kagu is a highly improbable-looking bird to find inhabiting a subtropical forest floor. Its shape is vaguely pigeon-like and reminiscent of an upright clockwork toy, the greyish and white plumage and brightly coloured bill and legs looking bizarrely out of place against the forest background. It has two features not found elsewhere in Gruiformes: the large eyes and the rolled corns or flaps that cover the nasal openings. The narrow, pointed bill is well adapted for digging to find prey and the longish, sturdy legs equip the bird for walking long distances without undue effort. Although flightless, it uses its wings extensively in displays and to help it glide or flap over sometimes difficult terrain. The spectacular crest and splendid patterning of the primary feathers are unsuspected when the bird is at rest.

[*Rhynochetos jubatus*, New Caledonia. Photo: Michel Gunther/ Bios]

long distances relatively quickly, over a wide range of types of terrain (see Movements), and run surprisingly fast, for example to escape danger. When foraging, their movements are usually slow and measured, with their heads tilted forward to detect prey, except when they are making a dash to capture food (see Food and Feeding). When they are not foraging, their movements can involve running, for example in disputes and interactions with other Kagus. When standing still, investigating a human intruder, birds commonly move their heads, and to a lesser extent their bodies, in sudden discontinuous movements. Birds can hold their tail feathers in a raised position somewhat in the manner of rails, but this behaviour does not appear common. As with their overall appearance, their movements too are a mixture of those of a small heron and a rail.

Powder-downs may also be beneficial for the Kagu in the New Caledonian environment. These relatively abundant feathers are distributed in tracts over much of the body, and may provide a degree of waterproofing and insulation from extremes of tropical weather. The presence of powder-downs provides another similarity with the herons.

The start of moult appears to be closely linked with the first substantial summer rains, which tend to come around January. The timing coincides with increased food supplies associated with the hot, wet weather. Completion of primary feather moult can take about two to five months, probably depending on food levels over the rainy season. Overlap of moult and breeding activity can occur in late nesting pairs (see Breeding).

The plumage of chicks consists of a combination of light and dark browns, with fawny streaks on upperparts, making chicks nearly invisible amongst the leaf litter on the forest floor. Juvenile plumage first appears when chicks are about 20 days old, and is complete by the time they are three to four months of age. Initially, the plumage is finely banded grey and brown, making it duller than that of adults, except on the head, crest and primary wing feathers, which are adult-like in colour. The change to adult plumage is mostly complete after about two to three years. However, some remnants of juvenile plumage patterning, such as faded banding on wing-coverts, secondaries and tail feathers, appear to be present on some birds for longer than this, so the complete change could be a gradual process. By the time full adult plumage has been attained, the bird is whitish on the underparts, with paler ash greys on the breast, head and crest feathers, and darker shades on the back, tail, wing-coverts and secondary wing feathers.

Habitat

Special morphological features allow the Kagu to move freely over most terrain and catch a wide range of prey in a variety of vegetation types, rather than limiting its choice of habitat (see Morphological Aspects). Thus, the bird is considered a generalist in selection of foraging areas, as long as sufficient soil and litter prey is available for it to eat. The species was widespread in mainland forests in the past and its now restricted distribution is due to human-associated factors (see Status and Conservation).

Kagus still occur from near sea-level up to mountain summits over 1400 m in altitude, principally in habitat ranging from rain forest to the drier forest at lower altitudes. They are occasionally found in certain shrublands associated with the island's ultrabasic rocks where prey is sufficiently numerous, for example along water systems or at higher altitudes, but they do not occur in the sclerophyll forest remnants along the west coast. Birds are not known to forage in thick undergrowth, such as ferns and grasses, where movement is restricted, or in the open and short shrubland associations on the ultrabasic rocks, where suitable ground prey is in very limited availability. However, they do negotiate through these vegetation types between foraging areas, often using tracks made by feral pigs or humans.

Birds usually roost within their foraging areas, but occasionally choose sites outside them, for example in neighbouring open shrubland. Steeper terrain tends to be selected, especially for ground roosts which are commonly in sheltered positions created by rocks (see General Habits). Nesting sites are sited within a pair's territory, commonly close to good food supplies.

General Habits

A Kagu pair occupies a permanent territory of about 20 hectares, defending it year round against other Kagus. Territorial disputes between birds can involve close contact fights, when the wings and bill are used against the other bird. Such disputes are not known to result in serious injury in the wild, but they can do so in captivity.

Defence and threat display behaviour mainly involves the use of the wings and the crest. When adults are threatened, they fully open their wings to show the patterned primary feathers, but the wings are not usually flapped. A parent defending a chick, though, can flap its fully opened wings on the ground in a typical distraction display, feigning injury. In these defensive displays the crest feathers are partially raised in "Roman helmet" fashion, but they are not usually fanned. When captured, birds right up from the age of young chicks instinctively spread their wings forward in a "shield" showing the banded primary feathers. In the case of an adult bird, the "shield" often covers the bird's head. Wing patterning may have acted to confuse or intimidate past predators, such as large reptiles. In disputes with other Kagus, and in courtship, the wings are used in a "Strutting" display: birds adopt an upright posture and hold their wings down and forward in the form of a cape, while circling each other. In this display, the wing patterning is concealed, and the crest is fully raised and fanned.

Kagus are diurnal, foraging most of the day while there is sufficient light, especially outside the summer rainy season, when food supplies are less plentiful. During the rainy season birds can rest between foraging bouts, when they often preen themselves. Preening activity is mostly carried out at night at the roost-site, either in the early evening before birds sleep, or the early morning before they leave their roost. Within pairs, birds tend to be solitary outside the breeding season, coming together occasionally to sing or roost, or while foraging. During this time partners can have different, but overlapping, foraging areas.

Kagus are rarely known to drink in the wild and appear to obtain most of their water needs from their food (see Food and Feeding). Water is scarce during the annual dry periods, which last for up to several months, and at these times water is commonly unavailable at high altitudes. Because of their relatively sedentary lifestyle, birds would benefit from a physiology which reduced the need for drinking water.

Temperature influences roosting behaviour at higher altitudes. Here, Kagus mostly roost sheltered on the ground in cooler months. When average minimum temperatures in the forest are above about 12°C, birds roost more often above ground level, mostly on low branches. The closely inverse relationship between increases in the minimum temperature and ground roosting frequency suggests that Kagus are sensitive to temperature change, and alter their roosting behaviour accordingly. Thus, it appears that birds seek shelter on cold nights to try to keep warm, perhaps to limit loss of body weight (see Food and Feeding). In the Rivière Bleue Park, in low altitude habitat, birds rarely roost on the ground, doing so mainly in strong wind or heavy rain during summer cyclones. Although average minimum temperatures are several degrees warmer at lower altitudes, winter night temperatures in the park can fall well below 12°C, when, interestingly, Kagus there still roost mainly above ground level. Factors such as habit or type of terrain may also influence whether birds roost on or above the ground.

Ground roost-sites in sheltered positions are mainly those naturally created by rocks, but they can be sited under tree roots or in cavities in dirt banks. Birds at higher altitudes also very occasionally roost on the ground on warm nights, but in unsheltered positions. Excrement at ground roosts sheltered from the rain is often preserved, the build-up of deposits at some sites suggesting their regular use over many years. Because Kagus have particular preferred roosting areas, sheltered ground roost-sites can be close together. This has probably led to the mistaken reports of multiple "nests" at the same site (see Breeding).

Kagus perch above the ground mainly on live and dead branches or tree trunks, but they sometimes use vines, raised roots or isolated rocks. Perches average about 30 cm in diameter; they are usually in climbable positions about 1·5 m above the ground, but they may be up to about 4 m high.

Roost-sites can be located throughout a bird's home range, but they tend to be grouped in favourite areas. While some sites are used regularly, others are used infrequently, or even only once. At high altitude, some ground roosts and above ground roosts are used seasonally, in association with cold and warm temperatures, respectively. A roost-site can be used by both partners, either when birds are separate or when they are together, but ground sites are rarely shared on the same night. During breeding activity, partners often share the same perch or are only several metres apart.

Voice

The sound created by Kagus singing has been likened to something between a rooster crowing and the bark of a young dog, and is distinctly different between the sexes. The female's song is shorter and more rapid than the male's. The initial "gou gou gou gou...", call which both sexes can make before singing, is also used by partners to locate each other. It is quite loud before duet song, but softer when used alone as a locating call.

Pairs sing a duet in the early morning, usually beginning at first light, but rarely at other times. The singing constitutes territorial behaviour, the birds often turning to broadcast their song in different directions. However, birds of either sex can sing alone, and this may be more related to the business of searching for a mate or partner than to territorial behaviour. Kagu song can be heard up to about 2 kilometres away in the wild, depending on the terrain and weather conditions. Juveniles make their first singing attempts from about six months old, or possibly earlier, joining in with their parents when they duet in the mornings.

Pairs in the same vicinity tend to sing one after the other. Generally, the higher the bird density, the longer the morning singing period. Singing can last up to about one hour when many birds are present, during which period two or more pairs often duet at the same time, and individual pairs often sing more than once. Duets, usually initiated by males, can last up to about 15 minutes. Birds sing in all months, but more frequently over the breeding season.

Kagus have a range of different soft calls, for example a warning hiss, another for communicating with a chick, and a

Sensing that its chick is in danger, the adult Kagu initiates a typical distraction display which involves the raising and flapping of its fully opened wings, and these almost scrape the ground when they are lowered. The crest is usually raised and fanned as the bird feigns injury in order to take the intruder's eye away from the vulnerable chick. It is at such moments that both wings and crest are shown off to perfection.

[*Rhynochetos jubatus*, Pic Ningua, New Caledonia. Photos: Gavin Hunt]

soft clucking which is made during disputes with other conspecifics.

Food and Feeding

Kagus find most of their prey in the litter or soil, and less commonly just above the ground on rocks and vegetation, and on and in old logs. Birds also apparently foraged on beaches in the past, and they are reported to try to catch small animals in fresh water, from the edge of shallow pools. The species is only known to eat animal prey, taking a wide range of available fauna including larvae, spiders, centipedes, bugs, cockroaches, millipedes, beetles, snails, worms and lizards. The last five of these prey types are considered to be the most important. Amphipoda and Orthoptera species are relatively common in the forest litter at high altitudes, where the birds feed on them too, despite the rapid springing movements used by such animals when disturbed.

Kagus spend a considerable amount of foraging time standing motionless, often on one foot, listening and watching for prey. They sometimes stand on wood or rocks in an apparent attempt to get a better view of the forest floor around them. While standing on one leg, some birds try to flush out prey by gently brushing the litter with the open or half closed foot of the free leg. Once prey is detected, the bird will either move closer and stand still again with its head down and bill pointed directly at the probable prey area, or make a rapid "Run-strike" attack to catch the prey. Prey is often not caught on the first prey attack, and the bird must then use its bill to move litter and sticks or dig in the soil, pulling out soil in its bill, before finally catching its quarry. The feet are not used to move litter or soil, or scratch away debris. The relative importance of both hearing and sight in foraging is not known, but the number of prey items detected by sound may be considerable. Kagu digging marks in soil are obvious signs of their presence, and a hole about 7 cm deep by 5 cm wide remains, with soil spread out on one side of it. A consequence of searching for prey in soil is the large amount of this material that is present in the Kagu's excrement.

The Kagu is adept at pulling worms from soil. It usually pulls the worm out complete, but, if it breaks, the bird can drop the broken section then pull the remainder out, eating the dropped section last. The species also eats large millipedes, which are common in forest at low altitude. Most other birds avoid these animals as potential prey because of the noxious substance they secrete, but the Kagu simply breaks them into pieces before eating them; no ill effects have been recorded. The bird also regurgitates pellets, mainly in summer months, and these generally consist of entire snail shells or the parts of large nocturnal beetles.

New Caledonia's subtropical climate can be extremely variable, largely due to the cyclical El Niño effect (see Volume 1, page 341), which brings drier conditions to the island. However, a general seasonal weather pattern exists, which is responsible for changing the prey availability for Kagus, and also the prey type taken. Warm temperatures between September and March see prey such as beetles, millipedes, centipedes and lizards much more common. Worms and snails are far less numerous for the first two to four months of this period, the main dry season, but they become plentiful over the summer rainy season, from January to March. Prey is most abundant during the passage of summer cyclones in the rainy season, as these bring hot, wet weather. Dry conditions can also occur between periods of rain in summer, because of high temperatures, and resulting in lower food supplies for the birds. In the cool season, from April to August, soil conditions are generally damp, but a short dry period in the first two months is common. Kagu prey, such as lizards and beetles, are less active or in larval stages, respectively, over the cool season, when night temperatures can drop to below 5°C in July and August. Cockroaches are common year round in the forest litter, but their importance to Kagu diet is unknown.

The precise period when the Kagu's prey is least abundant is not known, but it definitely occurs some time in the main dry season. Changes in the body weights of non-breeding birds gives an indication of low prey levels, although cold temperatures may also cause a certain deterioration in body condition (see General Habits). At high altitude, body weight is generally lowest around late October, just before there is a significant change to wetter and warmer weather in the dry season. Body weight data for birds at low altitude are limited, but weights may be lowest around October as well, if not later, because of the hotter and drier conditions compared to high altitudes. Kagu body weights are highest at the end of the rainy season about March and April, when maximum weights for individuals can be as much as 20% or more above their lowest levels.

Breeding

Kagus have a low rate of reproduction, almost always raising at most one chick per year. This is not unusual for an island bird which evolved with little or no predation, and which displays notable longevity, commonly living over 20 years in captivity, as this facet potentially enables an individual to raise many offspring during its lifetime. Species showing these characteristics are extremely vulnerable to disturbance, such as increased predation (see Status and Conservation).

Kagus are monogamous, and pair establishment is generally long term, perhaps normally for life, although separation and remating have been recorded. Pairs breed on their territories (see General Habits). In the Rivière Bleue Park the main nesting period is from June to August, and most eggs are laid in July, but late breeding pairs nest up until December. Thus, breeding usually begins in mid-winter, before the start of the main dry season in September. This means that worms, for example, are quite

Display as a defence mechanism is common among Kagus even from an early age. The chick cornered by the photographer tries to escape detection by crouching down instinctively and extending its wings forwards and around it in a wide fan. The banded primary feathers are already developing, the mainly fawn and dark brown coloration helping the chick to melt into the leaf litter around it.

[*Rhynochetos jubatus*, New Caledonia. Photo: R. Seitre/Bios]

plentiful for feeding to young chicks. The two known nesting dates at high altitude were in early December, suggesting a much later breeding season there than in the Rivière Bleue Park, probably associated with the colder climate at higher altitude.

The factors influencing the timing of breeding are poorly known, but both availability of sufficient food supplies (see Food and Feeding) and tropical weather patterns are probably important determinants. Birds can lose some 200 g during incubation, so they probably need to start off with substantial body weight, or at least with access to adequate food supplies. Incubation generally seems to end before the summer rainy season begins, even though it is associated with plentiful food supplies; this wet season may not be ideal for nesting, and it is used by the birds for moulting.

Pairs generally breed each year in the Rivière Bleue Park. In the park, the loss of an egg or chick usually results in a second, often successful, nesting attempt two to four months later, starting well into the dry season, but before January. Birds may need the relatively long inter-nesting period to regain body condition after the first attempt. Nesting frequency at high altitude is little known, but two pairs on the same peak apparently failed to breed in 1993, a dry El Niño year.

The members of a pair remain in close proximity for about three weeks before the egg is laid. Little is known about Kagu courtship in the wild because it is difficult to observe, but captive pairs perform the "Strutting" courtship display (see General Habits), which often ends in copulation; the display may only be used in the early stages of breeding activity. After the "Strutting" display, one captive male performed what appeared to be ritualized nesting behaviour while holding a leaf in his bill.

Nests can be little more than the leaves, or the ground, that the egg is laid on, but most are simple constructions of layered leaves, 10-35 cm in diameter, gathered from around the nest-site. In the Rivière Bleue Park, nest-sites are not well concealed, if at all, but are often placed up against low vegetation, tree trunks or old logs. The only nest-site described at high altitude, at 1100 m, was well sheltered amongst rocks. Kagus lay a clutch of a single egg, which measures 43-47 x 59-65 mm and weighs 60-75 g. The egg carries smallish dots and blotches, umber and darkish grey in colour, that are intermingled with, and often overlie, similar light grey markings, scattered over a light creamy brown background.

Breeding duties are shared equally by the pair. The birds take 24 hour shifts when incubating, changing over around noon, which allows both of them to forage for a considerable period each day. Some ritual "Leaf-tossing" is carried out by the bird moving off the nest. At dawn, the incubating bird will sometimes leave the nest or young chick for over 30 minutes, in order to sing with its partner, perhaps also taking the opportunity to forage. Incubation lasts 33-37 days, which is rather long for an egg of this size.

Chicks are semi-precocial. Most chicks hatch with their eyes closed, and they do not usually move from the nest until they are about three days old. Parents will incite a chick less than 24 hours old to leave the nest, if they feel that it is threatened. While in the nest, the chick is fed and brooded by its parents, which take more or less alternate shifts of about one hour each. Chicks gradually move away from their nests after about three days, walking awkwardly at first between rests. Some travel up to 150 m from the nest in the first week. Chicks are fed on most of the typical items that adults eat, especially worms if available. Parents are exceedingly patient when feeding young chicks: an adult holds prey in its bill, close to the chick's head, and softly calls until it opens its bill, a procedure which can take quite some time; the parent then places the food in the chick's mouth. After about two weeks, chicks actively demand food, taking it from the parent's bill.

Chicks are cryptically coloured amongst the forest floor litter. When the parents signal danger, the chick remains motionless, or quickly hides amongst cover, until it is called again. The parents, sometimes helped by older offspring, will defend a chick, by trying to distract or intimidate the source of the threat. As an indication of the parents' determination to defend their chicks, captive birds will even attack a human intruder by biting at the intruder's legs.

Until the chick is around six weeks old it is brooded by one parent at night. The parent arranges a rough bed of leaves on the ground, usually up against cover, for the chick to sleep on. After six weeks, no bed of leaves is made, but the chick continues to sleep on the ground in the company of one of its parents. At 8-10 weeks of age, the chick begins to perch at night, at first on wide objects, such as fallen tree trunks.

The parents continue to feed the chick until it is about 14 weeks old, around which time it becomes independent. After this, they gradually spend more and more time away from it. A juvenile can remain on its parents' home range for up to six years or perhaps more, often leaving it for short periods. Consequently, a pair with high breeding success can have several offspring of varying ages in the vicinity, and as many as five have been recorded at the same site. Males can start breeding at two years of age; the age of first breeding for females remains unknown at present.

Movements

Movements vary considerably for individual birds, depending on their social status. Established pairs mostly stay within their territories, especially when neighbouring territories surround them. Territory boundaries do not appear well defined, and some overlap of foraging areas between neighbouring birds occurs; this is probably more likely outside the breeding season or when prey is not plentiful. Birds can travel widely within their home range during the day, for example foraging on one side of their range in the afternoon and roosting 500 m away on the other side that same night. They move regularly around their current foraging ranges, possibly on a more or less rotational basis.

In the Rivière Bleue Park, pairs with territories encompassing both damper, low-lying ground and adjacent sloping terrain "migrate" within their territories. When weather conditions are dry they forage almost exclusively on the flat, damper areas, but when soils are wet they also forage on the slopes.

At Pic Ningua, the deaths of many Kagus due to dog predation (see Status and Conservation) resulted in the remaining birds leaving, or changing their existing territories. The survivors increased their home ranges into areas where birds had been killed, and three widowed females quit their territories and wandered widely over the mountain. Two of these females made short visits to surrounding valleys at around 500 m in altitude, where other Kagus lived, away from their usual foraging areas at about 1250 m in altitude. One ascended 750 m in altitude over two days. The third female was found at an altitude of 300 m, perching with another bird; it may have repaired there and established a new territory.

Again in the Rivière Bleue Park, juveniles from about 11 months old make excursions from their natal area before pairing and establishing a territory. At first, they usually make short visits of only one to several days into neighbouring territories. Older juveniles can travel several kilometres away before returning, and in one case a bird stayed away for over a year. Two females aged 30 and 38 months left their natal areas and established territories about 2 km and 8 km away respectively. The age at which males may leave their natal areas on a permanent basis is unknown.

This adult male Kagu has been bamboozled into a "Strutting" defence display by a dummy bird placed on its territory in the wild. This display involves the adoption of an upright posture, the erection and fanning of the crest feathers and a subsequent spreading of the wings, which are held down and forwards like a cape, while normally the two birds would circle each other. Territorial rights are fiercely defended and infringements can lead to hotly disputed fights, but serious injuries are not usually suffered by birds in the wild.

[*Rhynochetos jubatus*, Pic Ningua, New Caledonia. Photo: Gavin Hunt]

Relationship with Man

The Kagu's place in indigenous Kanak culture varies between tribal regions. Around Hienghène, it is not prominent in legends, but plays an important role in tribal traditions. People are given the bird's name ("Kavu" in the local language), Kagu feathers were used in the chiefs' war head-dresses, and their song is sung in war dances. Also, the various calls of the Kagu are seen as different "messages": those hearing these messages would go to the chief for an explanation, for example a call to war. In the Houaïlou area, Kanaks call the Kagu ("Kagou" in their language) the "Ghost of the Forest", possibly due to its ghost-like coloration and its often elusive behaviour.

Before the arrival of Europeans, Kanaks snared and ate Kagus, thus viewing them as a food source on an island where terrestrial game was limited. A drawing in 1774 by a crew member of Captain Cook's Endeavour showed a Kagu next to a tribal house, and this has drawn some speculation that Kanaks had domesticated the birds. The introduction of dogs by Captain Cook facilitated the hunting of the species (see Status and Conservation). In the past, European colonizers and mine labourers also ate the birds, which were thought a delicacy.

The Kagu created much scientific interest among early taxonomists after its description in 1860, because it did not fit easily into any of the known bird families. This resulted in live birds and specimens being sent abroad for study.

Soon after the European colonization of New Caledonia began around 1853, it became fashionable to keep Kagus as pets, and in the past their plumes adorned women's hats. A demand for captive birds created commerce in the species, giving income to some Kanak people. However, the period 1977-1982 saw the ringing of all Kagus known to be held in private hands, a total of 94 individuals, during a campaign to stop the capture of the species. Many of these 94 birds are still living because of the Kagu's long life span. Domestication of birds is unknown, although they can become surprisingly tame in captivity.

In New Caledonia today the Kagu has a high profile because it is rare and the emblem of this French Territory. The species is an attraction for tourists and local inhabitants alike. Because of this, its image and name are used extensively on commercial and administrative logos, and Kagu-related souvenirs are common in tourist shops. Thus, the Kagu's continued survival is important for New Caledonia's image and economy.

Status and Conservation

The Kagu is Endangered and is listed on Appendix I of CITES, with full legal protection in New Caledonia. On a survey in 1991 covering much of the unprotected Kagu habitat, 491 birds were found, including 208 pairs. Most birds were in the Southern Province, with 177 pairs, whereas only a few were located in the Northern Province, with 31 pairs. Thus, birds in most areas appeared to be at low densities, those at higher densities occurring in the remoter areas of intact forest. With the 163 birds, including 63 pairs, known in the protected Rivière Bleue Park, the minimum total population in the wild in 1991 amounted to 654 individuals. The actual population was not estimated to be substantially greater.

Kagus were reportedly still in most of the island's forests earlier this century. Thus, their numbers and distribution have declined severely in recent times, and birds are now unnaturally restricted within their habitat.

The introduction of dogs to the island by Captain Cook in 1774 appears to have been the main reason, direct and indirect,

for the subsequent decline of the Kagu in its habitat. First, dogs facilitated Kagu hunting for the Kanaks, and were probably used for this purpose from soon after 1774, as the pair introduced by Cook is thought to have survived and bred successfully. This may have contributed to the apparent disappearance of the birds from the Panié Range in the north-east of the island, which is close to where the first dogs were introduced. There is no indication of the numbers of birds eaten, and no records to suggest that the practice has continued in any significant way during the last 50 years.

Second, dogs allowed the easy capture of live birds for sale as pets to Europeans. This resulted in localized reductions in the numbers of Kagus, particularly along the east coast. However, this activity cannot account for the species' widespread decline. The practice of keeping birds was significantly reduced from 1977, when existing Kagu protection laws were enforced.

Last, dog predation of Kagus appears to offer an explanation for the continued and widespread decline in their numbers within their habitat. Dogs are numerous on the island, especially in and around the dispersed tribal villages where they are often uncared for. Stray dogs are also common in municipal zones, where they are rarely controlled. However, much of the evidence linking dog predation to the Kagu's decline is circumstantial. For example, Kagus are not found in large numbers near settlements, but only in remoter habitat. This distribution pattern appears to rule out significant long-term impacts of two other introduced predators, pigs and rats, because they co-exist with high densities of Kagus in remoter areas.

In the past, actual evidence of dog predation on Kagus consisted mainly of reports by hunters whose dogs accidentally killed birds. In 1993, a doctoral research project on the Kagu, funded by BirdLife International and the Royal Society for the Protection of Birds (RSPB), documented the dog-related deaths of at least 21 birds at the study site on Pic Ningua. Dogs which strayed from a nearby tribal village killed or injured birds in a series of attack episodes over a period of 14 weeks. The behaviour of the dogs showed how dangerous they are to Kagus, as they returned repeatedly and attacked birds until only a few remained, and they also left birds injured or uneaten, thus killing many more than they needed for eating. They also climbed over 1000 m in altitude to reach the peak, demonstrating that Kagus on mountain tops are not necessarily naturally safe from such attacks. The attacks were detected because the birds there were under study, and many wore radio transmitters; similar attacks on Kagus have probably occurred regularly since dogs were introduced, but have gone unnoticed. The attacks provided graphic evidence that dog predation is presently the number one threat to Kagus in their habitat.

Introduced cats and pigs, and probably rats, also directly threaten Kagus at some stages in their life cycle, but there is little real evidence that their impact on the species is important. Feral cats are not known to kill chicks or adult birds, but one did kill a year old captive-bred juvenile newly released in the wild. Pigs destroyed two of the 26 nests observed in the Rivière Bleue Park during the period 1986-1991, and can thus be seen to have some direct affect on reproductive success. Rats are not known to prey on Kagu eggs in the park, but ship rats are suspected of preying on chicks up to about the age of ten days old. Survival rates of chicks increased when rat poison was distributed in a 100 m radius around nest-sites when incubation began, and again one week before hatching occurred. Further work is needed, though, to verify that the increased chick survival was really due to rat control.

Exploitation activities, such as agriculture, mining and forestry, are also, indirectly, responsible for the Kagu's decline, because their access roads greatly facilitate the entry of stray dogs, and hunters with their dogs, to Kagu habitat. For example, only low numbers of Kagus were recorded in unprotected logged forest in 1991. Logging of Kagu habitat is continuing, and is planned north-east of Mount Do, where the largest concentration of unprotected Kagus, 135 birds, was recorded during the 1991 census. In addition, only a small amount of Kagu habitat is fully protected from mining activities, the main industry on the island.

Pigs, widespread on the island, may have an indirect impact on Kagus, by limiting their numbers through competition in two ways. First, the pigs' habit of uprooting the forest floor causes enormous damage to the forest, and this probably reduces the amount of food available for Kagus. Second, they also eat some of the same prey items as the birds, notably insects and worms, and in relatively large numbers.

The diminishing area of suitable habitat also threatens Kagus in the long term, as only about 20% of the once extensive mainland forests remain. Annual dry season fires, often associated with agriculture, mining and forestry, are the main cause of forest loss, and these have been gradually reducing and fragmenting the Kagu's habitat since human arrival on the island. Habitat directly lost through exploitation activities is also a problem, especially as lowland forests are the most severely affected, further isolating Kagus from each other by restricting them to higher altitudes.

A saving grace for the Kagu is its receptivity to captive management. The first captive-bred bird was raised in Australia around 1920. Since 1977, four permanent breeding pairs have been kept in separate enclosures, totalling one hectare in area, in sclerophyll forest at the Nouméa Zoo, in New Caledonia. From 1977 to late 1994, 61 Kagus were raised with a 44% egg to adult success rate. Pairs at the zoo commonly raise two offspring during the course of a year. Since 1989, the Nogeyama Zoo, Yokohama (Japan), has also been developing a captive breeding programme for Kagus.

In a continuing successful local introduction programme, 32 Kagus bred at the Nouméa Zoo were released in the Rivière Bleue Park between 1983 and 1992, after about 12 weeks of adjustment to natural conditions in a one hectare enclosure situated within the park. Four released males are known to have paired and bred successfully with wild females, but the overall figure is likely to be much higher, as the fate of most of the released birds is unknown.

The successful turn around in Kagu numbers in the Rivière Bleue Park, from an estimated 60 in 1980 to 163 in 1991, has come about through introductions of birds, predation control, and the halt to hunting. Along with the 32 captive-bred birds, ten wild ones had also been introduced by 1992. Dogs, cats and pigs are subjected to continuing control measures, but the latter two species are not well controlled in the park. The management of humans, introduced predators and Kagus has been carried out simultaneously, but dog control is believed to be the principal management technique responsible for the large increase in the bird's numbers.

The future for Kagus in unprotected habitat is extremely precarious because of the dog menace, and the number of pairs protected in the Rivière Bleue Park is insufficient for the long-term persistence of the species. The recent establishment of the Upper Pourina River Valley Reserve bordering the park will protect additional birds and their habitat. However, the number of birds there is small, with only 21 recorded in 1991, and no predator control measures are planned for the area. Undoubtedly, additional managed reserves are still needed to protect significant numbers of breeding pairs. Also needed are efforts to try to reduce the risk of dogs preying on unprotected birds, for example by enforcement of appropriate dog control laws, and promoting increased responsibility about dog ownership by the public.

The Kagu conservation programme in the Rivière Bleue Park, managed by the Southern Province, should continue into the foreseeable future. The current work on Kagus there is focusing on the dispersal, pairing and territorial establishment behaviour of juveniles. The recently completed (1992-1995) fieldwork for the BirdLife International/RSPB research project concentrated on the frequency, timing and success of the Kagu's breeding attempts, and also on possible competition for prey from wild pigs, in high altitude habitat. Future projects centred on the conservation of the Kagu, for example the Biodiversity Project initiated by the Ligue pour la Protection des Oiseaux and funded by the European Union and the RSPB, will likely concentrate on awareness campaigns, to promote the establishment of additional managed Kagu reserves.

Genus *RHYNOCHETOS*

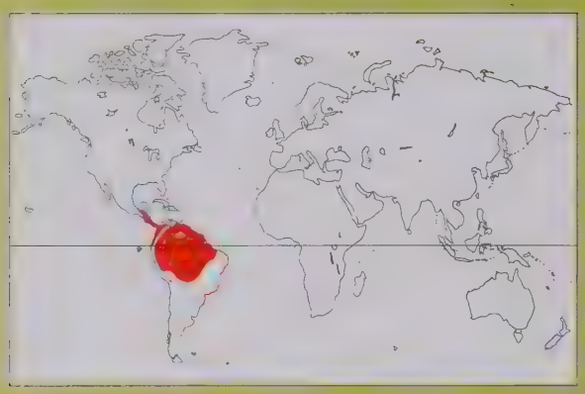
J. Verreaux & Des Murs, 1860

Kagu

Rhynochetos jubatus

French: Kagou huppé **German**: Kagu **Spanish**: Kagú
Other common names: Cagou

Taxonomy. *Rhynochetos jubatus* J. Verreaux & Des Murs, 1860, New Caledonia.
Relationships unclear (see page 218). Monotypic.
Distribution. New Caledonia.



Descriptive notes. 55 cm; c. 900 g. Flightless, but wings appear full-sized. Distinctive ash grey and white plumage, with contrasting longish orange-red bill and legs; underparts whitish, head, breast and crest paler ash grey; back, wings and tail darker. Long crest; large binocularly positioned eyes, iris dark red; rolled nasal corns; and abundant powder-downs. Black and white laterally banded primaries, with smaller area of brown, black and grey stripes (see page 218); striped area tends to be more extensive on females, with no other sexual dimorphism evident. Juvenile similar to adult, but browner and finely banded; bill and legs brown to orange; adult plumage attained at c. 2-3 years of age.
Habitat. Native forests, and occasionally damper and taller shrubland, from sea-level up to mountain summits over 1400 m. Species is generalist in choice of habitat, if sufficient prey available. Usually nests near good foraging areas.
Food and Feeding. Eats wide range of soil and litter prey, especially millipedes, snails, beetles, lizards and worms. Seasonality in prey abundance and in species taken; prey least abundant in the dry season, and most abundant during summer rains. Stands motionless until prey detected by sight or sound; can flush prey by gently brushing litter with foot. Uses bill, but not feet, to move material or dig in soil. Adept at pulling worms from soil. Apparently foraged on beaches in the past.
Breeding. Pairs monogamous, breeding on permanent territories of c. 20 ha. Main nesting period at low altitude Jun-Aug, with most eggs laid in Jul; possibly later at high altitude, due to colder climate, but before Jan; timing probably linked to food supplies and tropical weather patterns. Simple nest of layered leaves on ground, little hidden; sometimes no nest. Clutch 1 egg; incubation 33-37 days; parents share incubation and chick care; chick pale and dark brown with fawny marks; chick semi-precocial, fed by parents until independent at c. 14 weeks old. Successful renesting 2-4 months after loss of first egg or chick common at low altitude; no data at high altitude. Parents, and sometimes older offspring, protect chick. Juveniles can stay on parents' home range for 6 years, maybe more, thus several offspring can be present at same time (up to 5 recorded). Sexual maturity for males c. 2 years; unknown for females. In captivity, oldest bird lived at least 31 years; oldest breeding female aged at least 29 years.
Movements. Established pairs generally sedentary; some overlap of foraging areas between pairs. Moves widely within foraging areas, perhaps rotationally; can "migrate" within territory following food supplies. Females that lose partners can quit their territories and wander widely. Juveniles make short excursions from natal area before leaving permanently; 2 females were aged 30 and 38 months when they left and established territories with partners. Birds agile and capable of moving long distances relatively quickly over most terrain, e.g. ascent of 750 m over 2 days recorded.
Status and Conservation. ENDANGERED. CITES I. Drastic decline since European arrival on island. Within suitable habitat, species now unnaturally restricted mostly to remoter intact areas at higher altitudes. Minimum total population in 1991 was 654 birds (271 pairs); only 163 of these birds (63 pairs) were in protected and managed habitat, the Rivière Bleue Park. Predation by stray and hunting dogs is thought to be main current threat to species. Cats and pigs, and probably rats, also prey on species, but long-term impact may not be important. Pigs may limit densities of species through competition. Exploitation activities have important indirect impacts by facilitating access of dogs to habitat, and causing habitat loss by fires; continuing loss and fragmentation of habitat by fire, especially in lowland areas, further isolates birds from each other by restricting them to higher altitudes. Breeds readily in captivity; a 44% egg to adult success rate achieved. In Rivière Bleue Park, numbers of present species increased substantially, from c. 60 to 163 birds, after bolstering of population by introductions of birds, predator control, and termination of hunting activity; captive-bred birds introduced in park have bred with wild ones. Unprotected birds likely to disappear over time, because of dog predation. Insufficient pairs protected, thus new managed reserves required, and also efforts to reduce risk of dogs entering areas of unprotected habitat.

Class AVES

Order GRUIFORMES

Suborder EURYPYGAE

Family EURYPYGIDAE (SUNBITTERN)

- Medium-sized heron-like birds, with long bill and neck and beautifully patterned plumage.
- 43-48 cm.

- Central and South America.
- Humid tropical and lower subtropical forest, near water.
- 1 genus, 1 species, 3 taxa.
- No species threatened; none extinct since 1600.

Systematics

The Sunbittern (*Eurypyga helias*) is a monotypic species sufficiently different from other living birds that it is placed in its own family, Eurypygidae. At one time it was thought to comprise two species, *E. helias* and *E. major*, but now there is general consensus that it is a single species with three quite distinctive races differentiated by plumage characters, size and apparently non-overlapping ranges, or allopatry. There may also be differences in micro-habitat and food preferences, and probably in behaviour too, but no one has studied all three subspecies in the wild.

The nominate race, *helias*, occurs east of the Andes in lowland tropical South America. It covers a vast range from the Orinoco basin south through the Amazonian area, east and northeast to the Atlantic Ocean, from near sea-level up to 400 m. The other two subspecies are generally found at higher altitudes: *major* from southern Mexico to Ecuador, from tropical up to lower subtropical altitudes; and *meridionalis* only in the lower subtropical zone of southern central Peru at 800-1830 m. Within this huge range encompassing as many as 16 countries, representatives of both the higher and low altitude subspecies occur in only four, Venezuela, Colombia, Ecuador and Peru. This suggests that the Sunbittern was long ago separated by vicariant events, notably the uplifting of the Andes. In Central America, which has had a different geological history, the subspecies *major* is found at altitudes from near sea-level up to 1000 m, and often on both sides of the continental divide.

No fossil Sunbitterns are known, but, in the absence of their possible evidence, relationships with two other living bird families have been suggested. Well over 100 years ago it was found that the Sunbittern shares some morphological and behavioural characteristics with the poorly-known Kagu (*Rhynochetos jubatus*), a bird of the Australasian avifauna that is restricted to New Caledonia (see page 218). More recently, egg-white protein evidence has also implied this affinity. The other relationship may be with the painted-snipes (Rostratulidae), two species, one southern Neotropical and the other Old World, which share with Sunbitterns some behavioural characteristics (see General Habits). However, egg-white protein evidence supports the traditional view that the painted-snipes are Charadriiformes, and the resemblances may be a case of convergence.

In a study of the skeletal anatomy of gruiform birds, J. Cracraft postulated strong links between the Kagu and the Sunbittern. He suggested that their phylogenetic relationship and their distribution both indicate that they originate from the Mesozoic biota of Gondwanaland, the supercontinent that was broken up and separated by continental drift in the late Cretaceous and early Cenozoic. If this is indeed the case, a relationship between these two widely separated species is not so surprising. Although the gross anatomy of the Sunbittern and Kagu are dissimilar, they share the same kind of soft, lax feathers. The primaries of the otherwise nearly uniform pale grey Kagu are coloured, striped and vermiculated much like those of the Sunbittern.

Morphological Aspects

Male and female adult Sunbitterns are very similar in appearance, but small differences in the feather patterns of the head and throat make it possible to distinguish the sexes between individuals attending a nest. Occasionally, the female is reported to be paler. The weight of one adult in the wild was 188·5 g, and those of twelve unsexed captive birds were within the range 180-220 g.

The Sunbittern looks somewhat like a horizontal heron, as both the scientific and English vernacular names testify (see Relationship with Man). It has a fairly long, straight, pointed bill, a long, slender neck, a long protruding tail, and legs shorter than in most herons, more reminiscent of those of some Charadriiformes. The legs and feet are orange-yellow in the lowland birds east of the Andes, but in the Central American race they are sometimes much redder. The hallux is short, as in shorebirds and rails. Observations of foraging birds suggest that the species may have binocular vision.

Plumage and overall coloration are particularly striking in this species. The head is black with two prominent white stripes, above and below the eye, and the iris is bright red, while the bill is dark above, and bright orange-yellow on the lower mandible. The throat is white, the neck and breast brown finely striped black, and in some birds there is a long, dark, irregular stripe down the centre of the neck onto the breast. The buff-coloured belly is offset by the white undertail-coverts.

Most attractive of all is the handsome and beautifully variegated dorsal pattern, which is highly cryptic. The nape is brown with fine black stripes, while the back is barred with blackish stripes and vermiculated stripes of olive, grey and white in the subspecies *major* and *meridionalis*, as opposed to nominate *helias*, in which the dark stripes are broader and the vermiculated

Observers of Sunbittern behaviour initially interpreted the wing flash display as having sexual significance, but it is now known to be defensive in purpose. An adult on a nest indulges in a threat display to startle an intruder and thus shows off to perfection the dazzling plumage of its upperwings and uppertail in a sudden explosion of colour and pattern. The impression of terrific size and the eye-like appearance of the roundish chestnut patches are well calculated to strike terror into the eye of any would-be predator.

[*Eurypyga helias major*, Costa Rica. Photo: Michael & Patricia Fogden]

stripes are mixed with buff; the dorsal aspect of the three races is noticeably different. In a generally cryptic bird like the Sunbittern, such variation probably reflects the different amounts of strong sunlight in the lowland and higher altitude habitats. The tail, with rectrices of generally the same length, is irregularly mottled grey and white with two broad blackish bands edged towards the body with chestnut. When folded, the wings continue the cryptic stripes of the back, but display a line of large white dots along the upperwing-coverts.

When open in display and rotated toward the observer, the Sunbittern's wings appear enormous, greatly expanding the apparent size of the bird. On the dorsal surface each wing displays two conspicuous, large, bright, semi-circular chestnut patches, edged with black and white, and set against a vermiculated field of buffy-yellow and grey. These spots might be mistaken by a startled predator for large, intimidating eyes. When fully displayed the long tail is fanned and tipped forward, revealing two broad black bands edged with chestnut, that effectively join the wings in display. The effect of the whole has been frequently been likened to a sudden appearance of the sun (see Relationship with Man).

The bird's feathers are generally lax and soft, like those of owls (Strigiformes) and the Kagu, and this accounts for the silence of the species' flight. Like the herons and the Kagu, the Sunbittern possesses powder-downs, which are absent in all other Gruiformes except the mesites of Madagascar.

As in most bird species, moult takes place after breeding. The ten primaries, with a vestigial eleventh, moult in descendent order. The secondaries are diastataxic, as in many Gruiformes, and moult commences from three centres each proceeding inward in ascending manner, starting with the first, the fifth and the tenth secondaries, but there are some irregularities. The twelve rectrices moult normally, from the centre outwards. Young birds are hatched with abundant down, but have no juvenile plumage, gaining adult-like feathers even before they leave the nest (see Breeding).

The Sunbittern flies with quick flicks and long glides of its broad wings, and, when over water, its flight is low, roughly 1·5 m above the water surface. There are no reports of it swimming. Although the species has sometimes been characterized as a poor flier, one adult, accidentally caught in a mist-net set over mudflats for shorebirds, easily flew more than 150 m across a lagoon, after being released. When Sunbitterns are nesting, their flights from the ground up to nest branches as much as seven metres off the ground is noticeably light, buoyant and precise. These examples, coupled with their display flights above the 10-15 m high canopy at the beginning of the breeding season, suggest that they can fly better than is usually thought.

Habitat

The typical habitat of the Sunbittern is in humid Neotropical forests, generally with an open understorey, and near rivers and streams. Those birds that live at higher altitudes are found in the vicinity of rushing mountain torrents, while those of low altitudes live near slower-flowing rivers and streams, or likewise the pools that are often left standing as the result of flooding during the rainy season.

The association of the species with freshwater sites is no doubt rooted in the fact that much of its food is to be found there (see Food and Feeding). Nests are saddled on tree branches, but always under a closed canopy (see Breeding). The importance of an open understorey is conjectural: did the birds evolve their elaborate displays and vocalizations as a result of the open understorey which enhances both sight and sound, or did they choose this habitat because it makes their displays and vocalizations more effective?

General Habits

Sunbitterns tend to be wary but not shy. They appear elegant because of their slow, deliberate, stately manner, and these cryptic birds are masters of the slow, "melting" move. Rarely, when encountered, do they flee in abrupt haste, as so often is the case with other largish birds, but instead they frequently turn directly toward an intruder and abruptly flash open the large wings, displaying the spectacular ocelli, which look like huge eyes.

In aspect, rather like a heron but with the body held horizontally, the Sunbittern's feeding behaviour is similar to a heron's too. This species is very much at home on swift-flowing forested torrents where it will dart with agile movements from rock to rock or wade in shallow water to stalk its prey, the head drawn back and the formidable bill ready to make a sudden stab forwards as prey comes within striking distance; its accuracy is remarkable. Both vertebrates and invertebrates are included in the diet, and, curiously, food items are often washed, especially when destined for the chicks.

[*Eurypyga helias major*, Costa Rica. Photo: Roger Tidman/ NHPA]

Although early observers suggested that the Sunbittern wing flash, or "Frontal Display", was used in sexual display, numerous accounts show conclusively that the wing flash, and also its variation of a single wing display toward an intruder, is defensive (see Breeding). The "Frontal Display" sometimes lasts for over one minute, and the broad wings are not only fully opened, but are rotated forward, toward the observer, while the tail is raised almost vertically and fanned, as the bird bends its legs, so that the breast is lowered, while the bird itself looks directly toward the viewer.

While standing on the ground, and on and beside nests, Sunbitterns often gently swivel their bodies slowly from side to side in an arc, which, within the context of the use of this common behaviour, might indicate a measure of stress, or a mild threat. A variation of the "Frontal Display" is the "Broken-wing Display", which is used for distraction: the dorsal plumage is ruffled and one open wing is dragged lightly on the ground, while the bird gives rattles, hissing or trilled sounds. Other displays given by adults from the nest are a bittern-like facing, expanding the plumage, serpentine body-swaying, forward bill-darting and treading. The Greater Painted-snipe (*Rostratula benghalensis*) is reported to use many of the same threat displays in Australia, with the same startling effect, using the pattern on its open wings, lowered breast and fanned tail; it also hisses and makes "kak-kak-kak-kak" calls like the Sunbittern, and even its two week old chicks make threat displays (see page 220). The Kagu too uses its patterned wings in similar displays that are associated with threats (see page 298).

Rarely are two Sunbitterns found together, except quite briefly at the nest. In the forest understorey when two birds are seen together it is sometimes an adult still guarding and feeding a juvenile that looks very similar to, and nearly the same size as, its parent.

Voice

In the open understorey of the humid forests inhabited by Sunbitterns, vocalizations are far-carrying. The birds communicate with each other using a number of different kinds of trill, ascending or descending, long or short, harsh or soft. Trill communication has been suggested as being of great importance to the species, because even chicks as young as six days old, while they are still nest-bound, exchange trills with attending adults. Trills are also sometimes combined with bill-clatters, bill-snaps and vocal rattles.

A long, plaintive, somewhat ventriloquial whistle that is sometimes heard may be territorial, and the loud "kak-kak-kak-kak", often made by zoo birds, as well as those in the wild, is thought to serve for advertisement. This loud call also accompanies the aerial flight display (see Breeding). The only duetting reported is the vocal rattle recorded during the display of a pair (see Breeding). Defensive hissing with neck swaying, in the manner of a snake, is a frequent form of nest defence behaviour by both adults and nestlings, when confronted by an intruding animal, such as a human.

Food and Feeding

A large number of different kinds of prey have been identified as being eaten by adult Sunbitterns, and also fed to nestlings. The most numerous invertebrate prey are flies, spiders, dragonfly and dobsonfly larvae, cockroaches, katydids, water beetles, snails and crustaceans, such as crabs and shrimps; earthworms and moths, both larvae and adults, are occasionally taken. Vertebrate prey is frequent, including small fish, tadpoles and frogs. In the *llanos* of Venezuela, small freshwater eels (*Symbranchus marmoratus*) are eaten, as are toads (*Eleutherodactylus*) and lizards (*Norops lionotus*, *Ameva festiva*) in the mountains of Costa Rica. Sunbitterns often wash their food, particularly prey items intended for nestlings.

The Sunbittern stalks its prey with the neck retracted, by walking very slowly along the forest floor or in shallow water; it appears to have binocular vision. Often its stealthy movement is frozen, one leg in the air, just before it makes a lightning-fast head-dart toward prey, and this seldom misses. It will also pick and glean in the forest litter, and in thick moss. In Costa Rica, birds walk slowly upstream in shallow rushing torrents to hunt for dobsonfly (*Corydalis*) larvae. When prey is sighted the birds

poise with the head motionless for up to two minutes before stabbing at the intended victim.

There appear to be few published accounts of feeding in this species. In Venezuela, a Sunbittern foraged along the edge of a muddy pond sometimes wading in to a depth of about 4 cm, and making 15 strikes in ten minutes. The bird appeared to be feeding on small water-skippers (Hydrobatidae) only about 1 cm in size. After stalking for about two metres in one direction in the dappled shade of trees at the pond edge, the bird frequently reversed direction and reworked the same area again. Foraging beside it were Wattled Jacanas (*Jacana jacana*), a Grey-necked Wood-rail (*Aramides cajanea*) and a migrant Solitary Sandpiper (*Tringa solitaria*).

Breeding

Sunbitterns start nesting in the early wet season, which corresponds to late March in Costa Rica, or early May in Venezuela. In the dry season, at a study site in Venezuela, before breeding started, birds frequently made flight displays 10-15 m high, just above the tops of the gallery forest trees. They called the sharp "kak-kak-kak-kak" call, finishing with a trill, while gliding downward with wings outstretched but hanging down from the body, so that the colourful pattern was thus highly visible from a side view. This behaviour is believed to be related to courtship or pair formation.

Once, at this same study site, a case of what appeared to be pair-bonding occurred. At a nest with a single nine day old chick, one of the birds, believed to be the female, began to perform exaggerated begging behaviour, when its mate came to feed the chick, but the presumed female was never fed. The following day, the adults of this nest met on the ground below it after the presumed male made several loud "kak-kak-kak-kak" calls. This bird slightly opened its wings at the wrist and gave an accelerating vocal rattle, finishing with its bill raised vertically and its head tilted over its back. The female orientated herself parallel to him, facing the same direction, and the pair repeatedly gave the head-tilting display in synchrony, usually duetting the vocal rattle. Then the birds began to dip their heads rapidly with their necks stretched forward and their bills held horizontally. Following several head-dips, their heads were thrown back and they duetted with vertically pointing bills. The pair then parted and walked in opposite directions around a pool five metres wide beneath the nest, giving vocal rattles and trills that were not duetted. On meeting, the birds again began the synchronous head-dipping and duetted rattles. This display lasted for nearly five minutes. A few Horned Screamers (*Anhima cornuta*) share the same area as these Sunbitterns, and a form of behaviour described as pair-bonding for screamers (Anhimidae) may be similar (see Volume 1, page 532).

The presumed female of the Venezuelan Sunbittern pair was not seen again, but the male continued to care for the nestling until it fledged. At another Venezuelan nest, a single adult was present during the final nestling days. In Costa Rica one adult, on the nest, also began giving the begging display to its mate and one parent was later seen nearby, but no longer attended the lone nestling on the last five days before fledging. These fragmentary observations suggest that Sunbitterns maintain permanent pair-bonds, and that, when a nestling required only the care of a single adult, the other bird departed, either so that the nest would become less conspicuous, or in order to begin a second nesting attempt. To date, there are no studies of ringed birds that can confirm the permanence of the pair-bond or that second nesting attempts occur in the wild.

A single copulation was observed in the wild, lasting eight seconds. It took place after the close association of a pair that stood together engaging in extensive self-preening, which was also repeated afterwards. Later, the male made a single-wing display, while standing close to the female, and following a series of low trills; this might be interpreted as mate-guarding.

Although Sunbitterns probably maintain permanent breeding territories, this too has not yet been proved with field studies. In Venezuela, at all times of the year, Sunbitterns are found in open understorey gallery forest near permanent water, such as rivers, streams, ponds and lagoons. Nests are always sited under a closed canopy, but often in open, leafless sites, on bare branches over trails or woodland pools of water. The nest, constructed by both sexes, is saddled on a smooth, fairly horizontal tree branch, approximately 1-7 m high. Frequently the nest is set at the site of a small side branch or with some other lateral support, but sometimes without any extra support. The mean outside diameter of the slightly oval cup is about 21·5 x 16·5 cm, but the inside is nearly always about 13 x 13 cm, with depths of 5·4-7 cm on the exterior and 3 cm inside the cup. These fairly bulky nests are usually on small branches of 5-8 cm diameter, but a larger branch of 13·5 cm was used in two successive years. The nest foundations are made of long grass fibres, wrapped into an oval shape and attached to the branch with mud. On this base the birds build up the sides, using leaves, rootlets, moss and mud; the cup walls

An adult Sunbittern removes fragments of eggshell from the nest which now houses the newly hatched chick and a second egg. The normal clutch of one or two pale irregularly spotted eggs requires a full month of incubation, a task shared between the parents. The chicks hatch covered in abundant down varying from pale brown to cream, according to race, though all show black stripy markings on the head, neck and back. They are nidicolous and fairly helpless until about the tenth day when they start to develop more quickly.

[*Eurypyga helias major*, Costa Rica. Photo: Michael & Patricia Fogden]

When the Sunbittern chicks hatch, duties are shared by the parent birds, one searching for food and bringing it to the nest and the other brooding the young. These two captivating scenes feature the same two chicks being fed at the same nest. In the first instance, an adult presents a titbit of manageable proportions to the young, while the brooding parent stands aside, seemingly to supervise the feeding operation. In the second, a gargantuan meal of a whole lizard is on offer to the first greedy taker! The seemingly precarious nature of the nest emplacement is worthy of note. The leaves and vegetation used in the construction are bound together by mud, a requisite which means that Sunbitterns are unable to undertake breeding before the beginning of the rainy season. Often leaves from the support tree are built into the structure, and tiny seeds may begin to sprout on the outside of the nest, all of which helps in camouflage so that eventually, at a casual glance, the nest appears to be a sort of natural excrescence of the tree itself.

[*Eurypyga helias major*, Costa Rica. Photo: Michael & Patricia Fogden]

are deeper on the low side of a sloping branch, so that the cup itself is horizontal. Leaves incorporated into nests are most often from the nest-support tree, or from nearby vegetation. In some nests the bottom of the cup consists of layered leaves and mud, but in others so little material is used that the branch support may be visible. Occasionally seeds sprout in the mud, and increase the cryptic nature of the nest. Nests of this style could not be built without mud; in the Sunbittern's highly seasonal habitats, mud is not readily available until the beginning of the rainy season.

The clutch consists of one or two eggs. The eggs form a short ellipsoid, and are very smooth and moderately glossy; they are pinkish buff, with irregular purplish spots concentrated at the large end. Six Venezuelan eggs averaged 42·7 x 33·7 mm. Incu-

Having swallowed the body, but not yet the tail, of the crushed lizard, this chick has become so bloated that its smothered sibling is scarcely visible alongside it. The parent responsible for feeding the chicks has departed once again in search of further victuals, while its partner has resumed the business of brooding the chicks. Small chicks are brooded continuously for their first six days, and they continue to receive parental care throughout most of their first month of life, until they fledge.

[*Eurypyga helias major*, Costa Rica. Photo: Michael & Patricia Fogden]

bation is carried out by both the male and female and lasts for 29-30 days. In Costa Rica, incubation was continuous and shared equally, with sessions as long as two days early during the incubation period, and one-day sessions during the last twelve days. Costa Rican chicks of the race *major* hatched with pale brown down marbled with black.

Venezuelan chicks of the race *helias* hatch with abundant cream-coloured down, which is marked with black lines on the top of the head, the sides of the neck and the back. One chick at hatching weighed 17·8 g, gave a high-pitched peeping and gaped, but it was unable to grasp with its feet, or hold up its head for more than five seconds. By the third day, chicks still could not stand up or hold the head up for more than 15 seconds, but they shuffled to the edge of the nest on their tarsi, in order to defecate over the edge. Between the seventh and tenth days, nestlings begin to develop more rapidly. Thus, the young chicks, although appearing similar to plovers or snipes at hatching, are nidicolous, and are cared for by the parents until fledging at 22-30 days old. They are brooded continuously by both parents, with shared diurnal sessions of 2-4 hours, until they are six days old.

The off-duty parent brings food for the nestlings and feeds them, while the brooding parent leans aside or stands beside the nest during feeding sessions. Nestling Sunbitterns have a bright pinkish orange gape. They pick single items of food from the tip of the adult's bill, although a two day old chick was sometimes fed by regurgitation, putting its bill inside the adult's mouth. If the chick does not take the food, this is offered repeatedly until accepted. When food is dropped from the nest, the adult will fly down, retrieve it and present it again to the nestling. Most of the regular prey items of the species (see Food and Feeding) have been observed being fed to nestlings, except for moths and shrimps.

On about the nestling's ninth day, the sheaths of the primaries begin to show through the down, and by day 19 the emerging contour feathers are similar to the adults'. There is no apparent juvenile plumage. Around the time that nestlings are no longer continuously brooded, they begin to make a number of adult-like defensive displays in the nest. They practise the wing-spread "Frontal Display" with hissing, the body-sway, head-darting with serpentine neck weaving, and the bittern-stare. Such early development of these forms of behaviour by nestlings suggests that visual defence by Sunbitterns is very important. Two fledglings, perhaps premature, weighed 83 g and 115 g, well below an adult weight of 188·5 g. A 60 day old juvenile followed, and was fed by, an adult on the forest floor; it was nearly adult size, but had yellowish irides and mottled browner plumage.

In Venezuela, two Sunbittern eggs were seen to be taken by wedge-capped capuchin monkeys (*Cebus olivaceus*), but numerous other mammalian and avian predators of eggs and nestlings may account for nest losses. The tayra (*Eira barbara*), the grison (*Galictis vittata*), the ocelot (*Felis pardalis*), the Collared Forest-falcon (*Micrastur semitorquatus*) and the Ornate Hawk-eagle (*Spizaetus ornatus*) are some of the most likely other predators in this study area.

On three occasions, Hook-billed Kites (*Chondrohierax uncinatus*) harassed adult Sunbitterns brooding very young nestlings, but were rebuffed by the Sunbitterns using visual displays, mainly the "Frontal Display", while standing on or beside their nest. Once a pair of Green Ibises (*Mesembrinibis cayennensis*) spent 3 hours attacking a brooding Sunbittern. Singly and together the adults of this nest defended it by using visual displays, most often the "Frontal Display", which intimidated the far larger ibises. This was a dispute over the nest-branch itself and not an attempt to take the chick. Following the successful Sunbittern fledging, that branch was taken over by Green Ibises, which made a nest two metres from the deserted Sunbittern nest-site.

Captive Sunbitterns often lay replacement clutches after a failure. In Venezuela, several times a second nest was found close to the site of an early failed nest, and it was believed the nests were made by the same pair, although none of the adults had been ringed. More than once captive Sunbitterns have raised a second chick after the first fledged in the same season. Therefore, it is quite possible that wild Sunbitterns might, if the rainy season continued, make a second nest after a first successful one, which could explain the early release of one bird, particularly the female, from parental duties at the first nest. Because several nests have been found in subsequent years on exactly the same branches, it has been suggested that Sunbitterns mate permanently. In captivity, both sexes can breed at the age of two.

Sunbittern chicks are unusual in that they develop no apparent juvenile plumage, but shed their downy coats to assume adult feathering directly. This young bird still on the nest shows adult coloration and patterning, but traces of down feathers are still plainly visible. Even at a tender age, the bird is already rehearsing the "Frontal Display", a clear indication of the great significance of this defence mechanism in Sunbitterns.

[*Eurypyga helias major*, Costa Rica. Photo: Michael & Patricia Fogden]

Movements

Sunbitterns do not migrate, and some birds may maintain territories all year round. In a highly seasonal habitat such as the *llanos* of Venezuela, and perhaps throughout much of the range of the race *helias*, where there is a long dry season, birds may be forced to move short distances temporarily to occupy forest areas bordering permanent water, because they feed on so many water-dependent organisms. Subsequently, they reoccupy traditional territories in the following breeding season. However, members of the subspecies *major* that occupy less seasonal sites at higher altitudes might not need to leave their territories.

Relationship with Man

Native people in both Brazil and Venezuela, and perhaps in other Neotropical countries, occasionally keep tamed Sunbitterns around their houses. The birds, taken from the wild when young, are semi-domesticated, free-roaming, and are not pinioned. William Beebe reported such a Sunbittern riding around on the shoulder of its Indian owner. These pet birds are prized for their fly- and spider-catching abilities. F. B. and A. P. Penard said that once brought inside a house, a Sunbittern would take all the insects within a few days. Since tame birds are so tranquil, it is not surprising that the species readily adapts to life in zoos.

The Sunbittern's spectacular displays have repeatedly been the object of awe. Eighteenth century Europeans, on seeing the flashy patches on the wings as resembling a sunburst, called the bird "Sonnenvogel" (Sunbird), "Sonnenreyger" (Sunheron) and "Oiseau du Soleil" (Bird of the Sun), and much earlier than this Spanish speakers had already named it "Ave Sol". In fact, the scientific name originally given to the bird by Pallas in 1781 was *Ardea helias* (Heron of the Sun). Both the heron and sun motifs are perpetuated in the vernacular English name. When Illiger named the genus in 1811, he called attention to another semi-circular feature: when fully displayed the long tail is fanned in conjunction with the wings; the name *Eurypyga* refers to the wide circle created by the tail.

Status and Conservation

Those authors who attempt to assess the relative abundance of the Sunbittern in Central America, where it is represented by the race *major*, describe it as very rare, local or uncommon, whereas nominate *helias* is described as fairly common in the Orinoco basin. Whether there is a genuine difference in the abundance of these two subspecies is uncertain, but precise comparisons between them have not been made.

The earliest behavioural observations of the nesting of Sunbitterns were made in 1865 in the London Zoological Garden, where a pair successfully raised two successive nestlings. There are abundant records of Sunbitterns living in captivity for 25-30 years, but there are no longevity records for wild birds. Zoological birds, both wild-caught and captive-raised, seldom lay more than a single egg in a clutch. An analysis of the Sunbittern Studbook in the USA for 1990 shows that, although 42% of the nestlings died before fledging, 57% lived a year or more. It would appear that enough Sunbitterns are raised in captivity to supply the zoological market, so that the bird, although not at present a listed CITES species, should no longer be taken from the wild for the trade.

Evidence of at least a certain degree of hunting pressure appeared during the 1960's, when P. Slud reported that local country people in Costa Rica said that Sunbitterns were good to eat. A. Wetmore said that they were once spread widely in Panama, "but hunting and casual killing have destroyed it over extensive areas". There are no first hand observations of human hunting of Sunbitterns for food, perhaps because the birds can not be found so easily, as the far more common, typical game species.

In so far as is known, all three races of the Sunbittern would appear to be secure, but extensive loss of their forested habitat to timber extraction or agricultural development is always a threat. Those populations that occupy higher altitude habitats might be the first to come under threat, as these cooler regions are more attractive for settlement to the ever-expanding human populations in the Neotropics. In particular, the subspecies *meridonalis*, which is reported to occur only in the departments of Junín and Cuzco in Peru, would be liable to become threatened much more quickly than the other two races, simply because of its highly restricted range. The other two subspecies have far more expansive distributions, not merely in terms of geographical surface area, but also with their occupation of a wider range of altitudes. Any form of extensive damming or channelling of rivers is likely to be highly detrimental to the survival of local Sunbittern populations.

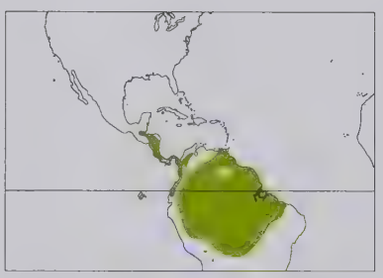
The single most important effort man can make for the well being of the species is to preserve, and protect adequately, large areas of suitable habitat where Sunbitterns are presently known to occur. Such reserves would, of course, also protect the bird's prey species, as well as a wide diversity of other birds and other organisms.

Genus *EURYPYGA* Illiger, 1811

Sunbittern

Eurypyga helias

French: Caurale soleil **German**: Sonnenralle **Spanish**: Tigana



Taxonomy. *Ardea helias* Pallas, 1781, north-eastern Amazonian Brazil.
Some morphological and behavioural affinities with Rhynochetidae and Rostratulidae respectively. Three subspecies recognized.

Subspecies and Distribution.
E. h. major Hartlaub, 1844 - Guatemala to W Ecuador; possibly also S Mexico.
E. h. meridionalis Berlepsch & Stolzmann, 1902 - SC Peru (Junín and Cuzco).
E. h. helias (Pallas, 1781) - Colombia, Venezuela and the Guianas S through Amazonia to E Bolivia and C Brazil.

Descriptive notes. 43-48 cm; one bird 188·5 g. Unmistakable. Cryptically coloured, with straight bill, slender neck and long tail; two white lines cross blackish head; upperparts vermiculated brown, black and grey; throat and vent white, belly pale buff; iris red, lower mandible and legs orange-yellow. Juvenile similar to adult, but iris yellowish, not red. Races separated mainly on pattern of upperparts and size: *major* larger, greyer above with thinner, dark bars, and sometimes with bill and legs much redder; *meridionalis* slightly smaller than nominate, and generally greyer above with very dark bars.

Habitat. Humid forests with open understorey, near water, in form of stream, river, pond or lagoon; from near sea-level up to 1830 m. Race *meridionalis* occurs only in lower subtropical zone, nominate *helias* only in tropical zone, race *major* straddles both zones.

Food and Feeding. Many aquatic organisms, both invertebrate and vertebrate, including flies, spiders, dragonflies, beetles, cockroaches, katydids, larvae, crabs, shrimps, snails and earthworms, as well as fish, tadpoles, frogs, eels, lizards and toads. Stalks prey by stealthy approach, with neck and head drawn back, then using lightning-quick forward lunge to capture prey, on land and in shallow water. Solitary feeder.

Breeding. Nests at beginning of rainy season, when mud available to enable nest construction; late Mar in Costa Rica, early May in Venezuela. Nest built mainly of mud, grass and leaves on narrow tree branch. Normally 2 eggs (1-2); incubation by male and female c. 30 days; chicks hatch with abundant down, pale brown (*major*) or cream-coloured (*helias*) with some black markings; fledging c. 22-30 days; may be dependent on one or both parents for food up to 2 months after fledging or longer. Sexual maturity of captive birds at 2 years, for both sexes. Has been known to live over 30 years in captivity.

Movements. Sedentary. Short displacements may occur in highly seasonal habitats where water dries up, birds moving to nearby permanent water-bordered sites.

Status and Conservation. Not globally threatened. Status poorly known, due to inconspicuous nature; no figures available for overall numbers or densities. Species widespread, but relative abundance varies from fairly common in some areas to very rare in others: rare to uncommon in N Guatemala, Honduras and Panama; declining in Costa Rica; widespread but naturally uncommon in French Guiana; traditionally said to occur in Chiapas, S Mexico, but no museum skins known, and no recent records from the area. Total dependence on forest with water makes species sensitive to habitat changes on both large and small scales. Easily tamed, and readily lives and breeds in captivity.

Class AVES

Order GRUIFORMES

Suborder CARIAMAE

Family CARIAMIDAE (SERIEMAS)

- Large, long-legged terrestrial birds, with hawk-like head and long neck and tail.
- 70-90 cm.

- C & E South America.
- Grassland, savanna, dry woodland and open forests.
- 2 genera, 2 species, 2 taxa.
- No species threatened; none extinct since 1600.

Systematics

The seriema family comprises two very closely related and perhaps even congeneric species, which have been placed in the monotypic genera *Cariama* and *Chunga*. The oldest fossil pertaining to the suborder Cariamae comes from the Paleocene of Itaboraí in Brazil, and several other records of related fossil families are known from the Oligocene-Pleistocene of South and North America. More distantly related fossil birds, pertaining to the family Phororhacidae, have been found in deposits of the Oligocene in France and the Eocene of Germany. Some of these extinct, flightless, sometimes giant, gruiform birds of the Tertiary, collectively known as phorusrhacoids, are thought to be the ancestors of present day seriemas.

The systematic relationships of the seriemas within the Gruiformes are uncertain, and even their placement within this order has been disputed at times. However, the prevalent view has been that they are more closely related to the cranes (Gruidae) and their allies than to any other birds, although their peculiarities have been considered sufficient to keep them in a separate suborder, in which they form the only extant family. They superficially resemble certain diurnal birds of prey, especially the Secretarybird (*Sagittarius serpentarius*) of African savannas, which is itself a bird of uncertain affinities, and which was even grouped with the seriemas in some older classifications.

A number of morphological characters shared by the seriemas and the trumpeters (Psophiidae) could point to a close relationship between these two groups, but the seriemas have normally been placed instead nearer the bustards (Otididae), which have quite similar cestode parasites. Adding to these uncertainties, recent work on DNA suggests that seriemas might perhaps be grouped with the Kagu (*Rhynochetos jubatus*), a species which, on a morphological basis, had never been suggested to be among their closest allies. Indeed, seriemas and Kagus do share some plumage and behavioural similarities, such as a nuchal crest and contrastingly barred flight-feathers that are displayed in similar manners during courtship and aggressive encounters, as well as similar loud barking cries. Nevertheless, the DNA evidence available for the Kagu was apparently rather limited, so this possible link should be regarded as highly tentative. Amidst all this uncertainty, for the time being at least it seems that the allocation of the seriemas to the Gruiformes is warranted, an idea reinforced by the evidence of DNA.

Morphological Aspects

The seriemas are among the largest ground-dwelling birds endemic to the Neotropics, and, in fact, are surpassed in size only by the rheas (Rheidae), with which they share a great deal of the same habitat and range, as well as a few convergent morphological and behavioural features.

The Red-legged Seriema (*Cariama cristata*) can measure up to 90 cm and weigh 1·5 kg, and is thus only slightly larger than the Black-legged Seriema (*Chunga burmeisteri*), which measures 70-85 cm and weighs around 1·2 kg. Standing up in a normal posture, they can reach 60-70 cm, which is approximately only half the height of the Greater Rhea (*Rhea americana*).

Seriemas have soft, somewhat loose-webbed plumage, especially on the neck and the underparts, and both species have elongated feathers on the hindneck that form an inconspicuous nuchal crest, rather reminiscent of that of the Kagu. A noticeable frontal crest, unique among South American birds, is found only in the Red-legged Seriema, and is certainly its most outstanding morphological feature. This crest is formed by a tuft of slender, slightly stiffened feathers that are inserted in the forehead around the base of bill. These feathers are kept permanently raised, partially directed forwards, and can be 7-10 cm long, thus exceeding the entire length of the culmen.

The greyish plumage of the seriemas is generally tinged with shades of brown, being lighter on the underparts and showing fine vermiculations on the upperparts. The belly is whitish, and the long tail is patterned black and white, as are the flight-feathers. These wing and tail patterns, however, are seldom appreciable, as seriemas possess short, rounded wings and rarely take flight. The sexes are alike or nearly so in plumage coloration. Immature plumage is similar to that of adults, but with the head, neck and back more strongly marked. The general coloration of seriemas frequently has a cryptic effect in their seasonal, often semi-arid habitats. The aberrant melanistic coloration recorded in a captive Red-legged Seriema, supposedly from Paraguay, may have been induced by some extrinsic factor such as high humidity, and has been interpreted as possibly corresponding to an hypothetical pattern of coloration of the ancestors of *Cariama*.

The vivid colours of the bill and legs of the adult Red-legged Seriema contrast with its dull body coloration, as with its pale yellow eyes, that stand out from bluish periophthalmic areas of bare skin. Young birds, however, have these parts dark grey or blackish, as does the adult Black-legged Seriema. The moder-

Bearing a superficial resemblance to the Secretarybird of Africa, the Red-legged Seriema is a remarkable-looking, large terrestrial bird with a long neck and tail, extremely long legs and a slender, elongated body. The colourful red bill and legs contrast with the rather sober body plumage. The pale yellow eye is ringed by pale bluish bare skin. The black and white barring on the wings is seldom seen, except when a bird is displaying. The most singular feature is the conspicuous frontal crest, a loose tuft of feathers held erect and sprouting from the forehead.

[*Cariama cristata*, Apore, Goiás, Brazil. Photo: Haroldo Palo Jr/ NHPA]

ately long, stout bill of seriemas has a strongly decurved culmen and ends in a small hook, thus resembling that of raptors.

Seriemas have very long, rather slender legs with extensively bare tibiae, and proportionally long necks. They stalk slowly about while not disturbed, but, like rheas, are swift runners, and, when chased, a Red-legged Seriema may attain speeds of 25-40 or even 70 km/hour. The running of the Black-legged Seriema has been described as "a graceful glide, at once both swift and deceiving". Birds only take flight occasionally, and this is usually not sustained for long, consisting of a burst of rapid flapping followed by a glide. Birds typically take flight only in order to escape an obstinate, hard-pressing pursuer, or in order to reach an elevated roost, although lower perches tend to be reached by jumping.

In accordance with the birds' cursorial adaptations, their feet have three short front toes and an elevated smaller hind toe. This conformation means that seriemas, like New World vultures (Cathartidae), are unable to catch prey with their feet, which are used instead, for instance, to step on food items while these are torn into smaller pieces with the bill (see Food and Feeding). Nevertheless, aided by very sharp claws, especially the large claws of the innermost toes, they may cling to the bark and thus climb the trunks of small trees, or similarly jump through the branches of vegetation with the aid of occasional flaps of the wings.

Habitat

Seriemas range over a variety of semi-open and relatively dry areas in the South American tableland east of the Andes and south of the Amazon. Included are some of the drier landscapes of the continent, such as the thorny scrub and other semi-arid woodland areas in the region of the *caatinga* in north-eastern Brazil and the Chaco in parts of Bolivia, Paraguay and Argentina.

The stronghold of the Red-legged Seriema is in the grassy, savanna-like *cerrados* of upland central Brazil. These usually occur on deep soils in a markedly seasonal sub-humid, tropical climate, with rainfall concentrated in the six summer months. Termite mounds, scattered over grassland areas, are one of the most characteristic features of this landscape. They may be locally extremely common and provide favourite look-out and singing posts for seriemas. Further south, the species is also found in the grasslands and *monte* woodland in subtropical parts of its range in south Brazil, Uruguay and Argentina.

The Black-legged Seriema seems to favour xeric wooded habitats in more lowland situations, being restricted basically to the Chaco and *monte* woodlands, while the Red-legged has expanded its range by colonizing man-created "grassland" and other semi-open habitats in parts of Brazil which of old were covered by tropical forest (see Status and Conservation). The two species are partially sympatric from southern Bolivia through the Paraguayan Chaco to Argentina. Locally, in northern Argentina and Brazil, the Red-legged Seriema occurs further upland and may reach elevations of 2000 m, for instance above the tree-line in the Itatiaia massif in south-eastern Brazil. At a study site in the Paraguayan Chaco, the two species were sympatric but appeared to be segregated by means of seasonal asynchrony controlled by the temperature, as the Red-legged became less abundant during the warm season, whereas the Black-legged was less frequent during the cool season. However, home ranges were apparently exclusive within, but not between, species, implying that other ecological differences are likely to exist.

Red-legged Seriemas, like other large predators in central Brazil, are not scared away by fires, which rule the region of *cerrados* during the annual dry season and are also still regularly used as common agricultural practice in many other parts of South America. On the contrary, they may often be seen in recently burned or grazed areas, where injured or disabled large arthropods and small vertebrates are more readily available as prey.

Although seriemas may forage in extensive *campos* or cultivation in which trees are non-existent, they tend to avoid these areas unless woods are present nearby, as their nests are invariably placed in trees, either in a more or less isolated situation or at the forest edge.

General Habits

Most frequently, seriemas are seen singly or in pairs, but they also occur at times in small groups of three or more birds; each group is almost certainly composed of a pair and their offspring. The members of a pair or of a larger group forage together and keep close to each other; they are very wary and always alert to the least disturbance, and when one of them is startled and runs, it is quickly followed by the other or others. In certain circum-

stances, a bird may prefer not to run to try to escape a pursuer, but instead it hides by lying down quietly, for instance behind a fallen log, waiting until the danger has passed. When a bird is under imminent threat of being captured, it may try to overawe the enemy by spreading its wings and tail to display the contrasting pattern (see Morphological Aspects), while the plumage of the neck and the head is ruffled. Ruffling of the whole body plumage occurs when birds defecate.

Seriemas are diurnal birds, although in the breeding season their songs can also be heard before dawn. At night, they roost high in trees, and members of a family group may sleep perched side by side on the same branch. A roosting bird will squat on the branch and, rather than hiding its head in the plumage of the back, it keeps it forward, with the neck shrunk in. During the day, birds rest by sitting on the legs and belly on the ground, and they sometimes sun-bathe, rolling the body over onto one side and spreading the free wing to expose the flank. Dust baths are also taken by both species.

Voice

One of the most outstanding features of the seriemas is, without doubt, their queer voice, which is at the same time the most characteristic and best known of bird sounds in their range. It has attracted the attention of virtually everyone who has travelled through the open landscapes of the South American wilderness, and references to it can be found in the accounts of some of the first European naturalists to visit the continent, such as Marcgraf in the seventeenth century and Wied early in the nineteenth century.

The full song of seriemas is a long, dramatic sequence of very loud yelping cries that form phrases, with a staggered variation in pitch. The quality of these cries has been described as being turkey-like, or recalling the yaps of young dogs, or as somewhat similar to the cries of an *Aramides* wood-rail (Rallidae). This noise can be heard for several kilometres, and may sound rather melodious at a distance. Singing activity is concentrated in the morning, but songs may be heard any time from before daybreak until late in the evening.

Singing certainly has an important role in the defence of the presumably large territory that is required to support a pair of seriemas and their young. One member of a pair usually responds to the song of the other by joining it in a duet, and sometimes a rather discordant chorus may be formed by more than two members of a family group singing together. An apparently continuous song may result from the partial overlap and frequent repetition of individual songs. Often, several such concerts can be heard at once, coming from different individual birds or different groups that are far apart and are responding to each other. In order that their vocal performances may carry farther, birds normally sing from a perch, which may be a termite mound, a fence post or a tree. A singing bird opens its mouth wide, and bends its neck, throwing its head back until it nearly touches its back during the loudest portions of the song. Members of a pair may leave their positions and continue singing while moving forward to inhibit the progress of a conspecific intruder of their territory. Young seriemas start singing the adult song by the age of 2-3 weeks, soon after leaving the nest, and thus may help their parents to defend a territory.

A low-intensity begging call of a single note has been reported in a two week old Black-legged Seriema. Other sounds recorded include a "growl" given by an irritated adult Red-legged Seriema; this species also may utter a "squeak" when courting and sometimes when resting.

Food and Feeding

The diet of seriemas consists largely of animal food, notably including a large variety of arthropods, especially: large grasshoppers, such as *Tropidacris* and *Schistocerca*; beetles, for instance Buprestidae, Scarabeidae, Cicindelidae, Curculionidae, Carabidae and Cerambycidae; and other insects. Birds often forage in areas with cattle and horses, and thus probably benefit by catching insects disturbed by these animals or those that may proliferate around their dung. Other favourite prey items include small vertebrates, such as frogs, lizards, snakes (see Relationship with Man), bird chicks and rodents. Green leaves, wild fruits and seeds are also taken, as well as corn (*Zea*) grains, beans and other cultivated crops, but these items certainly constitute only an occasional and secondary proportion of the diet. Odd as it may seem, the Red-legged Seriema has even been recorded consuming tree gum. Adults of this species brought snakes and worm-lizards to a nest that contained two young.

When foraging, birds walk deliberately, scrutinizing the ground and the lower parts of the vegetation, in search of prey, which is caught with the bill after a careful approach. Seriemas, like raptors, swallow smaller prey items whole, head first, but can use the bill and feet to tear to pieces larger animals, such as a snake or a rat (see Morphological Aspects). In order to kill a vertebrate, such as a frog or a chick, a seriema will hold it in its bill, and either beat it, or, rearing up to its full height, throw it against the ground or some other hard surface; this action may be repeated several times, until the prey is dead. A similar technique may be used to break open an egg, of which the contents alone are eaten, or a snail shell.

Breeding

At present, little has been documented of the breeding behaviour of the seriemas in the wild, and even the information obtained from captive birds is relatively scant. Particularly poorly known in this regard is the Black-legged Seriema; most of the following account thus refers to what is known about the Red-legged Seriema, although a fairly large amount of extrapolation would probably be not unreasonable.

The start and duration of the breeding season possibly vary locally throughout the birds' range, which encompasses areas under the influence of very different climates. Most of the breeding activity seems to occur in the period from September to May,

Seriemas are much more frequently heard than seen. The lengthy song, well known to local people and travellers alike, is remarkable for its loudness and has been likened to the yelping of young dogs or the gobbling of turkeys; indeed, so far does the sound carry that it can be heard at several kilometres' distance. Standing on a termite mound, the bird holds forth with its mouth wide open, a posture beautifully illustrated by this captive Black-legged Seriema. Such vocal performances can be heard throughout the day, but they tend to be most concentrated in the morning.

[*Chunga burmeisteri*, San Diego Zoo, California. Photo: Kenneth W. Fink]

Perhaps slightly surprisingly for such terrestrial birds, seriemas invariably build their nests in trees. The nest-site can be in an isolated tree or on the fringe of woodland. The Red-legged Seriema's nest is placed 1-5 metres up the tree, occasionally higher, and the bird typically gains access to it in stages, by jumping up from branch to branch. It is a fair-sized construction of small sticks, twigs and branches, lined with leaves and mud or cattle dung. Both parents help in the building process which may last as much as 30 days.

[*Cariama cristata*, Mato Grosso, Brazil. Photo: François Gohier/ Ardea]

which in central Brazil corresponds to the rainy season (see Habitat), and to be concentrated in the spring and early summer, at least from this region southwards, while it may extend to the autumn and early winter further north in the semi-arid region of north-east Brazil.

Seriemas are solitary in their breeding habits and usually silent in the immediate vicinity of the nest. Pairs keep at a considerable distance from each other, and nests may be scattered over a large area. Fights involving birds kicking one another have been observed during the breeding season, or at the start of it; these were not apparently linked to a particular nest-site, but rather to the establishment or maintenance of a larger territory. In one of these fights involving two birds on one side and one on the other, the entire fight, a long, tenacious conflict, was accompanied by intense vocalization, which continued after the single bird had been forced away.

Courtship displays of the Red-legged Seriema include an exhibition to the female of the male's contrastingly barred flight-feathers, which are exposed by lateral stretching, accompanied by a twist of the wings. There is also a ceremonial strutting walk, during which the male slightly raises its nuchal crest to one side, while the bill is held pointing vertically downward.

The nest is always placed in a tree, usually one to five metres above ground level, but on occasions as high as nine metres up. It is situated so that the adults can approach it on foot, generally reaching it by means of a series of jumps with the odd flutter. In order to facilitate such access, the nest may be sited on a sloping tree, or where a series of nearby branches may act as stepping stones. The nest itself is a large, rough platform of sticks and twigs, lined with leaves and clay or cattle dung. It is constructed by both members of the pair in roughly 30 days.

Seriemas usually lay two eggs, sometimes three. These measure 57-72 x 46-50 mm in the Red-legged and 56-61 x 42-46 mm in the Black-legged, and are white with a few brownish and pale purple spots, though they may become stained brown by the nest lining and the adults' feet. Incubation is carried out chiefly by the female and lasts 24-30 days.

The chicks are nidicolous and are covered with thin pale brown down, mottled darker brown on the back; the down is remarkably long and hair-like on the head. The young birds are fed by both parents, leaving the nest by the age of about 14 days, when they jump down to the ground and immediately follow their parents on foot. It appears that sometimes only one chick is reared, but it is not clear how often this happens or why. In captivity, young of the Red-legged Seriema fledged at about one month old. A newly-hatched chick of this species may weigh a mere 40 g; adult-like plumage, and adult weight of about 1·5 kg, may not be attained until the birds are 4-5 months old. The age at which they reach sexual maturity is not known.

Movements

Seriemas are generally sedentary and territorial. However, in the Paraguayan Chaco some local movements related to temperature were inferred from changes in the relative abundance of the two species in an area of sympatry (see Habitat).

Some sort of long distance dispersal must be involved in the colonization by Red-legged Seriemas from central Brazil of man-modified habitats in the Amazon zone and the south-east of the country, following deforestation in these areas (see Status and Conservation). This species has also reached the isolated, rocky grasslands on the high plateau of the Itatiaia Mountains in south-eastern Brazil. However, an alternative explanation of its presence there is that this may be a relict population from the Pleistocene, when the savannas of central South America were at times more widely distributed than at present.

Relationship with Man

The generic name *Cariama* is a straightforward derivation from the Tupi native Indian word "Çariama", meaning "the one that bears an erect crest" or, more simply, "crested". The popular Brazilian names "Sariema" and "Seriema" originated from the Tupi by influence of the name "Ema", which is used in Brazil to designate the Greater Rhea. Seriemas are, in fact, the only other large terrestrial birds of South American tableland, and, owing to their peculiar appearance, their loud voice and their habits, people have long been interested in them.

In Brazil, as well as in Argentina, seriemas are reputed among countrymen to eat large numbers of venomous snakes and other

The female Red-legged Seriema undertakes most of the month-long incubation of her two brown-spotted whitish eggs. Upon hatching, the nidicolous chicks are covered in long pale brown down which stands up hair-like on the head. They are fed by both parents and, about a fortnight after hatching, they jump down from the nest, and then proceed to follow in the wake of their parents. The young birds develop rather slowly, and may take up to 5 months to attain adult plumage. For reasons as yet undetermined, often only one of the chicks survives.

[*Cariama cristata*, Goiás, Brazil. Photo: Richard Matthews/ Planet Earth]

unwanted animals, and are therefore considered to deserve particular protection. In certain parts of Brazil, it is even said that "where there are seriemas there are no snakes". Although seriemas are known to include snakes in their diet, this popular belief is obviously an exaggeration, as is the one that they are immune to snake poison, which was demonstrated experimentally not to be true.

Seriemas have been kept and bred in aviaries around the world since at least the nineteenth century. Captive birds are easily fed and may survive long: in Uruguay, one bird in captivity in 1972 was known to have been caught more than 30 years before. In their native countries, tame birds kept as pets among fowls around houses may act as sentinels, giving warning of an approaching person or animal.

Owing to their wary nature and their capacity for running, adult seriemas are difficult to catch, but young birds adapt easily to captivity and become tame when taken from the nest only half-grown. Capturing an adult Red-legged Seriema alive may require a skilful horseman, a fast horse, and a long, stressful chase, as some authors reported having witnessed in Brazil. In one of these instances, the horseman died a few days later of heart failure, apparently as a consequence of the effort.

Egg-collecting and the hunting of seriemas for human consumption are not apparently widespread practices, but they certainly occur occasionally around settlements, mainly in the semi-arid areas within their ranges, and the birds may represent an additional source of food for the poor people of these regions. At the beginning of this century, the boiled meat of seriemas served with vegetables constituted a valued dish in the north of Argentina.

Status and Conservation

Neither of the seriema species is globally threatened. Possible threats are large-scale agricultural development of their native habitats and hunting, but these factors are not known to have affected either of the two species, except perhaps locally (see Relationship with Man).

Loss of habitat in the Brazilian tableland is a real threat to a number of grassland and savanna birds that are unable to adapt to man-modified and other semi-open habitats, but this does not seem to be the case of the Red-legged Seriema, which has colonized deforested areas in Amazonian Brazil, for example along the Belém-Brasília highway; and in parts of the states of Minas Gerais and Rio de Janeiro, such as the valley of the River Paraíba do Sul. This species was even found once in southern Brazil inside a large plantation of exotic *Acacia* trees that were otherwise nearly devoid of birdlife, which may also serve to demonstrate, to some extent, its exploratory nature and corresponding colonizing potential. Thus, at least in theory, birds might be able to recolonize areas from which they have been extirpated by hunting, provided this has ceased. Nevertheless, the Red-legged Seriema seems to be much scarcer in any of these secondary areas than in the core of its range. The Black-legged Seriema historically occurs in a much smaller area, and it is not known to be expanding this. Black-legged Seriemas were reportedly hunted by native Indians in the Paraguayan Chaco around the beginning of this century, and this was interpreted at that time as a potential source of local extinctions.

Although precise censuses have not been carried out, both species almost certainly occur at low densities throughout their respective ranges; at one study site in the Paraguayan Chaco Black-legged Seriemas were present at a density of 0·38 individuals per square kilometre. Their far-carrying, easily detectable loud songs probably evolved in association with this, and may be a source of overestimation of their real numbers in any given area by a stationary observer. However, even rough estimates of the present limits of distribution and regional abundance of seriemas are scanty and fragmentary.

While, for instance, the Red-legged Seriema has been considered one of the most frequently seen, and even more frequently heard, large birds in parts of central Brazil, it was rated uncommon in the extreme south of this country, and a scarce and probably vanishing bird in Uruguay. In Argentina, its apparent abundance varies from locally common to scarce, and an isolated population, recently rediscovered in the extreme north-east, is considered to be under pressure from habitat destruction and hunting, as may be populations in the semi-arid region of north-east Brazil. In north-eastern and south-eastern Brazil, Red-legged Seriemas are occasionally offered for sale by local illegal traders of live birds. The Black-legged Seriema seems to be at least a fairly common bird in Argentina, while the situation of both species in the Paraguayan Chaco and in Bolivia remains very poorly documented.

General Bibliography

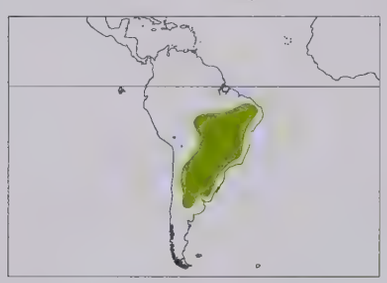
PLATE 22

inches 15
cm 38



Genus *CARIAMA* Brisson, 1760

1. **Red-legged Seriema**

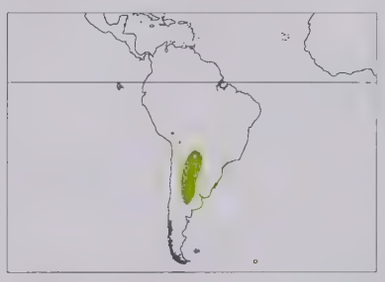
Cariama cristata

French: Cariama huppé **German**: Rotfußseriema **Spanish**: Chuña Patirroja
Other common names: Crested Seriema

Taxonomy. *Palamedea cristata* Linnaeus, 1766, north-eastern Brazil.
Monotypic genus, but could perhaps be merged with *Chunga*. Proposed races *leucofimbria* (S Mato Grosso), *bicincta* (Goiás and Mato Grosso), *schistofimbria* (N Mato Grosso) and *azarae* (Paraguay and S Brazil to Argentina) invalid, as based upon individual variants rather than geographical variation. Monotypic.
Distribution. C & E Brazil through E Bolivia and Paraguay to Uruguay and C Argentina.

Descriptive notes. 75-90 cm; 1·5 kg. Unmistakable, due to prominent loose crest on forehead, red bill and salmon-coloured legs; elongated feathers on hindneck; large, pale yellow eyes, contrasting with bluish periophthalmic areas of bare skin; black eyelashes on upper eyelids; flight-feathers banded black and white. Immature has dark brown bars on crown, neck and mantle; legs and bill grey, recalling pattern of partially sympatric *Chunga burmeisteri*, which lacks conspicuous crest.
Habitat. Open woodland, thorny scrub, savanna and ranchland; also hilly grassland with nearby woods in S Brazil and Uruguay. Typical habitats include *caatinga*, *cerrado* and Chaco. Occurs from near sea-level locally up to c. 2000 m in Argentina and SE Brazil.
Food and Feeding. Mainly arthropods (including grasshoppers, beetles, ants and spiders), insect larvae, lizards, snakes, rodents and other small vertebrates; corn (*Zea*) grains and other crops, wild fruits and tree gum have been recorded occasionally. In captivity, also seen to eat eggs and chicks of other birds. Usually feeds alone or in pairs, seasonally in small family parties; forages by walking slowly, searching for prey on ground or in low vegetation, when foraging bird often remains concealed due to cryptic colours of plumage; some vertebrate prey grabbed in bill, beaten to death against ground and torn into pieces with bill and claws, before being swallowed.
Breeding. Timing apparently varies throughout range: Feb-Jul in NE Brazil; Sept-Jan in C Brazil; Nov-Dec in Argentina. Solitary. Nest is rough, round structure of sticks and twigs, lined with leaves and clay or cattle dung; built on branches of small trees, normally 1-5 m above ground. Usually 2 eggs, sometimes 3; incubation 24-30 days, mainly by female; chicks have pale brown down mottled with darker brown on back, remarkably long and hair-like on head; leave nest at c. 14 days; fledging (in captivity) c. 1 month; adult-like plumage acquired in 4-5 months.
Movements. Sedentary. Some local movements inferred in Chaco zone (see page 237).
Status and Conservation. Not globally threatened. Widespread, but probably at low densities; at most, is commonly recorded at some sites, but certainly nowhere abundant, although frequently heard far-carrying call may give a false idea of abundance in many areas. Hunted for meat in places, but believed to be an important consumer of snakes and rodents, so in other areas is protected by farmers. Under pressure from habitat disturbance and conversion in southern parts of range, but deforestation in SE and Amazonian Brazil has allowed species to expand to new areas of favourable open habitat. Adapts well to captivity, and is easily bred.

Bibliography. Almeida (1988), Barlow & Cuello (1964), Belton (1984), Benirschke (1977), Blake (1977), Burmeister (1937), Canevari *et al.* (1991), Chebez & Maletti (1990), Contreras *et al.* (1990), Frieling (1936), Heinroth (1924), Hellmayr & Conover (1942), Miranda-Ribeiro (1937), Mitchell (1957), Moojen *et al.* (1941), Narosky & Yzurieta (1987), Newton (1889), Nogueira-Neto (1973), Ollson (1979), Olrog (1984), Olson (1973c), de la Peña (1992), Pinto (1964), Redford & Peters (1986), Redford & Shaw (1989), Rodrigues (1962), Schneider (1957), Schubart *et al.* (1965), Seth-Smith (1912), Short (1975), Sick (1985c, 1993), Sick & Teixeira (1979), Vigil (1973), Wied-Neuwied (1820-1821, 1833a).



Genus *CHUNGA* Hartlaub, 1860

2. **Black-legged Seriema**

Chunga burmeisteri

French: Cariama de Burmeister **German**: Schwarzfußseriema **Spanish**: Chuña Patinegra
Other common names: Burmeister's/Lesser Seriema

Taxonomy. *Dicholophus burmeisteri* Hartlaub, 1860, Tucumán and Catamarca, Argentina.
Monotypic genus, but could perhaps be merged with *Cariama*. Monotypic.
Distribution. S & SE Bolivia through W Paraguay to C Argentina.

Descriptive notes. 70-85 cm; 1·2 kg. Similar to partially sympatric *Cariama cristata*, but averages smaller, with an inconspicuous frontal crest, black bill and legs, and dark eyes. Immature has back and upperwing-coverts spotted white; head, neck and breast distinctly barred.
Habitat. Dry woodland, savanna and open forests, typically in Chaco and *monte* woodlands. Apparently restricted to lower altitudes than *Cariama cristata*, and may favour warmer temperatures.
Food and Feeding. Stomachs of a few specimens from Tucumán, NW Argentina, contained beetles, grasshoppers, an entire rodent, green leaves, grass and a few hard seeds. Has been observed near cattle and horses, and may benefit by increased availability of insects disturbed by them. Tame birds ate mainly arthropods, including grasshoppers, cockroaches, beetle larvae, spiders and myriapods, as well as water snails, small frogs, lizards, bats, mice and dead rats and birds; also fruits and green leaves; the corpse of a large bird was beaten against ground before being swallowed.
Breeding. In Paraguayan Chaco, breeds in local summer, season starting Nov-Dec; in Argentina, young caught in Dec. Nests in trees. 2 eggs. No further information available.
Movements. Sedentary. Some local movements inferred in Chaco zone (see page 237).
Status and Conservation. Not globally threatened. Little information available, but species has been considered common in Argentina. As with *Cariama cristata*, however, true numbers may be difficult to estimate due to often heard far-carrying voice; densities are probably low in general, e.g. 0·38 birds/km² recorded in Paraguayan Chaco. At least at beginning of present century, eggs were collected and adult birds hunted for food by natives of N Argentina and W Paraguay.

Bibliography. Beddard (1889b), Bertoni (1929), Blake (1977), Boyle (1917), Brooks (1995), Canevari *et al.* (1991), Contreras *et al.* (1990), Eisentraut (1935), Farnell (1983), Hellmayr & Conover (1942), Insfram (1929), Müller (1973), Narosky & Yzurieta (1987), Nores *et al.* (1983), Olrog (1984), de la Peña (1992), Schmitt & Cole (1981), Schmitt *et al.* (1986), Sclater (1870), Short (1975), Takagi & Sasaki (1980), Vigil (1973).

Class AVES

Order GRUIFORMES

Suborder OTIDIDES

Family OTIDIDAE (BUSTARDS)

- Large to medium-sized stocky terrestrial birds, with long neck and legs.
- 40-120 cm.

- Old World, with greatest diversity in Africa.
- Flat grassy plains, sometimes with scrub or light woodland, in tropical and warm temperate zones.
- 11 genera, 25 species, 44 taxa.
- 4 species threatened; none extinct since 1600.

Systematics

The bustards constitute a distinctive, homogeneous Old World family which most systematists, in this century and the last, have judged to have its ancient origins with the cranes and crane-like birds (Gruiformes), although at one time or another they have been placed with the ratites and the Galliformes. Recent DNA studies confirm the gruiform identity, but place all other members of the order in the infraorder Gruides, while the bustards remain apart in their own infraorder, established over 70 million years ago. This distinctiveness was also suggested by now abandoned work using egg-white proteins.

While certain behavioural traits appear to stress a link with the cranes, wide differences in display structures within the family itself indicate considerable evolutionary isolation. Anatomical features that render bustards distinct from other gruiform birds are the absence of a hind toe and preen gland, dense powder-down tinged pink with light-sensitive porphyrins, and hexagonal rather than transverse tarsal scutellation.

The generic limits recognized within the family continue to fluctuate, as various attempts to simplify the situation come up against genuine and interesting levels of difference. For years it was common for the heaviest and lightest of species, the Great Bustard (*Otis tarda*) and the Little Bustard (*Tetrax tetrax*), to be regarded as congeneric, and for members of both *Neotis* and *Ardeotis* to be placed alongside both, in the genus *Otis*. In more recent times there have been moves to reduce the genera of the smaller species by placing all within *Eupodotis*, although this plays down the very considerable differences not only in morphology but also in behaviour that these species exhibit. If generic separation is a guide to biological diversity within a family, then *Afrotis*, *Lissotis*, *Lophotis*, *Houbaropsis* and *Sypheotides* should all continue to be recognized as reasonable distinctions reflecting long isolated lineages, while *Eupodotis* serves to identify the five ecologically, behaviourally and morphologically most similar species.

The connections between genera, used to determine the lineages and sequence of species, are more vexatious still. *Chlamydotis*, for all its apparent uniqueness, may actually belong close to *Neotis*, given the similarity of its display pattern to that of *N. denhami*, and its seeming replacement of *N. nuba* on the northern fringes of the Sahara. *Ardeotis* and *Neotis* are uncontroversially close, but their relation to *Otis*, with which they share characteristics of size and display type, is confused by considerable morphological differences and by the traditionally assumed proximity of *Otis* to *Tetrax*, based on their sympatry and similarity of bill shape. *Tetrax* seems otherwise to show features, such as size, display type and wing feather modification, closest to *Sypheotides*, which in turn would seem inevitably close, in terms of colour pattern and biogeography, to *Houbaropsis*. These two Indian floricans have reversed sexual size dimorphism, the only bustards to do so, and this sets them at some distance from the black-bellied species in Africa, to which they are at least superficially similar, and with which they have commonly been lumped.

Whether the small African bustards are all more closely related to each other than they are to other genera is a further uncertainty. The "black-bellied" forms seem likely to represent offshoots from a single ancestral unit. *Lophotis*, with its retractile pink nuchal crest, is perhaps the most distinctive genus; but both the stocky *Afrotis* and tall, slender *Lissotis* also appear to be at considerable evolutionary distances from other genera. If, however, only females are compared, it is possible to suggest close links between the black-bellied *Afrotis* and *Lophotis*, and between the white-bellied *Lissotis* and *Eupodotis*. The situation is ripe for revision.

The white-bellied genus *Eupodotis* holds the most species, five, of which the White-bellied Bustard (*Eupodotis senegalensis*) itself, being the most widespread, is presumably the oldest. In southern Africa the Blue (*Eupodotis caerulescens*), the Karoo (*Eupodotis vigorsii*) and Rüppell's Bustards (*Eupodotis rueppellii*) are judged to have evolved from a common ancestor and to have radiated into grassland, karoo and desert steppe respectively. All three are superficially similar in habits and calls. The Little Brown Bustard (*Eupodotis humilis*) of Somalia and Ethiopia would appear to be very closely related to these three species, reflecting that important link between the grassland avifaunas of South Africa and the Horn of Africa, which is otherwise so strongly expressed in the larks (Alaudidae).

While most commentaries refer non-committally to up to 26 species in the family, recent treatments have been conservative in restricting the number to 22. Evidence accepted here suggests this total might better be 25, with the splitting of *Lophotis* (*Eupodotis*) *ruficrista* into three and of *Afrotis* (*Eupodotis*) *afra* into two. If number of species is a reliable guide to origin, then Africa is the first home of the bustards, with 21 present on the continent. Of these, 16 are purely Afrotropical African, and two more, both essentially Sahelian endemics, are almost so: the Ara-

The flattened head, robust body, thickish neck and long legs ending in small feet, together with the cryptic plumage of the upperparts and the stately, rather aloof, bearing are all typical features of the larger bustards, such as the Australian Bustard. This species also sports a black cap with a straggly crest and a black breast band, which is often largely concealed. At a distance, the finely vermiculated plumage on the neck and breast appears whitish grey, and the upperparts light brown, while black and white patterning is prominent at the bend of the wing.

[*Ardeotis australis*, central Australia. Photo: M. A. Chappell/ Animals Animals]

bian Bustard (*Ardeotis arabs*), which penetrates into the Afrotropical part of the Arabian Peninsula, has colonized the Palearctic in north-west Africa, and the Nubian Bustard (*Neotis nuba*) has been recorded just inside the debatable limits of the Palearctic in Mauritania. Three species are Palearctic, although they all occur in North Africa, another three are purely Oriental, confined to the Indian Subcontinent (with one remarkable outlying population in Indochina), and one is Australasian, occurring in Australia and southern New Guinea.

Within Africa the two centres of speciation are East Africa in a triangle formed by the Horn and the Nile above Lake Victoria, and southern Africa south of the Zambezi. Two species of *Eupodotis*, one *Lissotis* and one *Neotis* are endemic to the former region, and four *Eupodotis*, both *Afrotis* and one *Neotis* only occur in the latter. The Kori Bustard (*Ardeotis kori*) is endemic to both, and all the other exclusively Afrotropical species have major populations in them, while extending elsewhere within the continent. Superspecies are formed by the Kori with the Arabian; also by the congeneric Great Indian (*Ardeotis nigriceps*) with Australian (*Ardeotis australis*); by Denham's (*Neotis denhami*) with Heuglin's (*Neotis heuglinii*), unless the latter is closer to the Nubian; by the Black-bellied (*Lissotis melanogaster*) with Hartlaub's (*Lissotis hartlaubii*); and by Savile's (*Lophotis savilei*) with the Buff-crested (*Lophotis gindiana*) and Red-crested (*Lophotis ruficrista*). The southern African Black (*Afrotis afra*) and White-quilled Bustards (*Afrotis afraoides*), and Rüppell's and Karoo Bustards, are parapatric species pairs.

No hybridization has been recorded, except at one point in the contact zone between the Black and White-quilled Bustards. In general, the similarity of female bustards might suggest that the family is more homogeneous than the variety represented by the sexually selected males might imply, but the absence of hybrids may possibly owe itself in part to the nature of the copulation ceremony, greatly protracted in those bustard species in which it has been witnessed. This may be a key mechanism for the prevention of wasted parental investment.

Morphological Aspects

All bustards are highly terrestrial, never using trees, lacking as they do a hind toe with which to grip a perch, although an Arabian Bustard was once found roosting on a bush, apparently seeking to avoid predation at night by jackals. Bustards fly relatively little, and it seems probable that individuals of all species pass entire days, at some seasons possibly weeks, without taking wing. The word bustard comes from the Latin *avis* and a lost Spanish word *tarda*, which does not mean "slow" but is related to the English word "tread", and signifies walking: bustards are birds that walk, generally speaking at a deliberate, measured pace, although they commonly stand motionless for periods at a time. The smallness of their feet suggests that they run very little, especially the heavier species. When they do take wing, however, they prove to be capable of strong sustained flight, the larger species using slow deliberate strokes, sometimes slightly "flicked" at the end of the downbeat, while the smallest species have a much quicker, more duck-like tempo.

All bustards combine somewhat stout if tapering bodies with long legs and necks topped with rather flattened heads and short, straight bills. The proportions are roughly equal from the largest to the smallest species. Tails are all broad, with 18-20 feathers, but are medium-short, the longest being that of the Houbara (*Chlamydotis undulata*). The wings have 10 primaries and 16-24 secondaries, and in flight appear broad and rounded. The legs are quite stout, but the three toes are short, with thick soles and broad claws.

The largest and heaviest bustards are the mature males of the genera *Otis* and *Ardeotis*, which reach over a metre in height, and routinely weigh up to 10 kg, with a staggering 19 kg recorded for the Kori Bustard. The Great Bustard has been known to reach 18 kg, and hunters have claimed 24 kg for the species, which would place it on a level with the Mute Swan (*Cygnus olor*) as the heaviest flying bird in the world. In these genera, females reach roughly two thirds the height and one third the weight of the males, and are very roughly matched in size, but often surpassed in weight, by males of the genera *Neotis* and *Chlamydotis*. Females of these latter are again proportionately smaller and lighter than the males, and they are matched in turn by males of the genus *Lissotis*, but beyond this point mensural dimorphism becomes much less pronounced. The smallest bustards are the three *Lophotis* species, especially Savile's Bustard, the Lesser Florican (*Sypheotides indica*) and the Little Bustard. At a mere 450 g the Lesser Florican is only half the weight of many Little Bustards, although the latter's shorter neck and legs make it a much lower-standing bird.

Bustard plumages are all predominantly cryptic. The mantle, wings and tail are coloured in sand, tawny and buff tones barred, vermiculated or arrowed with sepia or black. White underparts supply counter-shading in open country species, although those that live in high vegetation have black on their bellies and

Strongly terrestrial like all members of the family, Great Bustards are most likely to be seen walking sedately across open grasslands in search of food. They fly little but when they do take to the air, their flight is powerful and majestic, the wingbeats slow and regular. The head and neck are stretched out in front while the legs are held straight beneath the tail, scarcely protruding; no other bustard species displays so much white in the wings or has such a pale head. When flying, these huge birds become highly conspicuous, yet on the ground it is amazing how easily they blend into the landscape.

[*Otis tarda*, Villafáfila, Zamora, Spain. Photo: Jorge Sierra]

sometimes on their necks, presumably enhancing their appearance during the flight displays their habitat requires them to make. The necks of many species are at least partly grey or bluish grey, and there is often rufous on the hindneck and sides of the breast. Black or white commonly features on the head, and most species have an individual crown pattern, often with a slight crest. The bill is usually dull horn and the legs dull yellow, but in a few species these parts are brighter, notably in the two *Afrotis*. The wings in flight often reveal large areas of white on both surfaces, notably in males that in breeding plumage have black on the neck or belly.

The most sexually dimorphic bustards, in terms of plumage, are those in which only the males possess black feathers on the neck (Little Bustard) or on the undersides in general (both floricans, both *Afrotis*, and both *Lissotis*), although non-breeding Little Bustards and Lesser Floricans revert to female-type dress. Otherwise the plumage differences between the sexes are ones of degree, with males chiefly having much brighter colours, at least when courting, than females. In the breeding season males of many species, *Otis*, *Ardeotis*, *Neotis*, *Chlamydotis*, *Lissotis* and *Houbaropsis*, develop elongated filamentous breast plumes that are puffed up in display. The most exaggerated are those of the Houbara, sometimes referred to as the Ruffed Bustard on account of such feathers running either side of the neck as well as down the breast itself. Male Great Bustards grow bushy grey "moustaches" from the base of their lower mandibles, and male Lesser Floricans have a few delightful spatulate feathers on long, bare, upcurved shafts growing from the cheeks.

The mechanisms whereby the filamentous breast plumes are displaced for display are not well understood, although the Great Bustard develops a gular pouch into which exhaled air is diverted through an aperture under the tongue, so that the entire neck becomes grossly inflated. In the Australian Bustard, a similar distortion is achieved by means of a modified oesophagus, and it seems likely that this feature is present in many other species. The Houbara also has elongated crest-plumes that are generally kept concealed. The three *Lophotis* bustards have a curious pinkish nuchal crest which likewise is only revealed in display, and which in shape is akin to the bouffant crest of the crowned cranes (*Balearica*). The male Little Bustard develops a fleshy hindcollar that allows its "hackles" to rise when calling.

The precocial chicks have a plush down subtly camouflaged with dark lines and mottling on paler ground colours varying from buff to tan. However, many chicks, including those of such widespread species as the Arabian Bustard and the three *Lophotis* species, remain to be described. In the Great Bustard, the first contour feathers and bloodquills begin to show after one week, and this first juvenile plumage is replaced by a second within three months, with an immature pre-breeding partial moult at the end of the first year. The adult pre-breeding moult is also partial, affecting the head, neck and breast only. The post-breeding moult is complete, occupying around three months, with flight-feather replacement serially descendant, starting in the primaries with the innermost, although wings may have several active moult centres.

The feathers of bustards are relatively loose, not densely packed, reflecting the high temperatures of their environments for the most part. The birds' down and plumulaceous parts of contour feathers, particularly on the wings and undersides, are tinged basally rose pink with light-sensitive porphyrins. Bustards compensate for their missing preen gland by producing powder-down instead, and they maintain and waterproof their feathers by grooming them with the bill, transferring the powder to all surfaces. They also frequently dust-bathe.

The bill itself is a stout dagger-shaped all-purpose tool, slightly decurved at the culmen. The shorter, broader and more curved bills of the two most northerly species possibly reflects their proportionately greater dependence on vegetable food at least seasonally, the shape converging on that typical of herbivores like grouse. However, the caeca in all bustards are well developed, indicating the dependence of the family as a whole on fibrous parts of plants, while the absence of a crop suggests strategic adaptation to steady rates of ingestion.

Habitat

Bustards are classic denizens of temperate and tropical grassy plains, mostly open in character, largely at elevations well below 2000 m, and always in areas that are at least seasonally dry. They have colonized all major tracts of such habitat in the Old World, also pushing into near-desert and salt steppe on the one

A Kori Bustard makes a most imposing sight as it moves at a stately pace across the open plains, sometimes in the company of big game herds. The African continent boasts 21 out of the world total of 25 bustard species and most of them are endemic, the Kori Bustard being the largest one found south of the Sahara. A male can measure as much as 120 cm tall and weigh up to 19 kg! Although the sexes are similar in plumage, the female is considerably smaller. Two distinct populations exist, one in east Africa and the other in the southern part of the continent, but the differences between them are minor ones of size and plumage detail. Fairly plainly-clad, the Kori Bustard shows certain noteworthy features, especially when seen at close quarters; the bill is dagger-like, the crest backward lying and dishevelled, the throat and neck ashy white with fine darker vermiculations, the tarsi are covered in hexagonal scales, and the feet, small for the size of the bird, have three short, rather broad toes, but no hallux.

[*Ardeotis kori kori*, Kruger National Park, South Africa. Photo: Nigel J. Dennis/ NHPA]

Most bustards are found on open plains, where they can scan far into the distance and have early warning of any danger. Seven of the smaller African species, among them the White-quilled Bustard, opt for less open bush country, clearings in thorn scrub and savanna with tall grass cover, where danger is less readily detected, but concealment easier. This male White-quilled Bustard slinks away into cover with neck and head held in a characteristic alarm posture.

[*Afrotis afraoides damarensis*, Kalahari Gemsbok National Park, South Africa. Photo: Richard Packwood/ Oxford Scientific Films]

hand, and dense bushland and thorny country on the other. This radiation has led to some interesting behavioural and morphological adaptations.

Altogether 18 species, representing the full complement of the genera *Ardeotis*, *Eupodotis*, *Houbaropsis*, *Neotis*, *Otis*, *Sypheotides* and *Tetrax*, are chiefly or exclusively to be found in flat or rolling, broad, open landscapes with vegetation low enough to allow long distance vision. They feed, sleep, display and nest in these habitats, and among these species are those that are most geared to follow rainfall, and indeed to move into burnt areas. The selection of terrain with wide horizons must certainly in part serve as an anti-predator strategy, since the birds are clearly major potential targets for the larger aerial and middle-sized terrestrial carnivores; the strategy trades off the risk of being seen against the advantage of early warning. Planting of hedges and shelterbelts is a common cause of site desertion by Palearctic bustards.

Many of the species above, however, show varying degrees of tolerance to partially closed terrain. The Great Bustard, in the western Iberian Peninsula at least, has a moderate tolerance of oak parkland. The Arabian Bustard also penetrates open woodland in places, and indeed there are some accounts by early observers that suggest an unusual degree of acceptance of such habitat. The only good field observations of the Moroccan race *lynesi* were in a now cleared tract of land actually called the Forest of Marmora, the observer noting that the bird could be found in all but the thickest parts. Kori and Denham's Bustards occupy savanna in parts of their ranges, and the Kori at least is known to retreat into the shade of woodland during the hot dry season in Kenya, and has been reliably reported as sometimes using dense closed-canopy miombo woodland in Zimbabwe. The two Indian floricans occupy grassland tall enough to reach beyond eye level for much of the year.

Seven species, all those in the black-bellied genera *Afrotis*, *Lissotis* and *Lophotis*, generally prefer "bush" in its various forms: light woodland, thorn country, high scrub and tall grass cover in dense savanna or on the fringes of water bodies; there is some evidence that they actively shun, rather than seek, burnt areas. These species have reversed the strategy of the others, having presumably gained in a trade-off between enhanced levels of concealment and the increased risk of ambush; but they are all smaller bustards, and are therefore more capable of rapid take-off in the event of a close-range attack. The flight displays of the males, which also distinguish this group from the others, with the exception of the floricans, are quite possibly used by females to gauge the quality of individual flying, and hence fleeing, capacity.

Male bustards commonly select small prominences from which to display, so such features, although very common, may play some part in the general location of exploded leks within a uniform landscape. Decaying termitaria are much used for calling and display-flight launch "stalls" by the savanna-dwelling Black-bellied and *Afrotis* bustards. The repeated presence of a male in a chosen display stall renders the site identifiable, with the herb layer trampled or the ground flattened. Little Bustard males enhance their bare stalls by defecating on them (see Breeding).

Female nest-site selection is poorly understood, as so few nests have been found for so many species. In general, there seems to be little evidence of differential habitat use between displaying males and breeding females, but Bengal Florican (*Houbaropsis bengalensis*) hens breed in taller, denser grassland than their "mates" use for display, and, similarly, many female Great Bustards choose to nest in the shelter of high cereal crops or dense patches of oak or olive where canopy cover may be as much as 50%; Kori Bustards in Zimbabwe also use semi-open groves of trees. Many one-off accounts refer to nests being placed near small landscape features such as grass clumps, fallen branches, and the like, and it is at least possible that some such bias in site selection exists in this regard, but for what reason remains obscure.

Measures of climate and altitude can sometimes be used to indicate habitat partitioning in species. In East Africa, the 500 mm isohyet generally marks the boundary between the more temperate-dwelling Denham's Bustard and its close relative, the arid-country Heuglin's; the sub-humid Black-bellied occurs mostly above the 1500 m contour, while the semi-arid Hartlaub's remains almost entirely below that level. In south-central Africa, the Red-crested Bustard is apparently replaced by the White-quilled in more open areas; the White-quilled, in turn, is replaced to the north of its range by the White-bellied. This last replacement involves the most open country species of the seven closed country types and perhaps the most closed country species of the 18 open country types; indeed in Kenya, White-bellied Bustards retreat from grassland into woodland shade in the middle hours of the day.

Many species of bustard are tolerant of farmland, so long as it is worked in a traditional, labour-intensive way. In Europe the Great and Little Bustard live exclusively on land cleared and worked by human hand. In many parts of its range the Houbara will forage in crop fields. In South Africa, Denham's, Ludwig's (*Neotis ludwigii*) and Blue Bustards live for large parts of the year on cultivated areas. Disturbed substrates often result in the strongest flushes of vegetation or the most intense outbreaks of

A female White-quilled Bustard peers over the tall savanna grass to see if danger is lurking. This species tends to prefer aeas of grassland where the grass is about 50-100 cm tall. While the male is noisy and conspicuous, the female is secretive and is seldom observed. In general, bustard plumages are all cryptic, but the male boasts brighter colours than the female, as befits their roles: the male's mission is to attract a mate, whereas the female, left alone to nest and rear the young, needs to escape detection at all costs.

[*Afrotis afraoides*, southern Africa. Photo: Peter Pickford/ NHPA]

insects, and so locally benefit some species. Nevertheless, for the most part bustards prefer relatively pristine conditions, and their future will largely depend on such conditions prevailing in the face of increasing human pressures.

General Habits

All larger bustards are known or thought to be at least mildly gregarious. The most markedly sociable of them is the Great Bustard, which is commonly to be found in flocks, usually fairly small and often loose aggregations, although sometimes ranging into groups of 50 or more. The least sociable are perhaps the most desert-adapted forms, the Houbara and Nubian Bustards. Some of the other species flock loosely on migration or when feeding, but most of them are often solitary. Flocks tend to be larger in the non-breeding period, especially in winter, and small or virtually non-existent over the breeding season.

In the larger species the sexes remain segregated by flock and mingle only rarely, as when, for example, two flocks converge temporarily at a particular food source. Males tend to be more consistently sociable; in Ludwig's Bustard any groups appear to be male, while females remain alone. Males also tend to be more philopatric: display grounds are traditional, and in the Great Indian Bustard an individual male will occupy the same territory in repeated seasons. Pair-bonds are not certainly known to form in any of these species, and the frequent reports of "pairs" in many cases seem likely to reflect mistaken, self-perpetuating assumptions about pair-bonding in birds or else refer to female parent and male offspring.

The small African bustards break down into two types: those with black underparts are solitary, occupy less open habitat, and perform spectacular aerial displays; while those with light underparts are gregarious and group-territorial, occupy open terrain, and use their voices for display with no accompanying flight. In three of the latter type, the closely related Blue, Karoo and Rüppell's Bustards, the birds are commonly encountered in small groups composed of parents and the previous year's offspring. Group size is apparently a function of habitat quality, and increases in response to increased intruder pressure, thereby keeping defence costs to a minimum.

In the Karoo Bustard, there is a highly significant negative correlation between group size and rainfall, with the largest group sizes occurring in low rainfall areas. As rainfall decreases, groups tend to be larger and more widely dispersed. In the Blue Bustard, which forms the largest family groups, group size varies seasonally from a mean of 2·8 birds in summer (September-February) to 3·5 in winter, but it is not known whether this fluctuation, presumably produced by breeding recruitment, is accompanied by an expansion of territory size.

By far the most gregarious of all bustards is the smallest species, the Little Bustard. In Iberia and at least formerly in Russia, flocks of many thousands form from autumn through to early spring. There appears to be no clear sexual segregation in these flocks, which evidently reflect a response to predation, the species being much targeted by eagles and large falcons.

Many species, particularly the larger ones and usually when already in small flocks, have been noted to form loose, short-lived associations with herbivorous mammals. This is likely to assist with predation avoidance, although the birds may conceivably be seeking to forage for dung-living insects. On the other hand, the association between the Kori Bustard and Carmine Bee-eaters (*Merops nubicus*) appears to benefit only the bee-eaters, which use the bustard as a "beater", perching on its back and flying up to catch insects flushed from the grass as it passes, although the bustard's apparent indifference suggests that it possibly gains from the bee-eaters' additional vigilance for predators. The Great Indian Bustard is rather less tolerant, however, when used as beater and perch for Black Drongos (*Dicrurus adsimilis*), and as beater for White-eyed Buzzards (*Butastur teesa*) and Red-necked Falcons (*Falco chicquera*), all of which can provoke aggressive responses from the bustard.

The idea that bustards themselves associate with large animals in order to forage on insects that the latter flush has not received confirmation in field observations. However, Ludwig's Bustards assembling at locust outbreaks have been seen to string out in lines to "drive" the insects and thus profit from each other's presence. Very rarely, two species of bustard may group temporarily together: this has been observed in Zimbabwe with Kori and Denham's Bustards, which tolerated each other in spite of their presumed ecological competitiveness.

Known enemies of bustards in Africa include Martial Eagles (*Polemaetus bellicosus*), Tawny Eagles (*Aquila rapax*), Verreaux's Eagles (*Aquila verreauxii*) and Verreaux's Eagle-owls (*Bubo lacteus*). The result is that the open country species, in particular, are highly vigilant, pausing frequently and scanning, necks raised like periscopes. Rüppell's Bustard, a common target of Martial Eagles, makes sudden, very rapid and twisting manoeuvres when in normal flight, particularly when taking off or landing, and these are speculated to be innate "exercising" reflexes that betray a permanent condition of exposure to the risk of avian predation.

In India, nesting female Great Indian Bustards exhibit strong avoidance behaviour towards Egyptian Vultures (*Neophron percnopterus*), whereas other vulture species elicit little or no response. This difference is believed to be due to the Egyptian's singular ability to break open large eggs of ground-nesting birds, so presumably similar responses will be found in African bustards. Other known or suspected nest predators include baboons, warthogs, mongooses and monitor lizards.

The seasonal abundance of food in grasslands, and the fact that these birds are long-lived, slow breeding species with reduced clutch size and precocial young, have led males, apart from those of the genus *Eupodotis*, to abandon pair-bonding and care of their offspring, since this can be undertaken by the female alone. Predator avoidance during nesting is of cardinal importance, and the breakdown of pair formation may even also have resulted in part from the additional conspicuousness of two parents rather than one in open terrain. At any rate, females of all species become supreme mistresses of secrecy and evasion in this season, combining their cryptic coloration with an astonishing physical ability to vanish, by pressing very close to the ground in almost snake-like fashion, even in thin, boot-high grass. They also disperse rather widely to nest, often selecting very secluded and sometimes partially wooded habitat for the purpose; because they are so efficient at hiding, it is very uncertain how far they actually spread for this purpose! The young imprint themselves on their mother over a period of several days after hatching and respond acutely to her different vocalizations, including those that prompt silent, still, hiding behaviour. There are few bird families which invest so extensively in stealth and crypsis to avoid breeding failure.

Faced with ground predators threatening themselves or their eggs or young, bustards have a shock-display in which the bird will face the source of alarm, tilt the body forwards, raise the tail in a broad fan and partially open the wings, the carpals pointing downwards. The effect of this is greatly and suddenly to increase the apparent size of the bird, and must serve to discourage closer approach; the same display is sometimes used towards conspecifics. Females in greater adversity sometimes resort to injury-feigning distraction displays.

The four common activities of bustards over the course of the day are feeding, walking, resting and feather maintenance. Like the majority of diurnal birds in tropical and subtropical regions, bustards are most active in the early mornings and late afternoons, and this is when most feeding takes place. Even so, feeding is, like walking and feather maintenance, conducted with a cautious, steady rhythm, and is rarely hurried. Feather maintenance involves much dust-bathing, birds shuffling on their tarsi, writhing their necks in powdery earth and flipping it back into their ruffled feathers, then grooming the plumage attentively with the bill. Resting, often by simply standing still, but frequently also by dropping onto the tarsi with the belly against the earth and head drawn down, is most characteristic of the period from midday till four or five in the afternoon.

In Houbaras, research using movement-activated transmitters has shown that on moonlit nights males, at least, can be very active indeed, females much less so, but the nature of the activity remains unknown. The Great Bustard has been recorded displaying during moonlit nights. Otherwise, birds at night are assumed to roost with minimal activity, moving slowly in the last light to a place of some seclusion or vantage, but not a traditional site; Great Indian Bustards have been recorded seeking open, bare areas, apparently in response to the presence of wolves (*Canis lupus*) in the region.

Voice

All bustards have some vocalizations, but many of these are confined to situations in which they would not be heard by a field observer, for example contact notes between the female parent and her offspring. Some of these informal sounds are attractive and endearing, but for the most part the self-advertising repertoire of the bustards is composed of relatively primitive booming, grunting and grating noises of little beauty or charm.

The larger bustards are all very silent birds. The females are silent throughout the year, in keeping with their typically unobtrusive demeanour. Male Great and Houbara Bustards behave likewise, relying entirely on visual signals to advertise their presence during the breeding season, although excitable young male Great Bustards can sometimes be heard making a gruff nasal cough (basically an alarm note) as they move around in a group. All male *Ardeotis* produce a guttural far-carrying sound when

On the whole bustards are rather silent birds; most of the vocalizations they make are usually connected with displays during the breeding season. The three members of the genus Lophotis *are unique amongst bustards in producing clear whistles. The Red-crested starts off its advertisement call with an accelerating series of loud tongue clicks. These are followed by long, increasingly loud "kyip" notes, with a ventriloquial quality. Finally, the performance draws to a close with a series of piping "ki-kiwii ki-kiwii ki-kiwii" cries. Bustards often utter their calls from slight elevations such as termite mounds.*

[*Lophotis ruficrista*, Kruger National Park, South Africa. Photo: Janos Jurka/ Bruce Coleman]

displaying, characterized as a roar in the Australian Bustard, a deep boom in the Great Indian, a series of drumming notes in the Kori, and a liquid double-note in the Arabian, sounds that all carry a kilometre or more in still air. Of the four *Neotis*, only Ludwig's Bustard is known to produce a display call, a loud boom. Denham's may do so, but reported observations of displaying birds have been too distant or in too windy conditions to be sure; however, it is authoritatively described as largely silent.

This is certainly true of Bengal Floricans. When startled, or threatening intruders and chasing them away, they emit a "chik" call, given roughly every ten seconds. This rare call is also a component of the display-flight, being given every second for around five seconds in the middle of the flight; but the wing-clapping in its display-flight is a more powerful signal. Lesser Floricans likewise use their wings to produce a noise during their display-leaps, a wing-rattle at the peak of the leap so guttural as to be described as a "harsh frog-like croak" and widely assumed to be vocal in origin. Very few true calls from this species have been reported.

Perhaps the best known sound produced mechanically by a bustard is the whistling of the Little Bustard, from which the Spanish name "Sisón" is derived. The seventh primary is emarginated, and the resulting sound is heard throughout the breeding period, when the male characteristically flies with very shallow, rapid wingbeats. The sound figures in ground displays and display-leaps at dawn and dusk, both briefly preceded by specially amplified, but not far-carrying, foot-stamping accelerandos. The male Little Bustard also has a brief sneezing snort-call, "prrret", which features at the climax of the above displays, but which he also gives repeatedly throughout the spring day.

The small African bustards are much the noisiest of the family. The Black-bellied has a "song" which involves three different notes, a moaning "oooo" followed by a snoring "waaak" or "chikk", then "pop!" Hartlaub's, its close relative, goes "click" very quietly, followed by "tok" and then "boooom". The two *Afrotis* species have almost identical display calls, a clattering, raucous "kerrak-kerrak-kerrak" that continues for several minutes at a time. These species also have similar ground calls, but the White-quilled appears to have two calls not given by the Black Bustard. The songs of the three *Lophotis* species differ somewhat from each other, Savile's being the most distinct, but the species are united in being the only bustards to produce clear whistles. The Red-crested's starts with an accelerating series of clicks followed by long, increasingly loud "kyip" notes, to end in a minutes-long series of piping "ki-kiwii ki-kiwii ki-kiwii" calls.

The group-forming, white-bellied species have fairly similar advertising calls. The widest-spread species, the White-bellied Bustard, has a loud, far-carrying, crowing croak, "kak-warat", close to the Blue Bustard's normally disyllabic "kok-aw". Advertising calls in both Karoo and Rüppell's Bustards are in the form of duets in which the male leads, with his "squark" or "kwaaka": "squark-kok, squark-kok, squark-kok..." in the Karoo Bustard; and "kwaaka-kokka, kwaaka-kokka, kwaaka-kokka..." in Rüppell's. Young males in the family group also participate in this antiphonal calling, falteringly at first but rapidly becoming synchronized with the parent male's voice. The calls of all these *Eupodotis* species carry considerable distances, and commonly trigger response-calling by neighbouring pairs and groups.

Voices of birds are very variously transcribed, and they are very variously interpreted. In due course tape-recordings may reveal that there is a relatively small number of types of vocalization that are common across the family. The alarm call mentioned above for Great Bustard, a gruff cough, "ogh!", is certainly one that many other species appear to possess and use in similar contexts of excitement and stress. The vocabulary of pleasant, quiet calls between mother and young may also prove to be shared by many family members.

Food and Feeding

Bustards are omnivorous and highly opportunistic in their food habits, taking advantage of any local abundance whether of animal or plant, and seemingly capable of maintaining themselves on that single source for at least short periods. Nevertheless, although such biases are frequent in records of bustard food, there is generally a balance that all members of the family strike between animal and vegetable components of their diet. The bustard bill, shortish, straight and stout, is a simple, powerful, all-purpose instrument for snipping off, snapping up, probing, grasping

Bustards are well adapted to life in semi-arid conditions where water is scarce, and in the wild they are not often seen to drink, whereas in captivity where water is freely available they drink readily. It is supposed that wild bustards obtain most of the moisture they need from their food, which includes a large quantity of vegetable matter, but pools, puddles and other sources of water, when encountered, are certainly not disdained. Note the manner in which these Great Indian Bustards set about drinking by resting on their tarsi to reach the water more easily. The bird on the left, its mouth already full, will tilt the head right back before swallowing.

[*Ardeotis nigriceps*, Rajasthan, India. Photo: Joanna Van Gruisen/ Ardea]

Equipped with an all-purpose bill, bustards are omnivorous and opportunistic feeders. They are well known for taking advantage of swarming locusts and grasshoppers, and certain species gather at bush fires to feed on the victims, dead and dying insects and also vertebrates. Almost all bustard species take vertebrate prey at times, mainly small snakes and lizards, like this Kori Bustard. At the same time, research has shown that vegetable matter makes up a surprisingly large proportion of the bustard diet.

[*Ardeotis kori kori*, Kalahari, Africa. Photo: Régis Cavignaux/ Bios]

and crushing, and as such it serves its owner in a wide variety of foraging contexts.

It is commonly assumed that bustards are primarily insectivorous and take vegetable matter as a supplement. However, detailed studies of the gut contents of certain species have shown that vegetation constitutes a very significant proportion of the diet. In the case of the Karoo Bustard, the stomachs of 15 birds all contained animal material, but this made up only 6% of the aggregate volume and 12% of the aggregate mass, and it seems likely that this proportion will be found to exist for most bustard species in normal conditions (that is, when no local infestation of insects is taking place), as post-mortem assessments of diet may often underestimate or ignore the bulk of unrecognizable plant matter found in the stomachs of birds that do not possess a crop.

Bustards take all kinds of vegetable matter. They are keen consumers of green shoots, flowerheads and fresh leaves of plants in the herb layer, with Compositae much favoured in the European steppes. In a recent study of Karoo Bustard stomach contents, leaves were found to have contributed some 40% of the samples, indicating their considerable importance, perhaps chiefly as a source of water, though possibly also as a source of salt, for the more desert-adapted bustards. Soft roots, bulbs and corms are dug up and consumed, and seeds, fruits and berries are taken in season.

Palearctic and Indian bustards commonly forage in cultivated areas. They have a particular taste for legumes such as clover (*Trifolium*) and lucerne (*Medicago sativa*), and for crucifers such as black mustard (*Brassica nigra*) and turnip (*Brassica napus*), and in the past, at least, could become pest species at certain times of year. Any strong-tasting food, which bustards appear to prefer, supposedly taints their flesh, and it used to be claimed that birds that have fed on garlic are inedible.

In the Sahel and other parts of Africa, *Acacia* gum is much utilized, although perhaps this is as much for its water content as for its nutritional value. Perhaps best known for this habit is the Arabian Bustard, which in some gum-growing regions of Chad is regarded as a pest. The species is also, however, well known for its depredations on locusts and swarming grasshoppers. Stomachs of shot specimens have been found packed with Orthoptera, and the economic, and indeed direct human, benefit of such consumption may be far greater than credited. A rough calculation suggests that a single White-quilled Bustard might consume around 200,000 termites a year, and that this and other species may well play a significant role in reducing the impact of agricultural pests. There has even been a case of a Denham's Bustard defending a termitarium during an emergence from the attentions of other avian species, but this is clearly unusual. Such opportunism in exploiting local abundances of insects is mirrored in the way certain species gather at bush fires to seize fleeing, dying or dead insects and small vertebrates. Indeed, the carrion habit appears to extend to roadkills, as both Kori and Black-bellied Bustard have been found at the roadside carrying or eating the corpses of birds.

Beetles and grasshoppers are the chief animal food of bustards, although any ground- or grass-dwelling invertebrates, crickets, termites, mantises, caterpillars, ants and bugs among the insects, spiders, scorpions, centipedes and snails among the rest, are readily taken. It may be that grassland bustards take more Orthoptera, bushland bustards more Coleoptera, and there may be some interesting niche adaptations, yet to be elucidated, reflected in the bill morphology of the various genera.

Almost every species of bustard has been reported taking vertebrate prey at least occasionally. Mostly the victims are small snakes and lizards, but the eggs and nestlings of ground-nesting birds must be very common seasonal prey items. Small mammals are also taken occasionally, or even relatively frequently by Great Bustards, in the more northerly parts of their range. Amphibians are also sometimes reported, and some curious observations exist that appear to refer to this source of food: in one case a Denham's Bustard seen wading thigh-deep in a pool was assumed to be foraging for frogs on emergent vegetation; in another case, in New Guinea, Australian Bustards gathered to feed in shallow water, although the presumed or known food was not specified.

In captivity, it has been noted that bustards have a liking for bright objects, a trait they share with the Ostrich (*Struthio camelus*), while in Chad it has been found that all species there commonly take coloured beads, notably yellow and white ones. Over half of all stomachs examined contained them, and one held no fewer than 41. Presumably such objects are taken in the belief that they are or were animate, the only other such shiny

Male bustard behaviour in the breeding season varies widely according to the species and displays can be of several types. The Houbara Bustard is in a category all of its own, since no other species has the so-called "Trotting" or "Running" display. Male Houbaras defend quite extensive territories and during the breeding season are scattered out over the plains with at least 500 m between individual birds. Their displays take place at certain slightly elevated spots within the territory. The bird will begin by depressing his tail, then fanning out the normally hidden white crown feathers. As the head is retracted onto the back, he begins to trot or strut in a bizarrely erratic fashion. After a minute or so the neck plumes cover the head completely; at this stage, seemingly headless, his vision is totally obscured and birds have been seen to crash into obstacles!

[*Chlamydotis undulata macqueenii*, Saudi Arabia. Photo: Xavier Eichaker/ Bios/Foto Natura]

objects presumably being certain beetles. However, bustards frequently and regularly ingest gastroliths, which are important in abetting the digestion of plant matter. Indeed, all species investigated have well developed caeca, often associated with a heavily vegetarian diet, although this feature may also be of importance to those species of more arid environments, implying possible physiological and thermoregulatory functions as well as a digestive adaptation.

Whether seeking animal or vegetable food, a bustard always commences a feeding bout walking slowly in a posture with the body oriented slightly downwards, the neck somewhat bent back on itself, and the bill pointing down. When a vegetable item is encountered, the bird pauses, maintaining its hunched posture, and gives repeated, short, precise pecks at the object. If the item or items are on the ground, whether plant or small animals such as ants, the body is tilted forward and the precise short pecks are given, although for items in, rather than on, the substrate the bill is used to probe and work the ground. Animals larger than grasshoppers are generally held in and processed by the bill for a short time, the body angled forward so that the head is low, ready to release and avoid, or release and recapture, the animal with maximum ease. Birds will sometimes run briefly, head forward, to capture a moving prey item, and even jump to attempt to catch passing insects or to take berries from bushes.

The timing of breeding in bustards appears to reflect the need to hatch young at the start of the period of maximum insect avail-

ability in the annual cycle, since, as in many granivorous species, young birds need easily digested protein-rich food sources for rapid growth. Nonetheless, even very small chicks soon peck at green stems and leaves, and so begin ingesting vegetable matter at a very early age.

Bustards are adapted to arid environments, and seem to be able to survive well for extended periods without access to water, presumably, as suggested above, obtaining their needs from vegetable material. Nevertheless, opportunities to drink in the wild, at rain puddles, along small watercourses, are not missed, and in captivity most species appear to drink very freely on a daily basis. Large bustards often sit on their tarsi to drink: water can either be drawn in directly by a pumping action of the throat or else drawn into the mouth and then emptied down the neck, the head being lifted and tilted back.

Breeding

Palearctic bustards breed in the spring, although the season may be very protracted in the case of the Houbara, where local rainfall may produce suitable conditions at different times in different areas within the same year. At the foot of the Himalayas, the Bengal Florican also breeds within the period of the northern spring, as do the species in the Horn of Africa and Ethiopia. Species in the Sahel and West African savannas generally breed with the rains from July onwards, as does the Lesser Florican in western India. In East Africa there may be several breeding seasons, directly related to the rainfall regime, but all species have been recorded breeding within the period from December to May. In Central and southern Africa the season lies generally between October and March. The Great Indian Bustard has a protracted season, being distributed within three rainfall regimes; and the Australian Bustard is aseasonal in northern Australia, simply responding to unpredictable rains, but breeds from April to November in the south.

It is in the mating system and associated displays of bustards that their most obvious biological interest and aesthetic appeal lie. Twenty years ago only a very small proportion of the family had been the subject of even qualitative, anecdotal studies, yet although in the intervening period there has been some important work on the behavioural ecology of several species, the obstacles to quantitative investigations have barely begun to be overcome. Chief among these obstacles are the difficulty in capturing and marking birds, the difficulty of making sustained observations owing to their often cryptic dress and wary behaviour, and the sheer remoteness and inhospitability of the habitats they occupy. Moreover, as K-selected species, long-lived and low in reproductive output, bustards take many years to furnish data that can be tested for significance. None of this is conducive to academic programmes of study, nor even to sustained observational work by committed field ornithologists working independently of tight academic reporting schedules.

The upshot is that even now there are three species, the Nubian, Heuglin's and the Little Brown Bustards, of which mating systems and displays are entirely unknown and can only be inferred from their generic position. It was only in the past few years that casual observations (by two observers once) have shown that Hartlaub's Bustard has a display-flight. Even more surprisingly, the Arabian, Denham's and the Black-bellied Bustards, supposedly familiar birds given their size and their ranges, have only been subject to brief, non-quantitative studies of their display behaviour in the wild. The display behaviour of the Australian and Kori Bustards, despite the latter's presence in many of the more accessible East and southern African reserves, has been described in detail only in captive studies.

Inevitably, therefore, the function and nature of bustard displays in relation to mate attraction, rival deterrence and territorialism remain largely unclear. What is emerging with increasing certainty, however, is that the majority of bustard species establish no true pair-bond, depending instead on "dispersed lek" behaviour in which males advertise themselves on traditional areas, often at traditional individual sites, at least sometimes in moderately clumped groupings although still preserving distances of one or several hundred metres between each other. The females are left entirely alone to undertake nesting, incubation and rearing of the young.

Observations of the seven Palearctic, Indian and Australian species indicate that this is unequivocally the case in all these birds, and the evidence from Africa matches the pattern, except in the case of the sexually rather similar white-bellied *Eupodotis* bustards. In these open country species there is evidently a strong need to defend a resource base for survival and reproduction, and all the indications are that this is achieved by an apparently year round monogamous pair-bond and territorial defence, often with the additional help of an extra bird, which, in those species studied, is a male offspring of the pair. Group-territorial behaviour is best documented in Rüppell's, the Karoo and the Blue Bustards, seems likely to occur in the closely related Little Brown Bustard of the Horn of Africa, and appears to exist in the White-bellied, although this last has such an extensive range that different ecological conditions may result in different strategies. Nevertheless, all five certainly appear to be recorded as monogamous breeding birds.

The fact that a pair of *Eupodotis* bustards will often allow a male offspring to remain on their territory to help with its defence may be attributable to the fact that young males even in these pair-forming species defer their maturity by a year or so and hence present no threat to the parent male. What happens in the other small African bustards, and indeed in the small Indian ones, is unknown, but males of the larger species certainly exhibit delayed maturity of up to six years, whereas females may take as little as two before starting to breed.

Deferred maturity in these cases is the result of sexual selection acting on males by female choice: if the females are to be left to undertake all parental responsibilities with no assistance whatsoever, and their only social contact with adult males is at the moment of copulation, then they clearly must choose males with characteristics most desirable to pass on to their offspring, including, of course, the capacity to mate with as many females as possible. Hence, males in these species grow to be larger and many times heavier than females, which inevitably takes time, and meanwhile the older, more mature males tend to be left to compete among themselves while suppressing the attempts and opportunities of younger birds to become established as rivals for female attention.

Hartlaub's Bustard is generally rather scarce and it has a much more restricted range than the very similar Black-bellied Bustard (Lissotis melanogaster). *Little seems to be known about either its feeding or its breeding behaviour, and only recently has it been observed to perform aerial displays. Here a male presents a splendid sight as, standing on a slight eminence, he inflates his throat and neck in the so-called "Balloon-display" in which he takes on a shape distinctly recalling an hourglass.*

[*Lissotis hartlaubii*, Kenya.
Photo: N. Gore/FLPA]

At the beginning of the breeding season, the male Great Bustard chooses a conspicuous elevated site on which to make his spectacular display and thus to attract a mate. First, the gular sac is inflated, and the tail is raised and laid flat on the back, exposing the white undertail-coverts. In addition, the inner secondaries are twisted over and fanned out. At the peak of his performance he seems to have turned himself inside out to become, in a matter of seconds, a brilliant white ball visible at a distance of several kilometres. Highly convoluted and utterly transformed, he may remain stationary like this for some time in the expectation that some female will succumb to his many gorgeous attractions.

[*Otis tarda tarda*, La Moraña, Avila, Spain. Photo: Carlos Sánchez Alonso]

In the case of the Great Bustard this situation results in a high proportion of under-age males in any healthy population. Outside the breeding season it is difficult, if not impossible, to distinguish these birds, as the winter plumage of all males is largely uniform by the second autumn. However, at the onset of spring the fully mature birds begin to break away from the winter flocks for increasing periods of time to display separately on the dispersed lek, leaving the younger males to roam together in and around this area. Year by year these younger birds develop more fully the appearance of the mature birds, but are presumably lighter and less experienced. They behave as an unruly gang, becoming highly excited by events amongst and around them, adopting incomplete display postures, which are chiefly aggressive in signal, and sometimes singling out members of the group for sudden concerted aggression.

The general impression from these groups is that these young males are developing and testing their strength and display repertoire prior to the time when they will contest a place on the dispersed lek itself. Fighting in male Great Bustards is not frequent, doubtless because the genuinely mature males maintain respectful distances from each other, while newcomers will only put themselves forward for combat when their condition really matches that of their opponents. Most confrontations involve a long preliminary face-to-face, but when and if a struggle ensues it is a violent and bitter event; it may well be that to lose in such an encounter involves such physical stress that no further attempts at self-establishment would be made within the season.

In the course of the spring, and almost certainly from year to year, a hierarchical order builds up among male Great Bustards. The most powerful males dominate the lek area, but there is no territorialism, although very occasionally an unmovable male may, at least in appearance, hold a given piece of land over one or more seasons. The dominant males move slowly about on the lek, displaying at different places for extended periods. Females concentrate on the fringes of the area and move slowly through it, feeding and watching the performances. A female approaches a displaying male very cautiously, and is often quite slowly drawn into the protracted copulation sequence. However, because the males, although dispersed, have no territorial boundaries inhibiting one another, copulation sequences are often interrupted by other males attracted to the spot, particularly if the courting male is a relatively young bird that has managed to infiltrate the area.

It is usual to describe this mating system as promiscuous, inasmuch as successful males mate with several females and no bond is apparent. However, it is by no means certain that females choose at random among males, and it is at least possible that research with marked birds might reveal repeated selection of a given male by a female over successive years, indicating some vestigial type of bond. Such selection may also occur in other species, and this may be the explanation for the apparently anomalous "courtship feeding" and nest-site attendance witnessed in Kori and Denham's Bustards respectively.

The Great Bustard is perhaps unique in possessing a non-territorial dispersed lek system, and it is the only species of bustard that remains silent throughout its display. In the other very large bustards of the genus *Ardeotis*, males appear to establish territories from which other males are excluded. In the case of the Great Indian Bustard these territories are of considerable size, with evidence that display by a potential rival up to a kilometre distant may not be tolerated, although this is probably extreme. In the closely related Australian Bustard, male territories are sometimes solitary but are generally clustered so as to render the birds within sight or sound of each other, and they may be as close as 50 m apart. The territories are located near abundant food, mainly at the interface of treeless plains and shrublands, the birds using a slight eminence or low rise on which to perform. The occasional acceptance of clearly subordinate males in the territories of both species suggests that it is less the resource base of the area that is being defended than the incumbents' access to any female within it. The other two *Ardeotis* show similar behaviour,

A male Little Bustard performs its "Jumping-display" from a raised site of bare earth. The sequence begins with a bout of foot-stamping; then the bird leaps more than a metre into the air, at the same time giving its nasal "prrt" call, while the wings produce the characteristic "sisisisi" sound which has given rise to its Spanish name of "Sisón". The whole performance, aimed supposedly at attracting a female, takes about a second and is given both at dusk and dawn.

[*Tetrax tetrax*, Pinto, Madrid, Spain. Photo: L. M. Ruiz Gordon]

with males spaced a hundred metres or so apart, using small rises on which to display.

In a South African population of Denham's Bustard, the only *Neotis* species in which breeding behaviour has been described, males established territories in a dispersed lek in which each bird was at least 700 m from the next and occupied an area of approximately 60 ha. In Kenya, males of this species have actually been seen in boundary displays, walking parallel to each other at the evident borders of their territories. There have been observations on the Nyika Plateau in Malawi of extended associations between male and female Denham's Bustards, even to the point of their appearing to share incubation duties, but this circumstance appears anomalous, and may have involved a mother and her yearling male offspring, a combination recorded in the Great Indian Bustard; the sexual size dimorphism of the species, and other evidence available, suggests the absence of bonding behaviour between the sexes.

Ludwig's Bustard also possesses traditional display territories and has a similar display to Denham's, except that the brown foreneck produces a dark rectangle on the front of the otherwise white balloon, and, apparently unlike Denham's, a loud booming call is produced. It seems likely that Heuglin's and Nubian Bustards would show broadly similar display behaviour to their two congeners. However, to some extent the Nubian is the ecological equivalent on the Sahara's southern fringes of the Houbara: if environmental factors determine breeding systems and behaviour, it may turn out that the Nubian is the least typical *Neotis* in this regard.

The Houbara itself, which arguably shows affinities, albeit distant, to *Neotis* through its display pattern, also maintains display areas or territories that are roughly a kilometre apart, although sometimes half that distance. Territories are used in successive years, and females also tend to nest close to earlier successful nests, but again there seems to be no contact between the sexes except for copulation. This is true also of both Bengal and Lesser Floricans and the Little Bustard. The first, much the largest of the three and approximately the size of the Houbara, maintains territories which allow the nearest neighbouring males no closer than 350 m, although not necessarily within visual or acoustic range. Territory size in this species is certainly around 1 km² and probably much larger, although mostly only 20-30 ha are used for foraging and 3-10 ha for display purposes. In the Lesser Florican as many as three territories have been found in a 9 ha area of grassland, but the average territory density is 4·7 per km². This is a similar value to those for the only slightly smaller Little Bustard over much of its range, although in particularly favourable areas it reaches territorial densities of nearly 14 per km².

The various species of black-bellied bustard in Africa, namely the Black, White-quilled, Black-bellied, Hartlaub's, Savile's, Buff-crested and Red-crested, are too little studied to permit complete confidence, but all of them appear to conform to the family norm: none appears to establish a pair-bond. All these birds tend to inhabit well developed bushland habitat, and all, except apparently Savile's Bustard, advertise themselves with aerial flights over their territories.

The best studied of the five presumed monogamous members of the family is the Karoo Bustard. Pairs of this species defend territories year round, but these are "plastic", in that their boundaries shift concentrically to the pair during the course of the year in situations where resource availability is not constant. The area defended covers between 0·5 and 3 km². Young male offspring often help defend the territory, and the size of the resulting groups, though mostly three, can reach as many as five. Chief means of territorial advertising is the song, initiated by the male, given in the half-light at daybreak and dusk, or else in response to intrusion by conspecifics or to an outbreak of duetting by a neighbouring pair. Males play a greater role in territorial defence than do females, initiating the duet in response to territorial intrusion, and taking longer to return to foraging after a dispute, which can take the form of direct fighting. Inasmuch as the territory moves with the pair, it would seem that its function has also to do with mate-guarding, in other words the prevention of courtship of the mated female by other males, and as a spacing mechanism to help avoid conflict, as well as with physical resource protection.

Even where three individuals have been witnessed at the nest, there is no evidence that the extra birds involved in groups contribute directly to breeding success by helping with the care of, or food provision to, newlyhatched birds, but simply make those things more feasible by reducing the parental burden in territorial defence. Whether any males of these species actively help at the nest with incubation, brooding or food provision appears still to be unresolved.

Display in the *Eupodotis* bustards (as here constituted) is basically confined to their vocal signals. The male Karoo Bustard

Two phases of a typical male Kori Bustard display have been caught by different cameras. This display, one of the "Balloon" type, is very similar to that performed by the other members of the genus Ardeotis. *The male struts to and fro, often on a low rise, then standing upright he inflates the neck until it turns into a giant white puffball. With the neck thus inflated, the tail cocked and flattened down the back to reveal white undertail-coverts, and the wings drooping so as almost to touch the ground, he may stand still or strut around, at times emitting a drum-like booming.*

[Above: *Ardeotis kori kori*, Kruger National Park, South Africa. Photo: Nigel. J. Dennis/ NHPA

Below: *Ardeotis kori struthiunculus*, Masai Mara, Kenya. Photo: Hubert Klein/Bios]

Unique among bustards with its attractive blue-grey coloration, the Blue Bustard, like most other members of the family, nests in a small scrape on bare ground, in the midst of tufts of grass which provide camouflage. The eggs greenish with darker streaks can number one to three, but most commonly there are two. The female is responsible for the entire process of incubating the eggs and rearing of the young, while the male's contribution, as in most bustard species, would appear to be minimal.

[*Eupodotis caerulescens*. Photo: W. R. Tarboton]

puffs the black feathers of his throat in agonistic situations, and male White-bellied and Blue Bustards erect the feathers of the crown and neck in a ruff during courtship of females, with much rapid bobbing of the head in the latter species. However, this is the only group that does not undertake the wonderful and often astonishingly convoluted displays that the remaining 20 members perform.

In terms of display, these other species break down into two main types: those that give exclusively terrestrial displays; and those with self-advertisement that is primarily aerial. Terrestrial displaying bustards are the ten species that make up the genera *Otis*, *Ardeotis*, *Neotis* and *Chlamydotis*, while aerial displays are performed by the eight species of *Lissotis*, *Lophotis* (except, apparently, *savilei*), *Afrotis*, *Sypheotides* and *Houbaropsis*. The last two make more of a display leap, although both travel several metres into the air. Fitting neither or both of these types is the sole member of *Tetrax*, with rarely observed twilight displays that are clearly aerial in spirit but inescapably terrestrial in nature.

The display of the Great Bustard is the most remarkable, transforming a largely cryptic animal into an involuted mass of billowing white feathers, a shining ball discernible over many kilometres. The sequence begins with the inflation of a huge gular sac which extends right down the neck. This is done as the bird exhales, the air being diverted into the sac through an aperture under the tongue. Two bare dark strips of skin either side of the grey-white neck are exposed as the "balloon" swells massively. As this happens, several other contortions take place roughly simultaneously. The front of the body tilts forward, and the head itself sinks back and down as the inflated neck pushes up the long white feathers of the "beard", so that they point upwards, partly screening the eyes. The tail cocks flat along the back, so that the tips are under the head, and this exposes the pure white vent and undertail-coverts. The wings, with flight-feathers still tightly folded, are lowered so that the forewing from the shoulder to the carpal joint stretches down and slightly backwards, and the secondary coverts and tertials are lifted, exposing their pure white in a great cascading rosette. The position is held often for many minutes, the bird every so often shifting its orientation with a shuffle of feet and a shaking of body, redoubling the intensity of the posture. No sound is emitted: the signal is entirely visual.

Both *Ardeotis* and *Neotis* bustards also have neck-inflation or "Balloon-displays", but the Great Bustard's is very different and the taxonomic proximity of *Otis* to these two genera based on this character and on similarities in size remains largely assumed. However, the displays of the four *Ardeotis* bustards certainly reveal that they cannot be regarded, as they have in the past, as one species. The genus has a clear two-way split, with the Kori and Arabian on one side, and the Australian and Great Indian on the other. Each pair is, however, very closely related, as their displays clearly demonstrate.

In the Australian Bustard, the male performs at a repeatedly used spot within his territory. He tilts his body and head slightly upwards, and begins to inflate the oesophagal sac, which drops from the breast until it brushes the ground. The body of the bird tilts more upright, the neck extends vertically, the head points upwards and the tail cocks flat on the back; the neck appears inflated in two places, in the cheeks and down the throat, and in the broad dangling bag hanging from the breast. The bird then rotates on the spot, causing the sac to swing about, and opens and closes its bill in a stereotyped sequence, repeated ten times or more before commencing the calling sequence in which second-long guttural roars are produced every twelve seconds or so, the bird swinging its sac as it turns in various directions to deliver its call. The Great Indian Bustard appears to have an identical display, although it is possible that the oesophagal sac does not distend so far as to sweep the ground, and the calls may or may not be different in timbre and timing.

The other two *Ardeotis* species are far less well known, but the displays of the Arabian Bustard have recently been shown to be similar to those of the Kori. The male adopts a still, upright posture, and his neck balloons out. He then walks to a set position on a slight prominence (in Yemen, the only sites used were the tops of irrigation banks) where there he intensifies the neck inflation to become a huge whitish oblong, while his wings droop and his tail is raised into a laterally visible fan. In this position, at roughly half-minute intervals he appears to gulp in air as his head retracts into the balloon, and he then emits a liquid "puk-puk", which carries over a wide area; this is the sound described at the turn of the century as exactly like water running from a bottle. From time to time, the bird rotates on the spot through 90° or 180°. During the bout, the fan of the tail gradually folds and falls.

This description closely matches those for Kori Bustards in Namibia and Tanzania, and in captivity. The bird struts about on a low rise with tail cocked, occasionally stopping and fully inflating his neck, raising his crest and letting his wings droop so that the primaries trail along the ground. He then delivers a six note drum-like booming, which is evidently different from the two note call of the Arabian Bustard. However, more work is needed to show how different or similar the routines of the two species really are.

In Denham's Bustard, the male lets his head sink backwards close to his back, droops his wings slightly and erects, presumably through the inflation of a gular sac, the feathers of his white foreneck, breast and belly so that they billow out in a conspicuous ball in front of him, visible over several kilometres. In this posture he walks at varying speeds, sometimes rapidly, and occasionally breaking into fifteen minute periods of "Display-strutting", in which he balloons his neck more fully and then struts straight forward for up to 30 m, and for up to around one minute, then stops to raise his body in "Vertical-display", but with the head still mostly obscured by the balloon and by the raised and flared orange hindneck, which appears to be aimed at the object of display. After eight seconds the body shudders and the bird appears to call, although observations have been at too great a distance to be sure. He maintains his position for around 20 seconds, sometimes rotating slowly to display in other directions, before resuming his Display-strut. In one incomplete courtship sequence, the struts became shorter and the Vertical-display longer, the nape being turned each time towards the female.

Previously, the performances of *Otis*, *Ardeotis* and *Neotis* have been grouped together as Balloon-displays, with *Chlamydotis* classed on its own for performing a "Trotting-display". However, it is clear from what we now know of Denham's Bustard that the Houbara's display is by no means anomalous, and it may well be that when the repertoires of the other members of *Neotis* are known, the taxonomic position of the seemingly aberrant *Chlamydotis* will be resolved.

Houbara males defend fairly large territories, but they appear to have core areas within them in which they perform their displays. These are likely to be vantage points within the territory, with as few obstacles as possible, and range from 0·5 to 2·5 ha in extent, although even within these areas there may be stalls a few metres across where repeated circling displays flatten the ground. The male begins by an untidy-looking ruffling of the crown, neck and breast plumes: the black feathers of the neck sweep back, as the white ones of the breast fan out in front, first downwards, then upwards; presumably there is some inflatable pouch that causes this. As the bird begins a forward, high-stepping trot, the head drops backwards onto the back, causing the white breast plumes to rise up and over the front of the body in a loose white ball. In zig-zags, circles and long lines and curves, the seemingly headless bird runs for a minute or two, then abruptly halts, his head lifting slightly in watchfulness, before he resumes the performance.

Both Denham's and the Houbara have, very rarely, been seen to give some brief, sharply upward flight as if in display, but these seem unlikely to have any clear significance in their behavioural repertoire. Males of both species are perhaps too heavy to expend energy on display leaps and flights, which are characteristic of the lighter bustards. The intermediary between the two display types is perhaps *Houbaropsis*, the Bengal Florican, which, like other large ground-displaying bustards, has a display involving the erection of the neck plumes, the "Neck-fluff Display", although this lasts only half a minute or so. In over half the cases observed, this display then results in a flight display, in which the bird rises with loudly clapping wings 3-4 m into the air, descends with 4-6 "chik" calls to within a metre of the ground, then rises sharply with wings stiffly quivering, stalls, half folds his wings, and drops steeply back to earth.

The energetic costs of such a display in a bird weighing around 1·5 kg may be the reason why this performance is relatively little given, often only a few times an hour in the early morning and late afternoon. Curiously, these flight displays are often triggered by the calls of unrelated species, notably the Indian Peafowl (*Pavo cristatus*), and their number and distribution within and between dawn and dusk periods varies inexplicably from day to day.

In the similar-sized but somewhat heavier Black-bellied Bustard, two distinct display types are judged to have two distinct functions. An irregular and relatively uncommon flight display advertises the bird's presence over a wide area, well beyond the limits of his territory: this involves him rising to 7-15 m above the ground and flying with deep wingstrokes for 50-200 m, then gliding a further 50-150 m with wings held up in a V, head and neck angled upwards. In some reports, the breast feathers are greatly fluffed out during and at the end of these flights, and there is one account in which an extended version of the display-

Of sober, cryptic but finely vermiculated brown-grey plumage, the Karoo Bustard inhabits dry, open treeless regions. Only few data have been collected so far concerning its breeding system, though groups are known to be strongly territorial and to defend small areas. The nest is a scarcely perceptible depression on bare, often stony, ground and the clutch normally consists of a single egg, buff-olive in colour streaked with brown. It is remarkable how well both egg and bird merge into the stark surroundings.

[*Eupodotis vigorsii*. Photo: Peter Steyn/Ardea]

In all bustard species it is the female that selects the nest-site, incubates the eggs and rears the young. The male Denham's Bustard, one of the larger members of the family, has been observed apparently attending a nest, but to date there is not even circumstantial evidence that male bustards actively participate in incubation or caring for the chicks. The clutch of 1-2 eggs is laid in a bare scrape in tussocky grass and the female relies heavily on her beautifully patterned cryptic plumage to escape unwanted attention from predators.

[*Neotis denhami*. Photo: Roger Tidman/ FLPA]

flight took the performer so high in the sky as to be unidentifiable without binoculars, before dropping with wings horizontal and white primaries fluttering loudly to about 300 m, then briefly folding wings, cocking tail and retracting neck in typical (*Lophotis*) "rocketing" position, before rising again to repeat the performance.

Much more persistently given is a ground display thought to be intended for females already inside a male's territory. This is delivered from one of several traditionally used stalls within the territory, typically a patch of open, bare, raised ground, often a decomposed termite-mound; it involves standing upright, letting the neck angle forward then sharply upright, head and bill skyward, emitting a groaning "oooo" that shows off the bird's black chin patch. Then the head is drawn down onto the back for a few seconds before the bird makes a rumbling snore followed by a "pop", like a cork coming out of a bottle, and a slight shaking of the wings which shows off the white panel in sharp contrast to the black flanks.

Only very recently has it been established that the other *Lissotis*, Hartlaub's Bustard, also gives a display-flight in which the male rises steeply to 15-20 m, then descends in a glide, wings in a shallow V and legs trailing. Its ground display is similar to the Black-bellied's, although the sequence is approximately reversed and the volume much lower.

The parapatric Black Bustard and White-quilled Bustard have apparently identical display-flights, in which the male flies up and cruises round in circles, often for some time, while giving his incessant, raucous self-advertising call, then slowly parachuting or exaggeratedly "windmilling" down with wings held in a V and bright yellow legs dangling. Like the Black-bellied, these birds have one or more vantage points, usually termite mounds, on which to stand and call. In prime habitat, territories may be spaced only 300-500 m apart, and flying males commonly pursue each other.

The aerial displays of the Red-crested and Buff-crested Bustards of southern and East Africa are, by contrast, more vertical than horizontal, quickly over and, usually, given without warning, which makes them all the more dramatic. The bird flies up vertically for about 20-30 m, well above the canopy, then semi-somersaults backwards, feet up, head back, nuchal crest and breast puffed out, then rocks back forward and drops in a fluffed-up ball to the ground, pulling out in a glide just before impact. In East Africa, less dramatic, parabolic flights have also been observed. Puzzlingly, the West African counterpart, Savile's Bustard, has never been recorded making an aerial display, although, given the way so many displays of African bustards have been overlooked for years or remain unrecorded, it may yet turn out to do so. All three species use traditional calling stalls, but unlike other bustards these are not exposed or raised sites and appear to be deliberately selected for their inconspicuousness.

The two last species to consider, the Lesser Florican and the Little Bustard, both live in grasslands and both make their presence known through sustained bouts of short leaps just above the level of the grass. At the peak of the season the florican may perform well over 500 leaps per day, mostly, but not always, from a chosen stall within his territory. He stands erect, shuffles or stamps his feet, then abruptly retracts his head, crouches and springs flapping into the air to a height of 1·5-2 m, using his half-opened wings as a parachute in the short descent. The whole event lasts about a second. A loud rattling as the bird flutters up is produced by modified primary feathers.

In very similar fashion, the Little Bustard performs a "Jumping-display" from a chosen stall that commences with a short burst of foot-stamping; he then leaps 1·5 m into the air, giving his snort-call as he does so, while the wings, again owing to a modified primary, produce their characteristic "sisisisi". The event also lasts only about one second. The leap is given at dawn and dusk, but at slightly higher light intensities than a similar display in which a much stronger foot-stamping precedes a flashing of the wings without the bird becoming airborne. It is thought that this latter display is more agonistic in intent, exaggerating the sound of a forward attack; the bird's stall is a small patch of clear ground on which it tramples its faeces, so as to enhance the sound of its foot-stamping. The display-leap is thought to be more targeted at females. Throughout the full daylight hours, however, only the snort-call is given.

Copulation in bustards often involves protracted sequences of behaviour, at least in the larger species. They are rarely witnessed, partly because the absence of a pair-bond means that the event need only occur once between any two birds. Where they have been observed, there are some clear similarities in the ritualized procedure.

The most widely known is the Great Bustard. An apparently passing female shows her interest simply by wandering close to the male. Occasionally, a female may show sufficient interest to peck lightly at the cloacal area of the displaying male before becoming embroiled in the protracted mating sequence. Mostly, however, it is the male which, despite his posture, approaches the female and initiates the sequence, walking round her and weakly banging one of his carpal joints on her back until she eventually squats, always assuming that the event is not interrupted by other males, as it usually is! Then the male stands over her, pecking at her crown, often for many minutes, and as she eventually rises, tail lifted forward, insemination very rapidly occurs.

In captive Australian Bustards, the male leaves his display stall to follow a passing female, turns side on to her and calls, then continues following. The sequence can last up to 25 minutes, with the male calling every 7-8 seconds. The female, if receptive, will duly sit, and the male then circles her repeatedly, but gradually reducing his calling frequency the more he stays behind the female, trampling on the spot, and pecking gently at her head. This may last as long as 33 minutes before the male lowers himself on his tarsi, both birds outstretch their wings for balance, and insemination rapidly occurs. As in the Great Bustard, the female then immediately moves from under the male, flapping and ruffling feathers, to begin grooming at a short distance, and soon walking away.

In close courtship the Houbara repeatedly throws its head back on its mantle, and turns it from side to side. The Black-bellied Bustard makes a ruff of his neck, then stretches it forward, up and back in a sinuous, snake-like sequence. The Bengal Florican approaches a female with head retracted, breast feathers billowing, then stops, raises his head and jerks his neck from side to side, swinging his breast plumes. The Lesser Florican runs after the female with neck outstretched, auricular plumes over his head, stops in front of her, lowers his posterior to the ground, snaps back his head and simultaneously flashes open his wings. Little Bustard males chase females for long periods, the head retracted into the neck, stopping repeatedly to call and throw the head and body from side to side. Copulation in all species involves the male pecking repeatedly at some part of the female's head.

The female is entirely responsible for nest-site selection, incubation of the eggs and, with the possible exception of the *Eupodotis* bustards, rearing of the young to fledging. Male Kori Bustards both in the wild and captivity have been seen to offer food items to females, and male Denham's Bustards have been watched apparently attending nests, yet no clear evidence has ever been furnished that in these, or any other species, the male truly contributes to parental duties. In many cases, it appears that the female removes herself entirely from the general area in which males are clustered in their dispersed leks. Consequently, the nests and patterns of nesting dispersion of many species remain virtually unknown.

The nest is always on bare ground, sometimes having been scraped clear of vegetation and perhaps slightly moulded, and occasionally bits of grass may be pulled down to form a weak rim. Statements about the nest being near to bushes, clumps or other minor landscape features are sufficiently frequent to suggest that there is often a deliberate choice by the female not to sit in the complete open, but the extent to which one or two observations have become generalized is not clear. Certainly many nests of some species have been found far from any distinguishing landscape feature.

The eggs of bustards are similar to those of cranes in shape and pattern, generally being matt olive green or buffish grey with rough blotches and dapplings of dark or reddish brown and grey around the big end. However, the eggs of species adapted to particular substrates or habitats show variations from this, and those of *Lophotis* are glossy. Clutch size is generally two to three in the three Palearctic species, although the largest has been known to lay four, the middle five and the smallest six; singletons are rare. Only the Lesser Florican, as small as the Little Bustard, lays a comparable clutch of three to five eggs; this relatively large investment in offspring probably reflects the relatively unstable conditions under which the species has to pursue patchy rainfall in both breeding and non-breeding periods. Otherwise, only the Australian Bustard and three of the five *Eupodotis* species have been recorded laying as many as three eggs; the remaining *Eupodotis* and *Ardeotis*, plus *Neotis*, *Lissotis*, *Afrotis* and *Lophotis*, lay one or two only.

The incubation period is 20-22 days in the Little Bustard, 24-25 days in the Australian and Great Bustards, and almost certainly between these extremes for the remaining species, although very minor variations owing to climate and season may occur. Hatching is asynchronous, suggesting that incubation starts with the first egg.

The young are precocial, but not immediately nidifugous, requiring several hours, in some cases a day or more, to develop the capacity to walk. When all young are able, the female leads them from the nest and broods them for the night at any secure site reached during the subsequent days. She draws attention to food items by pecking gently at them or dropping them in front of the young: the young themselves quickly learn to peck at grass stems, pebbles and small invertebrates. Parent and offspring maintain contact through very quiet purrs and trills.

Fledging occurs at four to five weeks, although the young are still only half-grown at that stage. These first weeks of life are lived in such secrecy that in all probability the young only disclose that they have fledged during comfort behaviour, when stretching and flapping wings. Unless hard pressed to escape from a predator, many young bustards may not truly take wing until weeks after "fledging" occurs.

Independence certainly occurs only when the young are full-sized, which may be several months after fledging. In Palearctic species the parental bond therefore lasts into the autumn, and there is circumstantial evidence that it can last through the winter. Female Great Indian Bustards have been watched incubating in the presence of highly attentive offspring, suggesting a year long association; circumstantial evidence indicates the young may be of either sex. In *Eupodotis* bustards, as noted above, single young males may stay with their parents into the following year, helping with territorial defence; young of both sexes may do so in the Blue Bustard, in which group size sometimes reaches five. Some, probably all, small female bustards are capable of breeding after one year, but females of the largest species usually only commence breeding when three years old. Maturity in males, meanwhile, is to some extent an artefact of the breeding system, so that breeding condition may be behaviourally suppressed. There are no studies on wild populations of large bustards that

A female Rüppell's Bustard with chick in tow walks with deliberate tread across a stony arid plain, the typical habitat of this species. Young bustards tend to become independent only when they are fully grown, several months after fledging. The breeding biology and ecology of Rüppell's Bustard are very poorly known.

[*Eupodotis rueppellii*, Namibia. Photo: J. J. Brooks/Aquila]

disclose age of first breeding, but in the Great Bustard, for example, the received wisdom is that six years is probably the age at which first copulations are likely.

Breeding success is virtually unknown and unquantified in any species, although it is inevitably low in intensively farmed areas (see Status and Conservation).

Movements

It is not certain that any species of bustard is completely migratory, in the sense that none of its populations is completely sedentary. At the other end of the scale, only a handful of species are believed to be sedentary, and even in those cases there must be considerable doubt whether all populations are entirely so. Most species appear to be at least dispersive, some outrightly nomadic. The largest species tend to move in small flocks, and the Little Bustard can do so in large assemblages. Migration appears to take place chiefly, though not exclusively, at night. The height at which birds move may vary between species, but the largest species remain fairly low.

Areas of low resource availability, such as the seasonally influenced grassland and savanna in which bustards dwell, are characterized by high temporal and spatial concentrations of resources, mostly in the form of annual plants, but also outbreaks of orthopterans and mass emergence of curculionid beetles, and concentrations of both types are usually triggered by rainfall. These variations appear to dictate breeding schedules, and they must lie behind most, if not ultimately all, local and long distance movements that bustards make.

The two main regions in which bustards are strongly migratory are, first, Eurasia through Central Asia to eastern Russia and China, and, second, the Sahelian and savanna zones of the southern borderlands of the Sahara. All three bustards occurring in the first area, Great, Little and Houbara, are compelled by long, cold winters to move southwards from the steppes into warmer areas within the region. The first two, for the most part, remain to the north of the great mountain barriers to the Indian Subcontinent and the Middle East, but the Houbara moves from its cold Kazakh deserts into both regions in large numbers, crossing to the Arabian Peninsula. Patterns of movement in the easternmost populations of Great and Houbara, in Mongolia and China, are poorly understood, but the Great Bustard is a regular, if scarce, migrant at the major Chinese watchpoint of Beidaihe, east of Beijing.

The movements of the Houbara coming down into, and beyond, the deserts of Iran and Baluchistan are basically unknown. Weather conditions may compel nomadism over the winter quarters, just as they do in the remainder of the species's range in Arabia and North Africa, or perhaps there is pressure from already resident or later arriving populations. Very recently, it has been possible to capture and fit birds with radio transmitters, and track them from satellites. It will take many years to build up a picture from which robust generalizations can be made, but already this study is providing some valuable insights, such as suggesting that males returning to the breeding grounds may pause at several localities, possibly displaying in each of them in an attempt to obtain a mating.

In the remainder of their range, the three Palearctic bustards are largely sedentary or dispersive rather than migratory, although the Little Bustard still makes clear north-south movements in France and the Great Bustard clears off the Anatolian Plateau in winter, moving into the warmer, lower plains on the Turkish border with Syria. In Iberia, both species wander in winter, and indeed the disappearance of birds after the spring display period is an uncanny phenomenon: the females are clearly on nests and keeping a low profile, but the males also melt away so that by late June it is difficult to find any, and all the evidence points to a general diaspora from the lekking centres deep into distant cropland.

Rainfall in the savanna and Sahelian zone in the period June to September causes a greening of the region and hence an influx of bustards from further south. Most prominent among these are the larger species, the Arabian and Denham's Bustards, but with the exception of the Nubian Bustard the smaller species in the region, the Black-bellied, White-bellied and Savile's, also then show some displacement northwards. All of them appear to breed at this time, although this is presumably dependent on sufficient rainfall. Some, at least, may also or alternatively breed in the southern parts of their West African ranges, if conditions are then more favourable. Black-bellied Bustards, in particular, seem to wander in response to rain patterns, and may well breed opportunistically as local conditions allow.

In north-east, East and Central Africa, very poorly defined local movements occur in the bustards of less arid habitats. Denham's, Hartlaub's, Black-bellied and Buff-crested have all been reported as appearing or increasing seasonally in certain areas. Even the Kori Bustard moves into woodland areas in the dry season, apparently on foot, although in this species, as in others, the displacements may concern only a certain class of the population, for instance non-breeding birds.

It is in southern Africa that the majority of the sedentary bustards occur, all of them small. The two *Afrotis*, the endemic *Lophotis* and all three endemic *Eupodotis* species are, so far as is known, essentially resident, moving over very short distances from one season to the next. The non-endemic *Eupodotis*, the White-bellied Bustard, is also sedentary, as it apparently is in East Africa. Given that all *Eupodotis* are known or believed to be group-territorial throughout the year, it seems only likely that these birds should be sedentary. Denham's and Black-bellied Bustards both tend to wander in response to local conditions, although there appears to be, or to have been, a small summer breeding population of Denham's on the tropical coastal Zululand plain.

Recently, an analysis of records, coupled with aerial surveys and questionnaires to farmers, has established at least partial migratory behaviour in Ludwig's Bustard. Individuals of this large species follow seasonal rainfall patterns, moving from the more inland summer rainfall regions south and west into the coastal winter rainfall regions. Another finding of this study, that despite the evidence for such a migration there was nothing to indicate a seasonal decrease in density in the summer rainfall regions, is explained first by the species being a partial migrant, and second by the fact that birds resident in the summer rainfall areas are much easier to see in winter. Counts of other, entirely resident bustard species in the summer rainfall area actually increased in winter, indicating the extent to which lush vegetation can hide bustards and obscure their true status in an area.

This indeed may be what happens to the Bengal Florican, which, like the Great and Little Bustards in Iberia, virtually disappears after breeding, probably dispersing over short distances, although perhaps simply remaining in the deep obscurity of long grass in quiet parts of the reserves to which, as a breeding bird, it is now almost totally confined. Easily the greatest mystery in this species surrounds the provenance of birds supposedly of a different race that have been recorded in tiny numbers in winter in Cambodia and Vietnam, with one bird even found in a Bangkok bird market. Recent records all refer to southern Vietnam and all appear to be from February and March. The area is so distant from the Indian Subcontinent that there is no real expectation that these birds are migrants from known breeding areas; yet it seems only marginally more plausible that they are members of an undetected population from some remnant natural grassland area in south-east Asia.

The Lesser Florican is more certainly known to travel considerable distances with the seasons. It migrates into north-west India with the rains in August, seeking out the most appropriate habitat, with the result that its density at given sites varies greatly from year to year. Afterwards it disperses south and east, although being so small, unobtrusive and unpredictable it is nowadays very rarely recorded anywhere in the non-breeding period.

The closely related Great Indian and Australian Bustards have closely related migratory habits, both being dispersive and nomadic, with some evidence of seasonality, always with rainfall, or its absence, being the key determinant of any movement. One challenge to field biologists is to confirm or deny the report that the population of Australian Bustards in southern New Guinea migrates across the Torres Strait to Australia: this may be the only regular movement the species undertakes.

All members of the Otididae have become increasingly threatened over the last 50 years or so, mainly through habitat change and the pressure of hunting. Among those that give cause for grave concern is the Houbara Bustard. Because of its wide yet patchy distribution, and the massive decline it has suffered in many parts of its range, it is very difficult to estimate present numbers with any accuracy. Captive breeding of Houbaras and other bustard species has been in progress for some time, but as yet its potential value has not been clearly demonstrated. Bustard conservation still needs much careful research; the classic solution of protected areas is hardly compatible with the nomadic nature of several of the species.

[*Chlamydotis undulata macqueenii*, Saudi Arabia. Photo: Xavier Eichaker/ Bios]

Relationship with Man

Bustards and human beings are largely incompatible, and have little to do with each other. However, cave drawings and rock engravings depicting Great and Kori Bustards indicate that prehistoric man valued these species, perhaps chiefly as game but possibly for less material reasons: the Kori certainly features in dances and songs performed by Botswana's Bushmen. Moreover, the Great and Little Bustard benefited from prehistoric human actions in clearing large areas of Europe of its original forest cover. It is difficult to judge what their ranges looked like in the immediate post-glacial period, but their survival now in part depends on the management of certain key areas in Iberia and Central Europe in which they cannot have been present a few thousand years ago.

Both species have at times been considered minor pests. In Germany in the eighteenth century Great Bustards were so common that royal edicts were issued to address the damage to crops they caused, with children being given time off school to go to the fields to drive them away. In Spain in this century a NATO airbase had to import Peregrine Falcons (*Falco peregrinus*) to reduce and disperse the flocks of Little Bustards feeding by the runways. Even today, flocks of either species can still be large enough to damage growing crops in Iberia and Russia. Houbaras on the Canary Islands used to harm chick-pea crops, and doubtlessly they do small-scale damage elsewhere. The only other significant impact is that of the Arabian Bustard on *Acacia* gum production in parts of the Sahel.

In general, however, bustards must be judged highly beneficial. Most importantly, they help control insect plagues, at times consuming huge quantities of grasshoppers and locusts, as well as termites, beetles, mice and other economically injurious creatures. These advantages have been noted from Germany south to Cape Province. There may also be an important role in seed dispersal. Karoo Bustards have been found to consume high numbers of seeds of early successional "nurse plants", and may therefore play a role in the spread of karoo pioneer vegetation and the reclamation of degraded areas.

More obviously, bustards and their eggs have, at least in the past, been much used by man for food, especially in Europe and Asia and on both fringes of the Sahara. Great Bustards were served in the courts of European nobility. Little Bustards were once a common delicacy in Tunis hotels. British imperial servants ate their way through the Indian florican populations; indeed, the Bengal Florican was even once known as *Otis deliciosa*! Local people in Chad hunt the Arabian Bustard for food, and frequently rob its nests, although eggs may be left at least until their presence has helped capture the incubating bird: in much the most remarkable bustard-hunting technique on record, a child is buried right next to a nest, with only a hand free under the eggs in the sand, so that when the female returns and sits, the child tries to grab its feet, and hangs on until help arrives.

Much the most important relation with man lies in the high significance attached to the Houbara as the chief quarry in the Arabian practice of falconry. Oil-rich royal dignitaries seeking to retain cultural links with their ancestors see the wintering hunting party as a vital expression of their roots, even though the nature of the hunt has been transformed out of recognition by the full engagement of modern technology. Camels, hardship and chance have been supplanted by desert-adapted, radio-equipped luxury vehicles that trawl in fleets across the terrain, supported by fleets of petrol tankers, mobile kitchens and other logistical palliatives. Dozens of falcons are used, and gyroscopically mounted rifles often assist in the pursuit.

The result is that thousands of Houbaras have been caught and killed annually since the mid-1970's throughout the species's massive range within Islamic countries, causing serious conservation alarm. However, the situation remains very unclear, with local declines and disappearances claimed, but with no certainty in many cases that these are real, or else that hunting has been their cause. Indeed, the resilience of the persistently hunted populations that winter in Pakistan has prompted the quantification of various data, revealing that the total number of birds breed-

ing in Kazakhstan alone is in the order of 50,000, a far better situation than was once believed. Nevertheless, the immoderate hunting of the Houbara, often resulting in great piles of discarded corpses or feathers after the "sport" is over, remains a cause for concern, chiefly because it is by no means clear that populations south and west of Pakistan have similar levels of resilience, but also because of the risks to desert ecosystems, indirectly through the "vacuuming out" of a possibly keystone species, and directly through the impact of the vehicles on desert substrates and floras.

Arabian dignitaries have, however, discovered that other species of bustard can be hunted with the same relentlessness in the Sahel, and this has placed a serious burden notably on the Arabian and Nubian Bustards. Moreover, an interest in keeping and breeding bustards, and in purchasing various species in volume for target practice by falcons, has caused the market in traded birds to burgeon. Captive breeding of the Houbara has long been touted, notably by people familiar with galliform birds, as the great solution to the falconers' needs, and enormously expensive facilities have consequently been established in various parts of the Arabian Peninsula. There is no evidence, however, that captive breeding is of any genuine relevance or value to this or any other member of the family.

Status and Conservation

Bustards are in general decline everywhere, retreating before the intensification of agriculture, hunting, and various kinds of modification of their habitat, including invasion by cattle, disturbance from roads and building, and the spread of overhead cabling.

The advent since around 1950 of mechanized cereal farming and pesticides has been particularly inimical, but the accumulating alterations in technique had all been contributing to declines in the Palearctic species ever since the industrial revolution. Nor is it simply a matter of intensification on existing farmland: it is also the spread of farming into areas not previously needed or considered viable. Cultivation in the Jamnagar District of Gujarat, in north-west India, a former stronghold of both Great Indian Bustard and Lesser Florican, grew from 40% in 1907 to over 70% in 1981, despite a small decline in the human population and a sharp decline in land needed to meet local food needs, owing to improved efficiency: the conversion of virgin land has been to cash-crops for export. Changes like this can be expected in the coming century throughout the lands on which bustards dwell.

All the other threats are more local or more targeted on individual species. Hunting is most focused in Islamic countries (see Relationship with Man). In the mid-1980's, this Arab interest fuelled a trade in some smaller African species which were used to train falcons prior to the winter hunting season; accordingly, all bustards became subject to trade controls, with the Houbara and Great Indian Bustards and the Bengal Florican being entered on Appendix I of CITES and the remainder on Appendix II. In some Islamic countries there have also been moves to encourage nomadic pastoralists to form permanent settlements: the resulting overgrazing has possibly irreversible consequences for the fragile semi-desert environments and the faunas they support. Power transmission cables and even telephone lines, crossing open terrain, connecting one town with another, and running to each farmstead, are a new and potentially serious hazard, known to affect larger species such as Great and Kori Bustards, although in some areas the attachment of large coloured balls to the wires has been effective.

Four species of bustard are currently treated as threatened with extinction: all three from the Indian Subcontinent and the Great Bustard. Four more, the Nubian, Blue, Little Brown and Little, are judged to be near-threatened. The Houbara is the next most obvious cause for concern and needs constant monitoring, while the four largest remaining species, Kori, Arabian, Australian and Denham's, are all showing signs of chronic decline and local extinction. Heuglin's and Hartlaub's need monitoring given

The Nubian Bustard occurs across northern Africa from Mauritania to Sudan. Bustard populations throughout the world are declining, with four species classified as threatened with extinction. They are birds particularly vulnerable to hunting and habitat changes. Unfortunately, the Nubian Bustard is under double pressure: the gradual desertification of the Sahel means suitable habitat areas are shrinking; and it is now also suffering from the attentions of Arab huntsmen. This species is very poorly known. While it is currently classed as near-threatened, there can be little doubt that survey work and research are urgently required in order to forestall the possibility of a calamitous decline.

[*Neotis nuba*, Sahara. Photo: Alain Dragesco/ Planet Earth]

A male Lesser Florican leaps dramatically into the air in a display intended to attract a mate. He first squats down in a flat grassy site, then with neck inflated he springs into the air with accompanying shallow wingbeats, rising to a height of up to two metres. As he leaps, the wings make a loud rattling sound. The display lasts only a second, and may be repeated over 500 times a day. This charming species is considered to be the most threatened of all bustards, with the latest available estimates suggesting a total population of merely some 2200 birds.

[*Sypheotides indica*, Sailana, Madhya Pradesh, India. Photo: Joanna Van Gruisen/ Ardea]

the land-use pressures within their relatively restricted ranges within the Horn of Africa. The remaining members of the family, ten small African species, are least affected by status changes and are at present reasonably secure.

Much the most highly endangered is the exquisite Lesser Florican, which, with its unpredictable use of breeding areas in western India and its basically unknown movements outside the breeding season, is rendered extremely hard to conserve, especially when its grassland habitat is under such intense pressure from agriculture and pastoralism. In 1994 it was classified as Critically Endangered, the highest of the new IUCN threatened categories, and its future depends on small pockets of grassland, known as *vidis*, that are given strict protection as an insurance for cattle against drought.

The Bengal Florican and the Great Indian Bustard are both classified as Endangered, the second highest category of threat. In purely numerical terms, with perhaps as few as 300 birds left, and in view of its extremely fragmented range, the Bengal Florican is much the more precarious of the two, depending for its survival on India and Nepal's permanent commitment to the management and protection of half a dozen parks and reserves, Dudwa, Manas, Orang and Kaziranga in India, and Sukla Phanta, Bardia and perhaps Chitwan in Nepal. The Great Indian ranges much more widely and responds fairly well to management, but still musters perhaps only 1500 birds in total scattered mostly over unprotected terrain, and represents an immense long-term challenge.

The Great Bustard possesses possibly the widest range of any threatened species of bird, distributed as it is from close to the Atlantic seaboard in Iberia and Morocco across to the Pacific coast of China, a distance of very roughly 10,000 km. However, within this range it survives in small and ever-diminishing pockets, and has already become extinct in a series of European countries, and is about to do so in several more. Its future depends on farming within its range remaining at low intensity only. Given that European Commission funding of zones of such land is still awaited, there can be no guarantee of this, so the species qualifies as Vulnerable.

Of the species that come close to meeting the criteria for threatened status, the Little Bustard will share the same fate as the Great, with which it is largely sympatric. It is still, however, numerically strong in Iberia, Russia and Kazakhstan, but has suffered a catastrophic decline in Russia for reasons that remain only partly understood. Meanwhile, recent intensive hunting by Arab dignitaries in parts of the Nubian Bustard's range, coupled with the steady desertification of the Sahel, suggest that this species too could soon be threatened. The Little Brown Bustard has a small range in a region where chronic warfare renders the future of its habitats unpredictable, and the Blue faces the danger of intensified farming within its even more restricted range.

The Houbara is the subject of a detailed recovery plan in the Canary Islands, and of various ecological and management studies elsewhere in its range. There is still a great deal of work to be done to obtain concrete data on population levels and recruitment and survival rates, so that some reasonable estimates of sustainable offtake levels can be determined. The hunting that so concerns many conservationists is conducted following agreement at the highest level, which thus overrides most national policies and laws. More dialogue between hunters and conservationists is needed to build consensus on the pattern and intensity of this hunting. The BirdLife Steppe and Grassland (formerly Bustard) Specialist Group has been a pioneer in this regard, as it has in many other bustard conservation issues.

In general, and for a variety of interrelating reasons, notably size, cost, pre-existing land-use patterns and the nomadism and migrations of the target species, it is clear that the kinds of area over which bustards range do not allow for conservation by the classic solution of protected areas. It is, of course, true that many national parks and other reserves, notably in the adjacent Sahel and savanna zones of Africa, and those at the foot of the Himalayas, play significant parts in bustard conservation, but they have all been created for other reasons. A few sanctuaries set up for the Great Indian Bustard are the only examples of protected areas targeted specifically at a member of the Otididae.

Far more important is the large-scale management of land at a level of intensity that permits bustards to remain on it as if it were unmodified. This has significant economic implications for local human communities that can only be addressed on a higher political and indeed philosophical plane; but it is increasingly being recognized that nature conservation cannot simply be relegated to reserves, but where possible must be integrated with other land uses. The bustards, being in such direct conflict with man over the use of the land, are one of the most significant challenges in this regard, and it falls in particular to India and Europe to take the lead to demonstrate that it is a challenge that can be met.

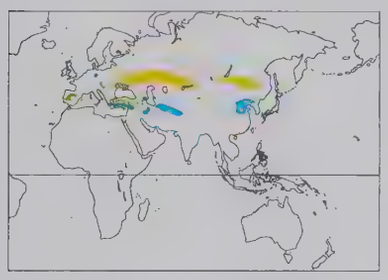
PLATE 23



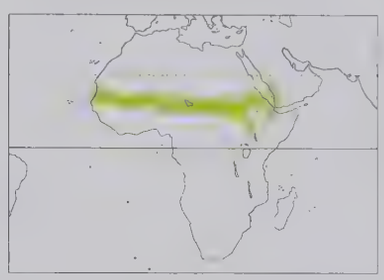
inches 12
cm 30

Genus *OTIS* Linnaeus, 1758

1. Great Bustard
Otis tarda

French: Grande Outarde **German**: Großtrappe **Spanish**: Avutarda Euroasiática

Taxonomy. *Otis Tarda* Linnaeus, 1758, Poland.
Genus has frequently been merged with *Tetrax*, and sometimes also *Ardeotis* and *Neotis*, but nowadays species normally considered sufficiently distinct to merit generic isolation from these forms (see page 240). Birds of C Asia formerly awarded separate race *korejewi*, but extensive overlap with nominate *tarda*. Two subspecies recognized.
Subspecies and Distribution.
O. t. tarda Linnaeus, 1758 - N Morocco and Iberia, Germany and Hungary, and S Ukraine; remnant populations elsewhere in E Europe. Also breeds in Turkey and W Iran, and from SW Russia through Kazakhstan to Kyrgyzstan, wintering from S Turkey and Syria through S Azerbaijan and N Iran to Uzbekistan and Tadjikistan.
O. t. dybowskii Taczanowski, 1874 - SE Russia, Mongolia and NE China.



Descriptive notes. Male 105 cm, 5800-18,000 g; female 75 cm, 3300-5300 g. Breeding male has upperparts barred black and gold, with broad white patch on closed wing, tail as back with broad black subterminal bar and white tips; head and foreneck pale blue-grey shading into white and then vinous russet on lower hindneck, sides of lower neck and breast; long whitish barbs point back from chin; undersides white; bill dull grey, legs olive brown to dull grey. Non-breeding male lacks chin-barbs, and has entire neck and breast pale grey. Female similar to, but considerably smaller than, non-breeding male. Juvenile similar to adult female, but has more buff on head and neck, and upperparts less distinctly barred. Race *dybowskii* has head and neck slightly paler grey and upperparts more distinctly barred, but barely distinct from nominate and geographical limits unclear.
Habitat. Flat or rolling open short-grass plains, usually clear of trees, although uses cork oak (*Quercus suber*) "savanna" and olive groves in SW Iberia. Insect- and flower-rich grassland and pasture provide important habitat in spring and summer, fields of stubble are favoured in late summer and autumn, lucerne in winter, but a high diversity of low-intensity land use and lack of disturbance are generally important for year round needs.
Food and Feeding. Mainly plant material and invertebrates, although small mammals, amphibians and nestling birds sometimes taken. Key plant families include composites, legumes, crucifers and grasses, while chief animal food is Orthoptera and Coleoptera. High proportion of cultivated plants utilized from late summer through to winter, with green matter increasingly important from mid-winter into spring, and insects from spring into late summer.
Breeding. Laying in Apr-May, also Jun in colder NE parts of range. Nest on ground with or without scrape, occasionally with fragments of grass stems and crop stems as lining. Nearly always 2-3 eggs (1-4); incubation c. 25 days; chicks cinnamon-pink to pale buff, with sepia streaks and other markings; fledging period 30-35 days, although full size reached at 80-120 days, which is also probably the minimum period of dependency. First breeding at 5-6 years in male, 2-3 years in female.
Movements. Largely sedentary or dispersive in Iberia, C & E Europe to Ukraine, depending on severity of winter, and on age and sex, males appearing to move over shorter distances, probably related to degree of maturity. Migratory in Asia, where southward shifts occur, generally over limited distances, from Aug to early winter, with birds returning Mar-Apr.
Status and Conservation. VULNERABLE. CITES II. Total population unknown, but European populations may amount to 26,000-32,000 birds, with strongholds in Spain with 13,500-14,000 birds, Portugal 500-700, Hungary 1000-1200 and Russia 10,000-11,000; other important populations include Turkey 145-4000 birds and Ukraine 300-500 birds; in rest of Europe, populations remain only in Germany with 150, Austria 50-60, Slovakia 25-40, Romania 10-15, Czech Republic 10-13 and Moldova 2-3 birds. Significant declines in most areas, as in Hungary, from estimated total of 8557 birds in 1941, to 3000-3237 in mid-1970's, to 1000-1200 in 1991; in Austria, from estimated 700-800 birds in 1939/40, to c. 400 in 1958, to 200-230 in 1969-1972, to 110-120 in 1977, to 50-60 in 1993. In NW Morocco, population had declined to c. 100 birds by mid-1980's. Recently extinct in Poland, Bulgaria and Yugoslavia; last bred in England 1832, France 1863, and Sweden and Greece respectively middle and end of 19th century. Bred in Azerbaijan until 1940's or 1950's, and formerly wintered in considerable numbers with flocks of 150-200 birds recorded in 1930's; few sightings nowadays, and total wintering population may number only a few 10's to a few 100's. Throughout range, irrigation and agricultural intensification (the first promoting the second, and the second leading to sterilized monoculture) are chief threats; also pesticide use, electric cables, illegal hunting, overgrazing and disturbance. Destruction of nests and chicks during crop treatment and harvesting is substantial. Habitat management in Austria involves minimizing disturbance and maximizing the availability of various favoured food plants. Populations can only survive through the maintenance of low-intensity farming over large areas; in Europe this may be achieved through European Union Zonal Programmes under the Common Agricultural Policy.

Genus *ARDEOTIS* Le Mahout, 1853

2. Arabian Bustard
Ardeotis arabs

French: Outarde arabe **German**: Arabertrappe **Spanish**: Avutarda Árabe
Other common names: Sudan/Great Arabian Bustard

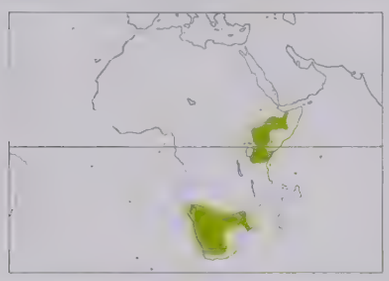
Taxonomy. *Otis arabs* Linnaeus, 1758, Yemen.
In past, genus frequently labelled *Choriotis*, but *Ardeotis* has priority; genus sometimes merged with *Otis*. Present species forms superspecies with *A. kori*. All four *Ardeotis* have occasionally been placed in same superspecies. Four subspecies recognized.
Subspecies and Distribution.
A. a. lynesi (Bannerman, 1930) - W Morocco (probably extinct).
A. a. stieberi (Neumann, 1907) - SW Mauritania and Senegambia E to NE Sudan.
A. a. butleri (Bannerman, 1930) - S Sudan; single record in NW Kenya.
A. a. arabs (Linnaeus, 1758) - Eritrea, Ethiopia, Djibouti and NW Somalia; SW Saudi Arabia and W Yemen.

Descriptive notes. Male c. 100 cm, 5700-10,000 g; female c. 75 cm, 4500 g. Back, wings and central tail sandy brown with fine black markings, white flecking on folded wing; some broad black and white subterminal bands on outer feathers of tail, often concealed under uniform central tail feathers; head, neck and breast appear grey, being finely barred dark grey-brown on ashy white; crown black with pale grey centre, slight backwards crest, supercilium white; belly white; legs and eyes yellowish. Similar to *A. kori*, but somewhat smaller, and lacks black on base of neck and black flecking in wing. Female similar to male, but smaller and generally greyer above. Juvenile similar to female, but with less distinct pattern on wing. Racial variation based on differences in colour tones and size, with much less white flecking on closed wing in nominate *arabs* and *lynesi*; general coloration of upperparts varies considerably with colour of local substrate.
Habitat. Semi-desert and open grassy plains, arid bush country, savanna, *Acacia* parkland, and sometimes even in open woodland. Requirements in Djibouti appear to be a sandy substrate with either a good density of tall trees (chiefly *Acacia*) with sparse ground cover, or good ground cover with reduced tree density. In Yemen, found in cultivated areas, retreating in the hot hours into high crops of sorghum and millet.
Food and Feeding. Chiefly grasshoppers, but also locusts when swarming, and beetles, bugs, crickets, caterpillars and other invertebrates, as well as small vertebrates. Seeds, fruits of trees, succulent parts of plants and gum from *Acacia* are also taken.
Breeding. Season linked to warmer periods in Palearctic fringes, thus Apr-Jun in Morocco, Mauritania and Arabia, although display noted Oct-Nov in Yemen; wetter periods in Sahelian range Jul-Oct, possibly later. In Niger, solitary breeding females found every 2-3 km. Nest is a shallow scrape, sometimes lined with vegetation. 1-2 eggs. No further information available.
Movements. Unclear. In Sahel zone, migrates at 150-450 m above ground, in flocks, sometimes with *Neotis denhami*, moving N in Jun, S in Oct after breeding; presence in Sahel in dry season also reported, and species is resident in Senegal, only moving locally if conditions become severe. Rare dry season visitor to extreme N Ghana.
Status and Conservation. Not globally threatened. CITES II. Widespread in very poorly documented areas, so might still be common in many places; however, in more accessible and better monitored parts of its range species is now generally uncommon, having declined sharply owing to habitat destruction and hunting. Moreover, in W Africa, where abundant into 1960's, has become rare owing to hunting, at first by technical workers but in recent years by Arab falconers, whose activities extend throughout the Sahel; notable decline in numbers in N Nigeria due to hunting and trapping, and species now uncommon, limited mainly to NE. Race *lynesi* has not been reported for over 50 years, and may be extinct; more recent Moroccan records of the species may refer to stray *stieberi*. Population on Arabian Peninsula is very small and likely to be declining from hunting, habitat loss and effects of pesticides; still fairly common locally in Tihamah plain of W Yemen, at Wadi Mawr-Al-Zuhrah and Al-Murah, but intensification of agriculture may pose threat.
Bibliography. Ash (1989), Ash & Miskell (1983), Britton, P.L. (1980), Brooks *et al.* (1987), Cave & Macdonald (1955), Coverdale *et al.* (1991), Cramp & Simmons (1980), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Étchécopar & Hüe (1964), Gore (1990), Grimes (1987), Hollom *et al.* (1988), Lamarche (1988), Mackworth-Praed & Grant (1957, 1970), Morel, G.J. & Morel (1990), Morel, R. (1989), Newby (1979, 1990), Nikolaus (1987), Porter & Goriup (1985), Rahmani & Shobrak (1987, 1990), Rands *et al.* (1987), Shobrak (1988), Shobrak & Boug (1990), Shobrak & Rahmani (1991, 1993), Short *et al.* (1990), Turner (1982), Urban *et al.* (1986), Welch & Welch (1989).

3. Kori Bustard
Ardeotis kori

French: Outarde kori **German**: Riesentrappe **Spanish**: Avutarda Kori
Other common names: Large Bustard

Taxonomy. *Otis Kori* Burchell, 1822, confluence of Vaal and Orange Rivers.
In past, genus frequently labelled *Choriotis*, but *Ardeotis* has priority; genus sometimes merged with *Otis*. Present species forms superspecies with *A. arabs*. Sometimes alternatively considered to form



On following pages: 4. Great Indian Bustard (*Ardeotis nigriceps*); 5. Australian Bustard (*Ardeotis australis*); 6. Houbara Bustard (*Chlamydotis undulata*).

superspecies with *A. nigriceps* and *A. australis*; these three have even been lumped together in single species, *A. kori*. All four *Ardeotis* have occasionally been placed in same superspecies. Two subspecies recognized.

Subspecies and Distribution.

A. k. struthiunculus (Neumann, 1907) - NW Somalia and C Ethiopia through SE Sudan, NE Uganda and Kenya to N Tanzania.

A. k. kori (Burchell, 1822) - S Angola and Namibia E through Botswana to S Zimbabwe and S Mozambique, and S to South Africa.

Descriptive notes. Male c. 120 cm, 10,900-19,000 g; female c. 90 cm, 5900 g. Back, wings and central tail brown with fine buff vermiculations, white panel with black spots on folded wing; two buffy white median bars on tail, often concealed; head, neck and breast appear grey, being finely barred dark grey-brown on ashy white, with often indistinct black band at shoulders and base of neck; crown black with pale grey centre, short straggling backwards crest, underlined by white supercilium; belly white; legs dull yellowish to greyish, bill grey, eyes orange-brown to yellow. Similar to *A. arabs*, but somewhat larger and with black on base of neck and black flecking in wing; however, many characters are variable for reasons not yet clear. Female similar to male, but much smaller, and with less black on crown. Juvenile lacks crest and is more spotted on mantle. Race *struthiunculus* slightly larger and less dusky, with more contrast in head pattern.

Habitat. Flat, arid, mostly open country, generally below 2000 m and usually with a short herb layer, e.g. grassland, karoo, bushveld, thornveld, scrubland and savanna, but also floodplains, duneland and fossil valleys; also man-modified habitats, such as wheat fields and recently burnt firebreaks. In the hot dry season in Kenya, many birds move into woodland, and use of closed-canopy miombo woodland is known from Zimbabwe. In one report, birds are commonest where grazing mammals are most plentiful.

Food and Feeding. Exploits a wide range of vegetable and animal resources: seeds, berries, bulbs, *Acacia* gum, snails, insects (chiefly Orthoptera), rodents, lizards and snakes (up to medium size), and birds (eggs and nestlings, also roadkills). Birds often gather in areas infested with locusts or caterpillars, or where fire is flushing small animals or has already scorched them. Importance of dung-dependent fauna in diet not clear, but possibly significant.

Breeding. Sept-Feb in S Africa, Dec-Aug (according to rains) in E Africa. Nests on ground often near a distinct feature, such as a grass clump or rocks, sometimes in partial tree shade; will breed in area just after herds have moved through the territory; nest is shallow scrape, sometimes with thin lining of grass. Usually 2 eggs, possibly 1 in drier years; incubation period c. 25 days; chicks have tawny down striped and mottled with dark brown. In E Africa, breeding success greater when wet season good.

Movements. Largely sedentary. In Kenya local movements, presumably on foot, occur into woodland habitat in the dry period, Jan-Mar, though possibly not by breeding birds.

Status and Conservation. Not globally threatened. CITES II. Where undisturbed, can still be common, as in parts of Botswana. Zimbabwe holds c. 5000 individuals, but the species is certainly declining there owing to habitat destruction, hunting pressure and disturbance; threatened in South Africa, where abundance has dropped since last century, although range thought not to have decreased, with same apparent causes of decline. Species suffers some mortality from collisions with electricity cables, vehicles and fences.

Bibliography. Allan & Davies (1995), Allen & Clifton (1972), Ash & Miskell (1983), Baker (1989), Britton, P.L. (1980), Brooke (1984a), Cave & Macdonald (1955), Chiweshe & Dale (1993), Dale (1990), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Hallager (1994), Hellmich (1988), Irwin (1981), Jubb (1981), Kok & Van Ee (1989), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957, 1962), Maclean (1993), Maozeka (1993), Morgan-Davies (1965), Mwangi & Karanja (1989, 1992, 1993), Nikolaus (1987), Penry (1994), Pinto (1983), Pollard (1986), Prozesky (1977), Rockingham-Gill (1983, 1989), Schmidl (1982), Short *et al.* (1990), van Someren (1925-1935), Urban *et al.* (1986), Viljoen & Viljoen (1987).

4. Great Indian Bustard

Ardeotis nigriceps

French: Outarde à tête noire **German**: Hindutrappe **Spanish**: Avutarda India
Other common names: Indian Bustard

Taxonomy. *Otis nigriceps* Vigors, 1831, Himalayas.

In past, genus frequently labelled *Choriotis*, but *Ardeotis* has priority; genus sometimes merged with *Otis*. Present species forms superspecies with *A. australis*; these two sometimes separated from their two congeners in genus *Austrotis*, or, erroneously, in genus *Choriotis*, but type species of latter is *A. arabs*. Superspecies sometimes considered to include *A. kori*, as well as *A. australis*; all three have even been lumped into single species, *A. kori*. All four *Ardeotis* have occasionally been placed in same superspecies. Monotypic.

Distribution. W & C India, from Rajasthan S through Gujarat, Madhya Pradesh and Maharashtra to N Karnataka and W Andhra Pradesh; relict populations elsewhere.

Descriptive notes. Male 120 cm, 8000-14,500 g; female 90 cm, 3500-6750 g. Often has extensive black crown; legs pale yellowish. Virtually identical to *A. australis*, but often with indistinct black breast band, some black on thighs, and either no distinct line behind eye or black cap descending through eye; tends to have less white on black wing patch. Female smaller, with greyer neck. Immature similar to female, but has buff spots on crown, hindneck and upper back.

Habitat. Optimally occurs in rolling grassland with vegetation 30-70 cm high, with or without scattered trees; but also found in open scrub, sandy semi-desert plains, broad pastures, marginal fields and lightly disturbed cultivation.

Food and Feeding. Opportunistic, exploiting local and seasonal abundance. Grain, shoots and berries, with a particular liking for the drupes of *Zizyphus rotundifolia* and the crops *Eruca sativa* and *Cicer arietinum*; also locusts, grasshoppers, beetles (including green blister beetles *Cantharis tenuicollis*), centipedes, lizards and small snakes and mammals.

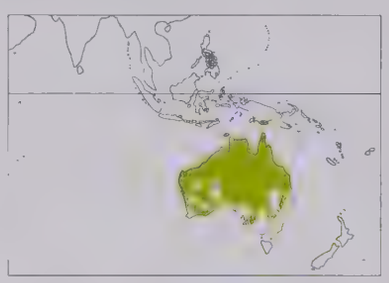
Breeding. Occurs throughout year, varying with area and rainfall, e.g. chiefly Mar-Jun in N of range, Aug-Oct in W Deccan, Aug-Jan in E Deccan. Nest is a shallow, sometimes sparsely lined scrape, often with virtually no adjacent cover. Normally 1 egg, rarely 2; incubation period c. 27 days; chick has buff-coloured down with black markings on head and back; fledging takes 35-40 days, but young bird remains with female until start of next breeding season.

Movements. Sedentary or seasonally nomadic, or may follow both strategies; generally dispersing, or at least disappearing, at various periods depending probably on availability of water; possibly some birds migrate between the Thar Desert and the Deccan Tableland, profiting from the monsoon rains in each area.

Status and Conservation. ENDANGERED. CITES I. In 19th century ranged from E Pakistan, in Sind and Punjab, E to W Bengal, and S to C Tamil Nadu; in recent times, only rare vagrant to Pakistan. Total population now estimated to number 1500-2000 birds, mainly in Rajasthan with 500-1000 birds, remainder scattered mostly through parts of W India. Hunting considered chief cause of decline, but habitat loss and disturbance, probably underestimated in the past, are certainly key factors now, with nest failure commonly attributed to cattle trampling eggs or simply keeping female off nest; nests often predated by House Crows (*Corvus splendens*).

Bibliography. Ali & Rahmani (1982, 1985), Ali & Ripley (1980), Bhushan & Rahmani (1992), Chandra (1990), Collar & Andrew (1988), Collar *et al.* (1994), Cornwallis (1983b), Dharmakumarsinhji (1957, 1971, 1983), Goriup (1983a), Gupta (1975), Hasan (1983), Kapoor & Bhatia (1983), King (1978/79), Kulkarni (1981, 1983), Lal (1993), Manakadan & Rahmani (1986, 1989, 1990), Mathur (1983), Neginhal (1983a, 1983b), Prakash (1983), Rahmani (1984, 1986, 1987, 1988a, 1988b, 1989, 1991, 1992), Rahmani & Manakadan (1985, 1986, 1987, 1990), Rego (1983), Ripley (1982), Roberts, T.J. (1991), Sangha (1994), Saxena (1983), Shukla (1983), Sinha (1983), Vardhan (1985), Vyas *et al.* (1983).

5. Australian Bustard



Ardeotis australis

French: Outarde d'Australie **German**: Wammentrappe **Spanish**: Avutarda Australiana

Taxonomy. *Otis Australis* J. E. Gray, 1829, New South Wales.

In past, genus frequently labelled *Choriotis*, but *Ardeotis* has priority; genus sometimes merged with *Otis*. Present species forms superspecies with *A. nigriceps*; these two sometimes separated from congeners in genus *Austrotis*, or, erroneously, in genus *Choriotis*, but type species of latter is *A. arabs*. Superspecies sometimes considered to include *A. kori*, as well as *A. nigriceps*; all three have even been lumped into single species, *A. kori*. All four *Ardeotis* have occasionally been placed in same superspecies. Monotypic.

Distribution. Australia, in all states, but generally rarer or absent in S and especially in SE; also S Papua New Guinea in the Trans-Fly, ranging W into Irian Jaya.

Descriptive notes. Male c. 120 cm, 5600-8200 g; female c. 90 cm, 2800-3200 g. Back, wings and central tail brown with fine dark vermiculations, black panel spotted with white on folded wing; outermost tail feathers chiefly black and white, but often concealed; head, neck and breast appear greyish white, being finely barred dark grey on white; black breast band often hidden; crown is black with slight backwards crest, underlined by white supercilium and a thin black line behind eye; belly white; legs and bill whitish, eye brown. Female smaller, with scattered dark blotches on upperparts, greyer neck and duller crown. Immature has pale grey and brown mottling on head, neck and upperparts.

Habitat. Mainly grassland dominated by tussocky forms, also in sparse low shrubland, savanna, open woodland and, in New Guinea, edges of swamps. Utilizes long grass areas in wet season, low open shrub plains in dry season. Often found in burnt or regenerating areas, sometimes in cultivated areas. Breeds mainly in ecotone between grassland and cover-yielding habitat such as hummock grassland, shrubland and woodland.

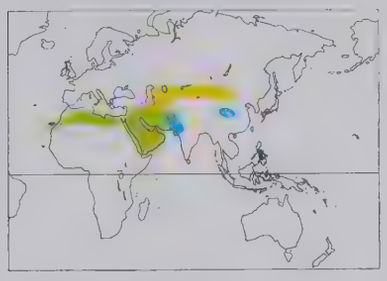
Food and Feeding. Shoots, roots, leaves, flowerheads, seeds and berries; molluscs, myriapods, arachnids, insects (especially grasshoppers, beetles and caterpillars), reptiles, young birds and small rodents. Often attracted to fire, taking live and dead prey; once recorded following a plough. In New Guinea, several birds may gather to feed in shallow water.

Breeding. Aseasonal in arid and semi-arid N regions, occurring in response to rainfall; Apr-Nov in S. Nests on bare ground, sometimes scraped clear of stones; on low sandy ridges usually with termite mounds and near gilgais. Normally 1-2 eggs, less commonly 3; incubation 23-24 days; chick has buff-coloured down, with darker brown stripes; fledging period apparently unrecorded.

Movements. Largely sedentary in parts of range, but may disperse nomadically in non-breeding season; in some areas shows small-scale seasonal displacements away from drying areas. Irrupts in response to inland droughts, regional rainfall and grasshopper and mouse plagues; also locally to bush fires. Report of migration between New Guinea and Australia requires substantiation.

Status and Conservation. Not globally threatened. CITES II. Range has contracted since European settlement, owing to heavy hunting for food and sport up to at least 1940, when formally protected; other main factors are habitat change and effects of introduced animals. Alteration of tussock grasslands by rabbits may be particularly important, as ranges of the two species are now largely mutually exclusive. Livestock may also have caused a decline; intensive land-use practices cause desertion of the areas affected. Locally common in Trans-Fly area of S New Guinea.

Bibliography. Anon. (1971b), Appayya (1982), Beehler *et al.* (1986), Blakers *et al.* (1984), Coates (1985), Fitzherbert (1978, 1983), Garnett (1993), Grice *et al.* (1986), Hoogerwerf (1964), Lindsey (1992), Lunt (1992), Macdonald (1988), Marchant & Higgins (1993), Mattingley (1929), Pizzey & Doyle (1980), Rand & Gilliard (1967), Roberts (1979), Schodde & Tidemann (1986), Simpson & Day (1994), Slater *et al.* (1989), White, D.M. (1985).



Genus *CHLAMYDOTIS* Lesson, 1839

6. Houbara Bustard

Chlamydotis undulata

French: Outarde houbara **German**: Kragentrappe **Spanish**: Avutarda Hubara
Other common names: Ruffed Bustard

Taxonomy. *Psophia undulata* Jacquin, 1784, captive bird from Tripoli.
Apparently close to *Neotis* (see page 240). Recent work suggests that race *macqueenii* might merit treatment as separate species. Three subspecies recognized.
Subspecies and Distribution.
C. u. fuertaventurae (Rothschild & Hartert, 1894) - E Canary Is.
C. u. undulata (Jacquin, 1784) - N Africa, E to NC Egypt.
C. u. macqueenii (J. E. Gray, 1832) - Middle East and Arabia E to Iran and extreme W Pakistan. Also breeds from NW Kazakhstan and NE Iran E to Mongolia and N China, wintering from Persian Gulf to Pakistan and NW India, and in C China.

Descriptive notes. Male 65-75 cm, 1800-3200 g; female 55-65 cm, 1200-1700 g. Upperparts pale sandy buff, mottled and lined with darker brown, clear and paler on folded wing, tail with up to four bluish grey bars; crown buff with sometimes hidden central line of white erectile feathers, rest of head pale greyish buff with black line down side of neck composed of erectile filamentous plumes which turn white (usually hidden) on side of breast; underparts white; eye pale yellow; legs olive grey to pale straw yellow. Female similar but smaller, with filamentous neck plumes much reduced. Juvenile similar to female but ornamental plumes on head and neck scarcely present, plumage yellower and white areas of wing duller. Race *fuertaventurae* darker; *macqueenii* has black in white crown feathers, a blue-grey foreneck, and is larger; latter race and nominate both show much individual variation in size, with considerable overlap.
Habitat. Arid sandy semi-desert with tussock grass, flat bare stony plains dotted with xerophytic and halophytic scrub, wormwood steppe and sandy grasslands, often visiting marginal cultivation in non-breeding period.
Food and Feeding. Variable and opportunistic, with no clearly discernible seasonal or geographical pattern. Vegetable matter such as fruits, seeds, shoots, leaves and flowers; animal material chiefly Orthoptera and Coleoptera, but includes various invertebrates and small snakes and lizards.
Breeding. Nov-Jun, but chiefly Mar-Apr, in N Africa and Canaries; Mar-May in Syria; Apr-Jun in CIS; apparently Mar-Apr in Pakistan. Nest is a shallow unlined scrape on ground, sometimes in open but usually near some cover. Eggs 2-3, though up to 5 recorded in *macqueenii*; incubation usually 24 days, but on occasion up to 28 days; chicks have golden and buff down, with white, black and sepia markings; fledging period c. 35 days. Young stay with female parent into first autumn.
Movements. Sedentary and locally nomadic in Africa and Middle East. C Asian populations strongly migratory, leaving breeding grounds in Aug-Oct on trans-Himalayan migration, and arriving Sept-Nov in wintering grounds from Persian Gulf states to NW India, some occurring W to Egypt; abundance in given areas varies from year to year, apparently in response to rain-related condition of habitat; birds travel N again in Mar-Apr. Vagrant S to Sudan; expected to occur regularly in NW Sudan, but no records located.
Status and Conservation. Not globally threatened. CITES I. Although reportedly in decline in almost every range state this century, true status very difficult to gauge owing to birds' highly cryptic coloration, elusive behaviour, and remote and inhospitable habitat. Even in Canary Is, population hard to assess, with an estimated 400 birds on Lanzarote in 1993, where 15-20 birds were believed present in 1979, and 60 birds in 1991, indicating a remarkable capacity to hide, or to colonize areas rapidly, or to expand numbers in favourable conditions; however, tourist facilities, including the use of off-road vehicles, are rapidly affecting habitat in the Canaries. In Western Negev, Israel, population reckoned to number 185-355 birds. Species is in considerable decline throughout N Africa. Population in Kazakhstan estimated at 40,000-60,000 birds, with substantial numbers also in Uzbekistan and Iran. In Pakistan, hunted in thousands over three decades, but no clear evidence of decline: 4360 birds killed by local and visiting hunters in winter 1982/83, and 4955 in 1984/85; also some 2000 birds trapped there being sold to UAE in period 1986-1988; but total population wintering there each year anticipated at 20,000-25,000 birds. Threats include intensive agricultural practices, human disturbance, habitat degradation through livestock overgrazing, and hunting both by local people with guns and Arab dignitaries with falcons.

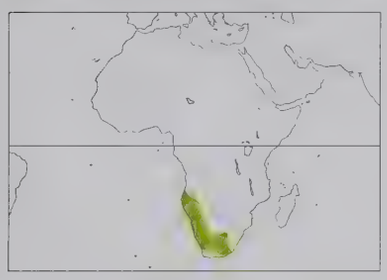
PLATE 24

inches 12

cm 30



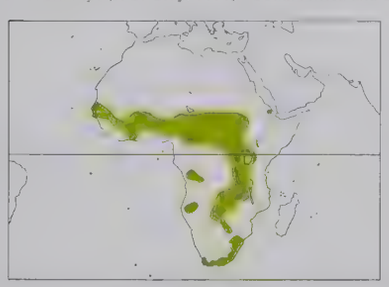
Genus *NEOTIS* Sharpe, 1893

7. Ludwig's Bustard

Neotis ludwigii

French: Outarde de Ludwig **German**: Ludwigtrappe **Spanish**: Avutarda de Namibia

Taxonomy. *Otis Ludwigii* Rüppell, 1837, South Africa.
Genus sometimes merged with *Otis*. Present species is most distinctive member of genus. Monotypic.
Distribution. Extreme SW Angola through W Namibia to S South Africa.



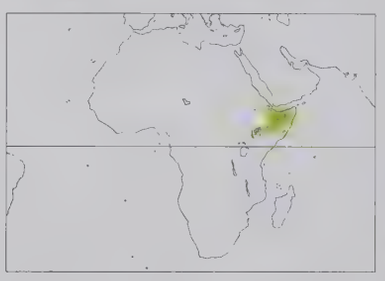
Descriptive notes. Male 85 cm, 4200-6000 g; female 2200-2500 g. Upperparts brown finely vermiculated with buff, tail similar with broad dark bars, white wing panel, usually concealed when wing folded; head, neck and breast dark brown to sooty brown, hindneck greyish white, base of hindneck dull orange, belly white; bill brown, legs yellowish. Female smaller than male, paler and more speckled on head and neck.
Habitat. Open lowland and upland plains with grass and light thornbush, sandy open shrub veld and semi-desert in the arid and semi-arid Namib and Karoo biomes.
Food and Feeding. Invertebrates, small vertebrates and vegetable matter have all been recorded, but strong evidence of movement with rains in pursuit of Orthoptera hatchings, although vegetation remains important and berries of *Lycium oxycladum* reported. Flocks (up to 70 recorded) may gather on cultivated areas or in natural vegetation after rain.
Breeding. Aug-Dec. Nest is a scrape on bare ground often among stones, on crest of low ridge or hill slope. Eggs 2; chick has reddish down streaked blackish.
Movements. Species is partial migrant towards SW from the more northerly and interior summer rainfall region (Nama Karoo), where present Nov-Apr, to the more southerly and coastal winter rainfall region (Succulent Karoo), for the period May-Oct.
Status and Conservation. Not globally threatened. CITES II. Total population size estimated at 56,000-81,000 birds. An assumed contraction of range, causing concern for its security in 1984, was based on birds that had in fact been *N. denhami*. However, snares set for mammals on farms, and electricity wires, appear to be two considerable threats to the species in some areas.
Bibliography. Allan (1993, 1994b), Allan & Davies (1995), Boobyer (1990), Brooke (1984a), Brown, C.J. (1993), Clancey (1967), Cyrus & Robson (1980), Dowsett & Forbes-Watson (1993), Earlé *et al.* (1988), Ginn *et al.* (1989), Herholdt (1987, 1988), Kok & Van Ee (1989), Mackworth-Praed & Grant (1962), Maclean (1993), van Niekerk (1993), Penry (1994), Pinto (1983), Sinclair (1987), Skead, C.J. (1967), Urban *et al.* (1986).

8. Denham's Bustard

Neotis denhami

French: Outarde de Denham **German**: Kafferntrappe **Spanish**: Avutarda Cafre
Other common names: Stanley Bustard; Burchell's Bustard ("*burchellii*")

Taxonomy. *Otis Denhami* Children, 1826, near Lake Chad.
Genus sometimes merged with *Otis*. Present species may form parapatric species pair with *N. heuglinii*. Normally considered to include form "*burchellii*" of uncertain status, known only by type specimen from E Sudan. In past, present species was at times known as *N. cafra*, but due to confusion in nomenclature with *Eupodotis senegalensis*, name *cafra* was officially suppressed. Three subspecies recognized.
Subspecies and Distribution.
N. d. denhami (Children, 1826) - SW Mauritania and Senegambia E to N Uganda and Ethiopia.
N. d. jacksoni Bannerman, 1930 - Kenya and W Tanzania S to Zambia, N Botswana and N Zimbabwe; S Congo and W Zaire; SW Angola.
N. d. stanleyi (J. E. Gray, 1831) - South Africa and Swaziland.



Descriptive notes. Male 100 cm, 9000-10,000 g; female 80 cm, 3000 g. Upperparts dull brown with fine black vermiculations, tail with several creamy bars; large panel on folded wing mottled white on black; crown grey bordered black, long white supercilium, black line through eye, chin white, cheeks, neck and breast grey, hindneck orange-brown, belly white; legs pale yellow, bill whitish horn with darker culmen and tip. Female smaller than male, with grey replaced by buff; more patterned upperparts and a finely barred foreneck. Immature similar to female; immature male generally rather variable, with neck almost black in form "*burchellii*". Race *jacksoni* slightly smaller, darker on hindneck (intermediates in SE Sudan); race *stanleyi* darker and more richly coloured on hindneck, paler on back, with foreneck white in breeding male.
Habitat. Grasslands including high plateau downland up to 3000 m, grassy *Acacia*-studded dunes, fairly dense shrubland, light woodland, farmland and crops, dried marsh and arid scrub plains; also grass-covered ironstone pans and burnt savanna woodland in NW Sierra Leone. In South Africa, a bird of high rainfall sour grassveld, and planted pastures and cereal croplands in fynbos, favouring natural vegetation in the breeding season and harvested cereal crop fields at other times.
Food and Feeding. Wide range of foods recorded, including many different arthropods (in places nymphal stages of invasive Orthoptera), small vertebrates and various parts of plants including flowerheads. Recorded defending active termite mound, pecking at animal droppings for arthropods, wading in pools apparently for frogs on emergent stems, and gathering in small numbers on recently burnt areas.
Breeding. Breeding schedule unclear in many areas, possibly reflecting opportunism based on rainfall; Jun-Oct in Sahel; nuptial display in Jan in Sierra Leone, Feb-Mar (dry season) in Ivory Coast; May in Nigeria; Dec-Feb in N Zaire, but in S Zaire nuptial display in Jun (dry season); Jan-Mar and Jul in E Africa; chiefly Oct-Jan (Aug-Apr) in C & S Africa. Nest is a shallow scrape on bare ground, usually amidst grass or on low prominence. Eggs 1-2; chick has buff down mottled and striped black.
Movements. Nominate *denhami* migrates N generally in May-Jun but as late as Aug; returns Sept-Oct or as late as Dec, following rains and usually, or at least sometimes, then breeding (but not in Senegal); only present in S Niger and Ivory Coast in dry season, but considered sedentary in Central African Republic. Movements of race *jacksoni* also unclear, but present May-Oct in SE Zaire, and Aug-May (mostly Dec-Apr) in Zimbabwe and Botswana, suggesting a N-S shift, though also present Aug-Jan in E Zaire; montane populations in E may move lower, Jun-Aug; records from S Congo and W Zaire are all of non-breeding birds. Race *stanleyi* also shows movements to lower regions in period Jun-Aug, with an apparently immigrant summer breeding population in coastal Zululand, South Africa, from Sept onwards.
Status and Conservation. Not globally threatened. CITES II. Common in Central African Republic and parts of Uganda, but decline in N of range in Sudan, and hunting widespread in Sahel zone; notable decline in numbers in Nigeria due to hunting and trapping. Threatened in Kenya, where range contraction well documented and population as low as 300-400 birds; also in South Africa, where total Transvaal breeding population only numbers c. 300 birds, and S Cape Province winter population an estimated 956 birds; in both countries decline related to competition with man for land.
Bibliography. Allan (1993), Allan & Davies (1995), Baker (1989), Benson & Benson (1975), Benson & Irwin (1972), Benson *et al.* (1971), Britton, P.L. (1980), Brooke (1984a), Carroll, R.W. (1988), Cave & Macdonald (1955), Cramp & Simmons (1980), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Herholdt (1988), Howells & Fynn (1979), Irwin (1981), Koster & Grettenberger (1983), Lewis & Pomeroy (1989), Lippens & Wille (1976), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Morel, G.J. & Morel (1990), Morel, R. (1987), Tarboton (1989), Tarboton, Kemp & Kemp (1987), Turner & Goriup (1989), Urban *et al.* (1986), Uys (1963), Wilson (1972).

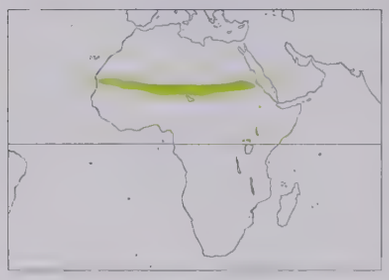
9. Heuglin's Bustard

Neotis heuglinii

French: Outarde de Heuglin **German**: Heuglintrappe **Spanish**: Avutarda Somalí

Taxonomy. *Otis heuglinii* Hartlaub, 1859, near the wells of Thushha, between Zeila and Harar.
Genus sometimes merged with *Otis*. Present species considered to form parapatric species pair with *N. denhami*, but perhaps in reality closer to *N. nuba*. Monotypic.
Distribution. Eritrea, E & S Ethiopia, Djibouti, N & SC Somalia and N Kenya.

Descriptive notes. Male 75 cm, 4000-8000 g; female 2600-3000 g. Generally similar to *N. nuba*, but with smudged black face, crown paler shading backward to whitish, chestnut extending across breast and bordered below with a dark band, and upperparts more distinctly blotched and patterned. Female has much greyer head than male.
Habitat. Arid lowlands in open desert with annual grass, semi-desert savanna and tussocky grassland; 93% of range in Kenya lies within areas that receive less than 500 mm rainfall annually.
Food and Feeding. Little known. Orthoptera, small vertebrates, berries and other vegetable matter recorded.
Breeding. Apr-Jun in NE Africa, Jan and June in N Kenya, timed for when rains make grass tallest. Nest is a scrape on bare ground. Eggs 2. No further information available.
Movements. Sedentary and nomadic.
Status and Conservation. Not globally threatened. CITES II. Fairly common in N Kenya and N Somalia; uncommon in most of Ethiopia, rare in Eritrea. Species requires careful monitoring, given relatively restricted range; biology and ecology remain very poorly known.
Bibliography. Anon. (1995c), Archer & Godman (1937-1961), Ash (1989), Ash & Miskell (1983), Britton, P.L. (1980), Dowsett & Forbes-Watson (1993), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957), Short *et al.* (1990), Urban *et al.* (1986).



10. Nubian Bustard

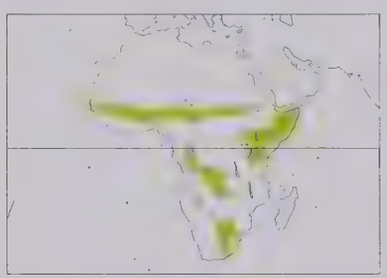
Neotis nuba

French: Outarde nubienne **German**: Nubiertrappe **Spanish**: Avutarda Núbica

Taxonomy. *Otis Nuba* Cretzschmar, 1826, Kurgos, near Shendi, Sudan.
Genus sometimes merged with *Otis*. Present species may be closely related to *N. heuglinii*. Claimed race *agaze* from Chad westwards is supposedly paler and smaller, but much more material needs examination to confirm that differences are not clinal or individual. Monotypic.
Distribution. Sahel zone from W Mauritania to E Sudan; distribution probably continuous, or at least with interbreeding populations, even though species very patchily recorded.
Descriptive notes. Male 70 cm, 5400 g; female 50 cm, no data on weight. Upperparts pale tawny buff, lightly vermiculated with black, tail similar but washed grey; crown as back, bordered by black line; face whitish, chin and throat black, neck pale grey, lower hindneck and sides of breast tawny buff; rest of underparts whitish; legs and bill pale yellow. Female smaller than male with much less black on chin and throat. Immature similar to adult, but black on head is browner, and amount of black on throat reduced to thin stripe.
Habitat. Arid and semi-arid scrub and savanna on desert fringes, penetrating further N into Sahara than other bustard species.
Food and Feeding. Invertebrates and vegetable matter: Orthoptera, Coleoptera, Hymenoptera, etc.; leaves and berries of desert plants, grass seeds and *Acacia* gum.

On following pages: 11. White-bellied Bustard (*Eupodotis senegalensis*); 12. Blue Bustard (*Eupodotis caerulescens*); 13. Karoo Bustard (*Eupodotis vigorsii*); 14. Rüppell's Bustard (*Eupodotis rueppellii*); 15. Little Brown Bustard (*Eupodotis humilis*).

Breeding. Jul-Oct; the finding of 3 nests in one day in Aug suggests synchronized response to suitable conditions (as well as degree of local abundance). Nest situated on bare sand; one nest was between forks of a fallen branch. Eggs 2. No further information available.
Movements. Sedentary and almost certainly nomadic; in Mauritania, tends to move S in winter, returning N with rains.
Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Apparently still fairly common in many places, although hunting, more recently by Arab dignitaries, may now be causing substantial regression in parts of its vast, if latitudinally compressed, range. Only one record from Nigeria, a pair sighted in 1959. Rare and very little known in Sudan. Widespread in Mauritania, with groups of 15-20 birds recorded.
Bibliography. Beaman (1994), Cave & Macdonald (1955), Collar & Stuart (1985), Cramp & Simmons (1980), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Fairon (1975), Gee (1984), Giraudoux *et al.* (1988), Lamarche (1988), Mackworth-Praed & Grant (1957, 1970), Newby (1979, 1990), Newby *et al.* (1987), Nikolaus (1987), Salvan (1968), Urban *et al.* (1986), Vaurie (1961).



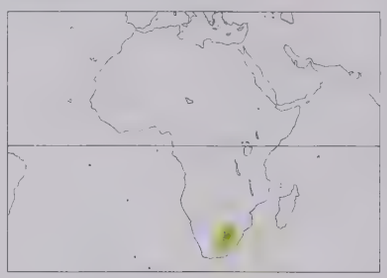
Genus *EUPODOTIS* Lesson, 1839

11. White-bellied Bustard

Eupodotis senegalensis

French: Outarde du Sénégal **German**: Senegaltrappe **Spanish**: Sisón Senegalés
Other common names: White-bellied Korhaan, Senegal Bustard

Taxonomy. *Otis Senegalensis* Vieillot, 1820, Senegal.
Populations of S Africa sometimes treated as separate species, *E. barrowii*; this form has alternatively been known as *E. cafra*, but due to confusion in nomenclature with *Neotis denhami*, name *cafra* was officially suppressed; slight differences from northern birds in plumage and voice probably do not justify treatment as separate species. Birds from Eritrea normally ascribed to nominate *senegalensis*, but more likely to belong to *canicollis*. Five subspecies normally recognized.
Subspecies and Distribution.
E. s. senegalensis (Vieillot, 1820) - SW Mauritania and Guinea E to Central African Republic, C Sudan and perhaps Eritrea.
E. s. canicollis (Reichenow, 1881) - Ethiopia S to NE Tanzania.
E. s. erlangeri (Reichenow, 1905) - S Kenya and W Tanzania.
E. s. mackenziei White, 1945 - E Gabon and C Congo to S & SE Zaire, E Angola and W Zambia; C & S Angola.
E. s. barrowii (J. E. Gray, 1829) - C & SE Botswana, E South Africa and Swaziland.



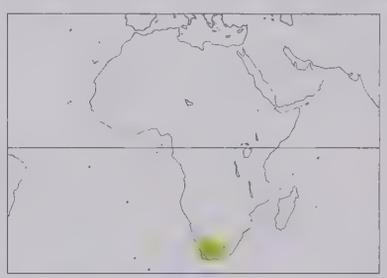
Descriptive notes. 50-60 cm, 1400-1500 g; female smaller. Upperparts tawny buff minutely vermiculated with brown, tail greyer with thin dark bars; crown black with grey centre, face whitish with black patch on throat, neck bluish grey, breast tawny buff, belly white; legs pale yellow, bill pinkish with dark culmen. Female similar to male, but lacks black on crown or throat; neck buff. Racial variation in size, shading, and degree and distribution of black on head or grey on neck or both.
Habitat. Open and relatively tall grassland and savanna, bushed or dwarf wooded grassland, clearings, cultivation, river plains; occurs up to 2000 m in E Africa. In interior W Africa, adapted to relatively dry conditions, penetrating well into desert in wet season, whereas in Central African Republic recorded from *Terminalia laxiflora* savanna woodland; in South Africa, prefers taller, denser grassland in more rolling country than *E. caerulescens*, although sometimes the two co-occur. In Sudan, present more on sandy than on cotton-soil areas. In Kenya, birds retreat to woodland areas in hot period of day.
Food and Feeding. Termites, locusts, caterpillars, beetles, spiders, scorpions, snails and lizards; also green herbage, grass seeds, bulbs, berries and flowers. Sometimes concentrates in areas recently burnt.
Breeding. Jul-Oct in W Africa; Jun and Aug-Oct in C Sahel; Mar-Jun in NE Africa; within the period Oct-May in various parts of E Africa; Sept-Oct in Angola; Dec in Zambia; Oct-Feb in South Africa. Probably monogamous, with group-territorialism; generally occurs in pairs or in groups presumed to consist of a mated pair and up to two offspring. Nest is a shallow scrape on bare ground or between grass tufts. Eggs 1-3; chick has pale sandy down, with heavy dark streaking.
Movements. Largely sedentary, but in Chad moves N in wet season, and in South Africa some birds winter at lower altitudes. Home ranges for family groups are around 40 ha.
Status and Conservation. Not globally threatened. CITES II. Apparently on decline in Sahel zone: only 3 recent records in Gambia, where was formerly commonest bustard species; apparently much rarer than in past in Ivory Coast; only one recent record in Niger; declining where formerly common in Nigeria; and formerly common but now uncommon in Sudan. Generally uncommon in E Africa, with a density estimated at 0·12-0·2/km², but frequent in Serengeti National Park, while a density of 3·0-4·6/km² was estimated in Nairobi National Park. In Ethiopia, Eritrea and Somalia rather common and widespread, with abundance increasing above 1500 m. Generally uncommon in C Africa; scarce in Zambia. Locally common in parts of South Africa, where outnumbered 4:1 by *E. caerulescens* when the two occur together.
Bibliography. Allan & Davies (1995), Ash (1989), Ash & Miskell (1983), Baker (1989), Benson *et al.* (1971), Britton, P.L. (1980), Carroll, R.W. (1988), Cave & Macdonald (1955), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Ginn *et al.* (1989), Giraudoux *et al.* (1988), Gore (1990), Goriup (1987), Grimes (1987), Johst (1972), Kemp & Tarboton (1976), Kok & Van Ee (1989), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Mwangi & Karanja (1989, 1992, 1993), Newby (1979), Nikolaus (1987), Pinto (1983), Short *et al.* (1990), Snow (1978), Tarboton, Kemp & Kemp (1987), Thiollay (1985), Urban *et al.* (1986).

12. Blue Bustard

Eupodotis caerulescens

French: Outarde plombée **German**: Blautrappe **Spanish**: Sisón Azulado
Other common names: Blue Korhaan

Taxonomy. *Otis Cærulesens* [sic] Vieillot, 1820, "Kaffraria" = eastern Cape Province.
In past, isolated by some authors in genus *Trachelotis*. Monotypic.
Distribution. South Africa in E Cape, Orange Free State, W Natal and S Transvaal (E & C Highveld); also Lesotho.



Descriptive notes. 55 cm; 1120-1612 g. Only bustard with blue-grey neck and underparts. Female has duller grey neck and buff ear-coverts. Immature has black and buff crown, black on upperwing-coverts and buff tips to flight-feathers.
Habitat. High grassveld, usually above 1500 m, with short-grazed grassland and termite mounds but no or few trees; old and fallow cropland, pastures and winter cultivation, usually in flat or undulating open Highveld grassland.
Food and Feeding. Caterpillars, grasshoppers, beetles, scorpions and small reptiles; also grass seeds, flowers and green leaves of various plants. In winter, often feeds on ploughed fields or land with crops such as turnips. Attracted to recently burnt grasslands.
Breeding. Aug-Apr, chiefly Oct-Nov. Nest situated on bare open ground, often in short, thick grass, also in old cropland. Eggs 1-3; incubation 24-28 days. Young may stay up to two years with parents, the breeding system appearing to involve group-territorialism.
Movements. Sedentary.
Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Reported decline in S and W of range unfounded, although now fairly scarce in lowland Lesotho owing to dense human settlement. Species remains generally common and locally plentiful with densities of c. 20 birds per 1000 ha in optimum habitat, in Transvaal, where the total population probably exceeds 10,000 birds. However, restricted range and the potential for intensified farming within it make this the small bustard of most concern in S Africa.
Bibliography. Allan & Davies (1995), Bonde (1993), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Kemp & Tarboton (1976), Kok & Van Ee (1989), Mackworth-Praed & Grant (1962), Maclean (1993), Maclean *et al.* (1983), Penry (1994), Sinclair (1987), Tarboton, Kemp & Kemp (1987), Urban *et al.* (1986), Vernon (1983a).

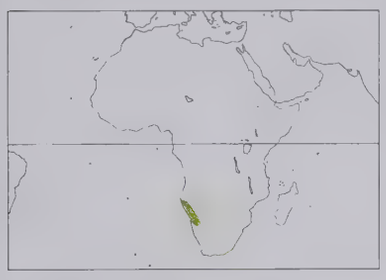
13. Karoo Bustard

Eupodotis vigorsii

French: Outarde de Vigors **German**: Knarrtrappe **Spanish**: Sisón del Karroo
Other common names: Black-throated/Vigors's Bustard/Korhaan, Karoo/Vaal Korhaan

Taxonomy. *Otis Vigorsii* A. Smith, 1831, South Africa.
Forms parapatric species pair with *E. rueppellii*, with which frequently considered conspecific; these two and *E. humilis* formerly placed in genus *Heterotetrax*. Two subspecies recognized.
Subspecies and Distribution.
E. v. namaqua (Roberts, 1932) - S Namibia and NW Cape Province.
E. v. vigorsii (A. Smith, 1831) - South Africa, in Orange Free State and S Cape Province.

Descriptive notes. 60 cm; male 1600 g, female 1350 g. Head, neck and upperparts greyish brown with minute dark vermiculations, paling to pinkish white on belly; chin and throat black with thin white border, nuchal area black, tail with three thin bars. Has browner neck and different face pattern from *E. rueppellii*. Female smaller than male, with less black on throat, and more mottled wing-coverts. Race *namaqua* pinker and paler.
Habitat. Arid, flat gravel or sandy plains with scattered dwarf shrubs (karoo and scrub zones), ranging into veld with taller bushes, and annual rainfall of up to 250 mm. Prefers vegetation 10-50 cm high; occurs at highest densities (1·85 groups per km²) in areas of predictable winter rainfall of 250 mm per year, and at lowest densities (0·34 groups per km²) in areas of sporadic rainfall of 100 mm per year. Isolated population in SW Cape Province in karooid-like coastal fynbos in areas of cereal cultivation.
Food and Feeding. Chiefly plant matter, with flowers of Asteraceae, Brassicaceae and Mesembryanthemaceae dominant at certain times of year, but many annual ephemeral plants important along with fruit, leaves and corms. Insects, notably harvester termites, harvester ants and weevils, are important throughout the year. Visits pools to drink.
Breeding. Aug-Mar in South Africa. Nest is a slight scrape on bare ground. Normally 1 egg, possibly sometimes 2. Young birds stay several months with parents, and birds can be group-territorial, such groups consisting of a monogamous pair and offspring.
Movements. Sedentary and broadly site-faithful, with pairs defending a movable territory all year round; however, individuals range over many kilometres. Females disperse more readily than males.
Status and Conservation. Not globally threatened. CITES II. Generally common, and possibly even profiting from human agricultural activity, since it favours slightly degraded veld.
Bibliography. Allan & Davies (1995), Boobyer (1988, 1989), Boobyer & Hockey (1994), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Hockey & Boobyer (1994), Kemp & Tarboton (1976), Kok & Van Ee (1989), Macdonald & Hall (1957), Mackworth-Praed & Grant (1962), Maclean (1993), Quinton (1948), Sinclair (1987), Snow (1978), Urban *et al.* (1986), Viljoen (1983).



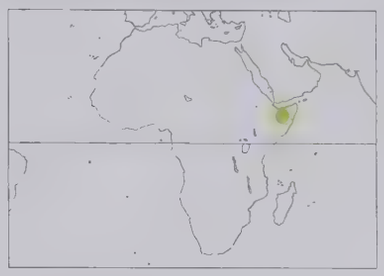
14. Rüppell's Bustard

Eupodotis rueppellii

French: Outarde de Rüppell **German**: Rüppelltrappe **Spanish**: Sisón de Damaraland

Other common names: Rüppell's Korhaan

Taxonomy. *Otis Rüppelii* [sic] Wahlberg, 1856, Onanis, Damaraland.
Forms parapatric species pair with *E. vigorsii*, with which frequently considered conspecific; these two and *E. humilis* formerly placed in genus *Heterotetrax*. Two subspecies recognized.
Subspecies and Distribution.
E. r. rueppellii (Wahlberg, 1856) - coastal S Angola (N to Benguela) and NW Namibia.
E. r. fitzsimonsi (Roberts, 1937) - CW Namibia.



Descriptive notes. 60 cm; no data on weight. Differs from *E. vigorsii* in being pinker above with grey and white head pattern and black lines down front and back of neck. Female similar to male, but cheeks appear more mottled, and tail often has c. 2 faint bars. Immature similar to adult, but with more mottling on face, more dark markings on back and barring in tail. Race *fitzsimonsi* darker and greyer.
Habitat. Desert edge and subdesert, on flat dark basaltic gravel plains and barren flats with thin grass and sparse stunted scrub.
Food and Feeding. Very poorly known. Takes insects including termites, and small reptiles; also vegetable matter including seeds.
Breeding. Probably at any time of year, depending on rainfall and food supply, but mostly Sept-Feb. Apparently monogamous. Nest situated on bare stony ground. Usually 1 egg, though possibly sometimes 2.
Movements. Sedentary.
Status and Conservation. Not globally threatened. CITES II. Very little information available on status. Species is frequent to common in habitat that is unlikely to be seriously modified by human development. Relatively common in coastal Angola. Biology and ecology remain poorly known.
Bibliography. Allan & Davies (1995), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Mackworth-Praed & Grant (1962), Maclean (1993), Pinto (1983), Sinclair (1987), Snow (1978), Urban *et al.* (1986), Viljoen (1983).

15. **Little Brown Bustard**

Eupodotis humilis

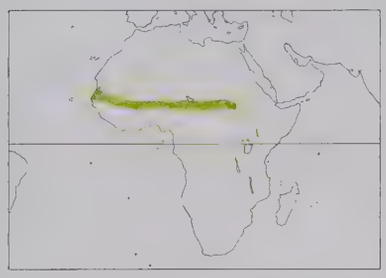
French: Outarde somalienne **German**: Somalitrappe **Spanish**: Sisón Somalí
Other common names: Somali Black-throated/Brown Bustard

Taxonomy. *Sypheotides humilis* Blyth, 1856, Somaliland.
Formerly placed in genus *Heterotetrax*, along with *E. vigorsii* and *E. rueppellii*. Monotypic.
Distribution. E Ethiopia and N Somalia.

Descriptive notes. c. 40 cm; 700 g. Upperparts light orange-brown with pale grey clouding and minute black vermiculations, tail with 2-3 thin bars; head, neck and breast buffy with grey wash, clear grey on hindneck, black spot below nuchal crest, and black chin and throat with white spots; belly white; legs yellow, bill brown. Female similar to male, but lacks grey and black, and has upperparts coarsely blotched with buff; female *E. senegalensis canicollis* larger and darker, lacking this blotching on upperparts.
Habitat. Dry, sandy, grassland with bushes, light open thornbush and adjacent tussock grass plains.
Food and Feeding. Virtually no information available. Known to take invertebrates and vegetable matter.
Breeding. Apr-Aug, chiefly May-Jun. Nest placed on sandy soil, usually without a scrape. Usually 2 eggs, but up to 3 recorded. No further information available.
Movements. Sedentary.
Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Fairly common in Ogaden, E Ethiopia, and common N of 7° N in Somalia. However, drought and warfare in the region may have caused a decline in this limited-range species, and current status is uncertain. Biology and ecology very poorly known; research and monitoring of populations highly desirable.
Bibliography. Archer & Godman (1937-1961), Ash (1977, 1989), Ash & Miskell (1983), Collar & Stuart (1985), Dowsett & Forbes-Watson (1993), Mackworth-Praed & Grant (1957), Urban *et al.* (1986).

PLATE 25

inches 11
cm 28



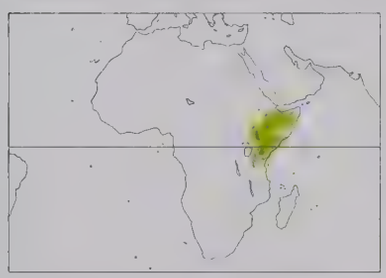
Genus *LOPHOTIS* Reichenbach, 1848

16. Savile's Bustard

Lophotis savilei

French: Outarde de Savile **German**: Saviletrappe **Spanish**: Sisón Moñudo de Saheliano
Other common names: Lynes's/Pygmy Bustard

Taxonomy. *Lophotis savilei* Lynes, 1920, Nahud, western Kordofan.
Genus frequently merged with *Eupodotis*. Present species forms superspecies with *L. gindiana* and *L. ruficrista*, but not known to perform their rocket-flight displays; all three often considered conspecific. Monotypic.
Distribution. SW Mauritania and Senegal through Mali, Burkina Faso, Ivory Coast, Niger, NE Nigeria and Chad to C Sudan.



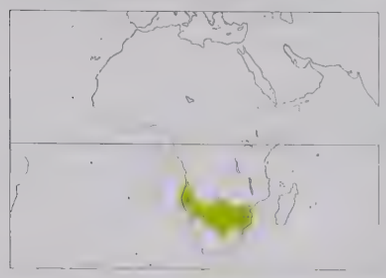
Descriptive notes. 42 cm; no data on weight. Smaller than *L. gindiana*, with more black on throat and less white on breast; more rufous sandy above with buff V-markings almost absent. Smaller than *L. ruficrista* with less grey on head. Female lacks grey on head and neck, which are tinged cinnamon.
Habitat. Bush and light woodland, thickets near dried pools and clearings, flat scrub with *Aristida* grass and *Acacia raddiana*.
Food and Feeding. No information available, but habits and food presumably similar to those of *L. ruficrista*.
Breeding. Sept-Oct in W of range; Jun-Aug (wet season) in Chad; Jul-Sept in Sudan. Nest details presumably similar to those of *L. ruficrista*.
Movements. Generally considered sedentary, but known to be a dry season (Dec-May) visitor to Park W in Niger, and may move N out of Nigeria during rains to breed.
Status and Conservation. Not globally threatened. CITES II. Little information available on status; species is said to be fairly common throughout its extensive range, but patchily so. Uncommon in Nigeria, where is restricted to NE. Biology and ecology very poorly known, in part due to taxonomic confusion regarding present species and congeners.
Bibliography. Anon. (1995d), Cave & Macdonald (1955), Chappuis *et al.* (1979), Clancey (1977c), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Koster & Grettenberger (1983), Lamarche (1988), Mackworth-Praed & Grant (1957, 1970), Morel & Chappuis (1992), Morel & Morel (1990), Newby (1979), Nikolaus (1987), Osborne (1989), Snow (1978), Urban *et al.* (1986).

17. Buff-crested Bustard

Lophotis gindiana

French: Outarde d'Oustalet **German**: Oustalettrappe **Spanish**: Sisón Moñudo Etíope

Taxonomy. *Eupodotis Gindiana* Oustalet, 1881, East Africa between Somalia and Zanzibar.
Genus frequently merged with *Eupodotis*. Present species forms superspecies with *L. ruficrista* and *L. savilei*; all three often considered conspecific. Birds of N & C Somalia formerly awarded separate race, *hilgerti*. Monotypic.
Distribution. SE Sudan, S Ethiopia, Djibouti and Somalia through Kenya to N & NC Tanzania.



Descriptive notes. Male 50 cm, 675-900 g. Similar to *L. ruficrista* and *L. savilei*, but has black throat stripe extending to belly and more white on sides of breast; upperparts darker, tail unbarred. Female lacks grey on head and neck, replaced by brown; generally similar to female *L. ruficrista*, but has pale buff line down throat, breast more whitish, and upperparts darker, tail unbarred.
Habitat. A bird of arid and semi-arid bushland, like *L. ruficrista*, extending up to 1200 m in Ethiopia, and 1800 m in Kenya, but peripheral to highlands.
Food and Feeding. Very little information available. Known to take seeds, green herbage and insects; may subsist heavily on ants.
Breeding. Mar-Jun or later. Nest situated on bare ground. Eggs 1-2. No further information available.
Movements. Sedentary, although local migration claimed to occur in Kenya.
Status and Conservation. Not globally threatened. CITES II. Common throughout range, except in Sudan, where generally uncommon; an estimate of 25-40 females per 10,000 ha in suitable habitat. Biology and ecology very poorly known, in part due to taxonomic confusion regarding present species and congeners.
Bibliography. Ash (1989), Ash & Miskell (1983), Baker (1989), Britton, P.L. (1980), Brown & Britton (1980), Cave & Macdonald (1955), Chappuis *et al.* (1979), Clancey (1977c), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Goriup (1987), Goriup *et al.* (1989), Hallager (1994), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957), Nikolaus (1987), Osborne (1989), Short *et al.* (1990), Snow (1978), van Someren (1925-1935), Urban *et al.* (1986).

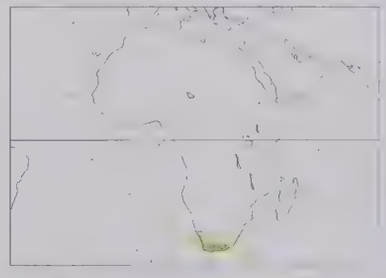
18. Red-crested Bustard

Lophotis ruficrista

French: Outarde houppette **German**: Rotschopftrappe **Spanish**: Sisón Moñudo Austral
Other common names: Red-crested Korhaan, Buff-crested(!)/Crested/Bush Bustard

Taxonomy. *Otis ruficrista* A. Smith, 1836, near Latakoo (= Kuruman), Griqualand West, South Africa.
Genus frequently merged with *Eupodotis*. Present species forms superspecies with *L. gindiana* and *L. savilei*; all three often considered conspecific. Monotypic.
Distribution. S Angola and NE Namibia through Botswana, SW Zambia and Zimbabwe to S Mozambique, N South Africa and Swaziland.

Descriptive notes. 50 cm; 680 g. Upperparts have distinctive cream V-marks giving mottled effect; grey on crown and lores, cream supercilium, indistinct pink nuchal crest (erectile in display), black on chin and throat, grey foreneck, buff hindneck and black belly; bill greyish, legs yellowish. Differs from *L. gindiana* and *L. savilei* in having more grey on head, especially on crown, and paler upperparts. Female similar to male, but grey areas on head and neck replaced with buff; cream V-marks on upperparts and absence of black on face distinguish from female *Afrotis afra*.
Habitat. Thorn country and other dry light woodland regions, bush savanna and riparian growth, often with long screening grass. In Botswana, commonest in *Acacia* and *Terminalia* savanna; occurs less commonly in more open habitat, where is generally replaced by *A. afraoides*. A population with different voice inhabits treeless grassy dunes in the S Kalahari.
Food and Feeding. Poorly known. Takes insects (beetles, grasshoppers, termites, ants) and other small arthropods; also berries, seeds and gum.
Breeding. Oct-Apr, with peak in Transvaal in Oct-Nov. Nest placed on ground, often near sapling or shrub. Eggs 1-2.
Movements. Sedentary.
Status and Conservation. Not globally threatened. CITES II. Common in much of range, with one calling male per 100 ha in C Transvaal; recorded as very common in 32% of squares in Botswana; still relatively common in Zimbabwe, where overgrazing may have caused a few local declines.
Bibliography. Allan & Davies (1995), Astley-Maberly (1967), Benson *et al.* (1971), Brown, C.J. (1993), Cassels & Elliott (1975), Chappuis *et al.* (1979), Clancey (1977c), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Irwin (1981), Kemp & Tarboton (1976), Kok & Van Ee (1989), Mackworth-Praed & Grant (1962), Maclean (1993), Osborne (1989), Penry (1994), Pinto (1983), Rockingham-Gill (1989), Sinclair (1987), Sinclair & Whyte (1991), Snow (1978), Tarboton, Kemp & Kemp (1987), Urban *et al.* (1986)



Genus *AFROTIS* G. R. Gray, 1855

19. Black Bustard

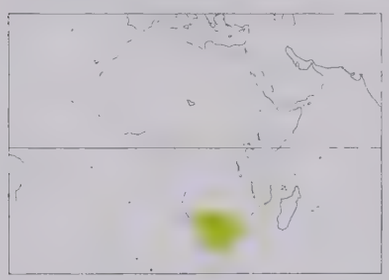
Afrotis afra

French: Outarde korhaan **German**: Gackeltrappe **Spanish**: Sisón Negro Aliosc uro
Other common names: Black Korhaan, Little Black Bustard

Taxonomy. *Otis afra* Linnaeus, 1758, Cape of Good Hope.
Genus frequently merged with *Eupodotis*. Present species forms parapatric species pair with *A. afraoides*, with which often considered conspecific. In past, species name commonly misspelt *atra*, the error originally arising probably from poorly printed text; scientific description has frequently been cited as Linnaeus, 1766, but pre-dated by valid 1758 description. Monotypic.
Distribution. South Africa in W & S Cape Province, from Little Namaqualand S to Cape Town, then E to Grahamstown.

Descriptive notes. 50 cm; c. 700 g. Strongly marked, with back and lesser upperwing-coverts regularly barred dark brown on whitish, and broad white panel formed by greater and median upperwing-coverts; tail greyer with two broad black bars; rest of body black, with slightly crested hindcrown barred gold and brown and ringed in white, ear-coverts white, and broad white collar on lower hindneck; bill pinkish red, grey on culmen; legs strong yellow; eye orange-brown. Very similar to *A. afraoides*, but primaries all black, conspicuous in flight. Female is browner than male and more mottled on upperparts, extending onto head and neck; whitish breast and black belly.
Habitat. Coastal fynbos, semi-arid scrub, dunes with succulent vegetation, extending into renosterveld scrub in the semi-arid karoo. Frequently associated with cereal cropland both in the fynbos and parts of the karoo.
Food and Feeding. Very little information available. Known to include vegetable matter and insects in diet.
Breeding. Aug-Oct. Nest is a grass-lined scrape. 1-2 eggs. No further information.
Movements. Sedentary.
Status and Conservation. Not globally threatened. CITES II. No detailed information available, but species is apparently common within its restricted range. No threats known at present. Because until recently normally considered conspecific with more widespread *A. afraoides*, very little precise information is available on biology and ecology of present species; extensive research of these aspects is highly desirable, as is further investigation with a view to establishing a clearer picture of taxonomic relationship of these two forms.
Bibliography. Allan & Davies (1995), Brooke & Dowsett (1969), Clancey (1967, 1986, 1989), Crowe *et al.* (1994), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Frandsen (1982), Ginn *et al.* (1989), Kemp &

On following pages: 20. White-quilled Bustard (*Afrotis afraoides*); 21. Black-bellied Bustard (*Lissotis melanogaster*); 22. Hartlaub's Bustard (*Lissotis hartlaubii*); 23. Bengal Florican (*Houbaropsis bengalensis*); 24. Lesser Florican (*Sypheotides indica*); 25. Little Bustard (*Tetrax tetrax*).



Tarboton (1976), Mackworth-Praed & Grant (1962), Maclean (1993), Sinclair (1987), Snow (1978), Urban *et al.* (1986).

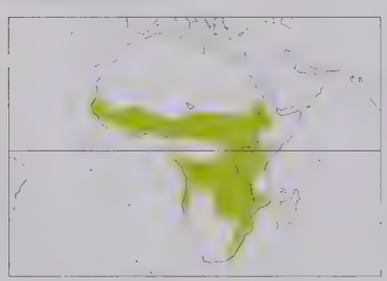
20. White-quilled Bustard

Afrotis afraoides

French: Outarde à miroir blanc **German**: Weißflügeltrappe **Spanish**: Sisón Negro Aliclaro
Other common names: White-quilled Korhaan

Taxonomy. *Otis Afraoïdes* A. Smith, 1831, flats near the Orange River.
Genus frequently merged with *Eupodotis*. Present species forms parapatric species pair with *A. afra*, with which often considered conspecific. Proposed races *mababiensis* (NW Botswana) and *kalaharica* (Kalahari Desert) nowadays included in *etoschae* and *damarensis* respectively. Three subspecies currently recognized.
Subspecies and Distribution.
A. a. etoschae (Grote, 1922) - NW Namibia and N Botswana
A. a. damarensis Roberts, 1926 - Namibia and C Botswana.
A. a. afraoides (A. Smith, 1831) - SE Botswana through N & NE South Africa (N Cape Province, W Transvaal, Orange Free State) to Lesotho.

Descriptive notes. 50 cm; 700 g. Very similar to *A. afra*, but much white in primaries, conspicuous in flight. Female is browner than male and more mottled on upperparts, extending onto head and neck; white breast and black belly. Immature similar to female, but has pale tips to feathers of crown, back and wings. Race *etoschae* much paler; *damarensis* paler and more finely marked, with white extending round eye in male.
Habitat. Flat grassland with grass 50-100 cm high, open shrub veld, semi-desert scrub, grassy dunes and dry bush savanna, often in heavily grazed areas or those with patchy, sparse grass cover including old cropland. Males use vantage points such as rises and termite mounds to advertise presence.
Food and Feeding. Wide variety of plant and animal material, with latter taken twice as frequently. Diet dominated by Isoptera (particularly in May-Jun, when the harvester termite *Hodotermes mossambicus* is most active), curculionid beetles and grasshoppers. Plant material is mainly seeds, notably *Lycium tetrandum*, *Conyza bonariensis*, *Rhus lancea*, *Zea mays*, *Myrsine africana* and *Melilotus*, some of these indicating that human-disturbed areas are sometimes used for foraging.
Breeding. Most of year in Transvaal, where recorded Sept-Apr and Jul; elsewhere, records fall within the Sept-Apr period, although males are actively self-advertising throughout year. Nests on open bare ground, usually near a shrub. 1-2 eggs; incubation period 19-21 days in captivity; chick has pale tan down with darker brown markings.
Movements. Sedentary.
Status and Conservation. Not globally threatened. CITES II. Generally common throughout its range, with males being spaced at 300-500 m intervals in prime habitat.
Bibliography. Allan & Davies (1995), Bell (1970), Brown, C.J. (1993), Clancey (1967, 1986, 1989), Crowe *et al.* (1994), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Gregson (1986), Kemp & Tarboton (1976), Kok & Earlé (1990), Mackworth-Praed & Grant (1962), Maclean (1993), Penry (1994), Sinclair (1987), Snow (1978), Tarboton, Kemp & Kemp (1987), Urban *et al.* (1986).



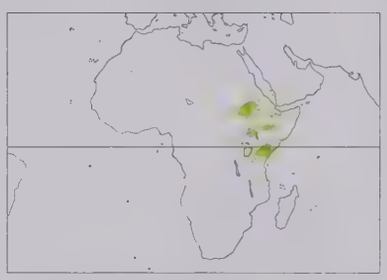
Genus *LISSOTIS* Reichenbach, 1848

21. Black-bellied Bustard

Lissotis melanogaster

French: Outarde à ventre noir **German**: Schwarzbauchtrappe **Spanish**: Sisón Ventrinegro Común
Other common names: Black-bellied Korhaan

Taxonomy. *Otis melanogaster* Rüppell, 1835, Lake Tsana, Ethiopia.
Genus frequently merged with *Eupodotis*. Present species forms superspecies with *L. hartlaubii*. Two subspecies recognized.
Subspecies and Distribution.
L. m. melanogaster (Rüppell, 1835) - Africa S of Sahel S to R Zambezi and S Angola; absent from regions of heavy forest and from most of Horn of Africa.
L. m. notophila Oberholser, 1905 - Zimbabwe and Mozambique S of R Zambezi to extreme E South Africa and Swaziland.



Descriptive notes. Male 60 cm, 1800-2700 g; female 60 cm, 1400 g. Upperparts tawny buff, with large dark arrow-shaped blotches, tail brown with four thin dark bars; face greyish white tinged buff on crown and cheeks, mottled black chin joining thin black line running back from eye to black nuchal crest; black line with white border down otherwise thin brown neck, merging in black of belly; much white in folded wing; legs and bill yellow. Generally browner than *L. hartlaubii*; coloration of rump and tail similar to that of back. Female has head and neck almost featureless pale buff, belly whitish. Immature similar to female, but has buff edges to wing feathers. Race *notophila* larger.
Habitat. Tall dense open grassland, grassland with bushes, and savanna woodland (including miombo woodland); also cultivation, pastures, fallow and old cropland and damper areas such as margins of vleis and dambos; also found in grass-covered ironstone pans and burnt savanna woodland in Sierra Leone. Normally found close to water in both Gambia and parts of S Africa; occurs up to 2500 m. Termite mounds and other prominences are used for look-out and display.
Food and Feeding. Takes chiefly insects, apparently mostly beetles, but also grasshoppers, bugs, caterpillars and other terrestrial and stem-haunting arthropods; also seeds, flowerheads and vertebrate roadkills. In Kenya, old cultivation much frequented for certain green herbs.
Breeding. Jun-Sept in sub-Sahel, with evidence in Nigeria also for Dec-Jan; Apr and Sept in Ethiopia; Feb-Jun and Sept in E Africa; generally within period Oct-Mar in C & S Africa, although not necessarily in the rainy season. Nest is a shallow scrape on bare ground in grass, commonly near a feature such as an anthill, a bush or water. Eggs 1-2; chick has brown and black down.
Movements. Both sedentary and at least partially migratory. Situation in Ghana unclear, where resident in area of Accra but dry season breeding visitor 50 km to W, in Winneba; elsewhere in Ghana birds may move N after dry season breeding. In other parts of Sahel, birds move N to breed in rains in Jun; recorded in Sierra Leone only in period May-Oct, whereas in Central African Republic only Oct-Jun. Numbers increase in Jun in Ethiopian uplands. Local influx in one part of Kenya, Aug-Nov, and to parts of Tanzanian coast in dry season. Occasionally wanders outside normal range in South Africa.
Status and Conservation. Not globally threatened. CITES II. Decrease in Senegal and Gambia since 1980, but apparently still common in savanna zone of N Ivory Coast, Ghana, Nigeria and Sudan. The most widespread and numerous bustard in Uganda, Tanzania and Zambia, but likely to have declined in Zambia as consequence of hunting pressure; still fairly numerous in Zimbabwe, where a distinct decline is attributable to overgrazing by livestock; commonest bustard species in S Mozambique.
Bibliography. Allan & Davies (1995), Ash & Miskell (1983), Baker (1989), Benson & Benson (1975), Benson *et al.* (1971), Britton, P.L. 22. Hartlaub's Bustard

Lissotis hartlaubii

French: Outarde de Hartlaub **German**: Hartlaubtrappe **Spanish**: Sisón Ventrinegro de Hartlaub

Taxonomy. *Otis Hartlaubii* Heuglin, 1863, eastern Sennar, Sudan.
Genus frequently merged with *Eupodotis*. Present species forms superspecies with *L. melanogaster*. Monotypic.
Distribution. E Sudan through Ethiopia to NW & S Somalia, NE Uganda, NW & S Kenya and N Tanzania.

Descriptive notes. Male 60 cm, 1500-1600 g. Similar to *L. melanogaster* but greyer and more cleanly marked, with lower back, rump and tail blackish. Female has head and hindneck cream to buff with darker brown markings, belly whitish and tail paler than in male.
Habitat. Open, tall grassland with scattered *Acacia*, up to 1600 m. In Kenya, occurs in lower, drier habitat than *L. melanogaster*; in Ethiopia, may prefer *Acacia* short-grass savanna, which extends up to 2000 m, whereas *L. melanogaster* occupies tall-grass savanna, extending only up to 1500 m.
Food and Feeding. Little known. Invertebrates and vegetable matter recorded.
Breeding. Apr in Ethiopia; Jan and Jun in E Africa (in both rainy periods when grass tallest), with aerial display recorded in Nov. Chick has creamy buff down with pale and dark markings. No further information available.
Movements. Sedentary and nomadic, although considered a partial intra-African migrant based on records in Jan-Feb and Sept-Oct in Serengeti.
Status and Conservation. Not globally threatened. CITES II. Locally common in Kenya and Sudan, although rare and local at edge of range in Somalia, and uncommon in Ethiopia. Grazing by cattle can quickly destroy habitat, causing desertion of site. Species requires careful monitoring, given relatively restricted range.
Bibliography. Ash (1989), Ash & Miskell (1983), Baker (1989), Britton, P.L. (1980), Brown & Britton (1980), Cave & Macdonald (1955), Douthwaite & Miskell (1991), Dowsett & Forbes-Watson (1993), Fanshawe & Kelsey (1989), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957), Nikolaus (1987), Schmidl (1982), Short *et al.* (1990), Urban & Brown (1971), Urban *et al.* (1986).

Genus *HOUBAROPSIS* Sharpe, 1893

23. Bengal Florican

Houbaropsis bengalensis

French: Outarde du Bengale **German**: Barttrappe **Spanish**: Sisón Bengalí

Taxonomy. *Otis bengalensis* Gmelin, 1789, Bengal.
Genus sometimes merged with *Eupodotis*, but differs notably from all other bustards except *Sypheotides indica* in showing reversed sexual size dimorphism. Two subspecies recognized.
Subspecies and Distribution.
H. b. bengalensis (Gmelin, 1789) - patchily along border of S Nepal with India, and into lowland NE India.
H. b. blandiini Delacour, 1928 - S Cambodia and S Vietnam (apparently non-breeding only; breeding grounds unknown).
Descriptive notes. Male 64 cm, 1250-1700 g; female 68 cm, 1700-2250 g. Upperparts and tail buffy brown, vermiculated and patterned black, with broad white panel on closed wing; slight crest, head, neck and underparts black, with elongated breast feathers; legs pale yellowish, bill dark horn to

plumbeous brown with yellow lower mandible. Female has black of head and underparts replaced with buff, and has no white on wing; crown brown with buff central stripe. Immature similar to adult female; first spring male partially black, often reverting to female plumage in second autumn, but thereafter retains full adult male dress. Race *blandini* apparently larger.

Habitat. Flat, moist, open grasslands with scattered shrubs and bushes; often prefers areas of relatively short tussocky *Imperata* grass, recently burnt tracts, or long grass grazed down to c. 50 cm high, feeding in the shorter grass, and retreating in hotter parts of day to the longer. Birds also visit undisturbed mustard fields, and in some places use lightly wooded grassland and heavily grazed land.

Food and Feeding. Shoots, flowers, grasses, seeds and berries, but also insects such as locusts, grasshoppers, beetles, ants, and occasionally lizards and small snakes. Vegetable matter predominates in winter and spring, invertebrates becoming important or even exclusive later in the year.

Breeding. Mar-Jun. Nest is a scrape in thick grass cover. Eggs 1-2; incubation period c. 25-28 days; chick has rufous buff down marked with rufescent brown.

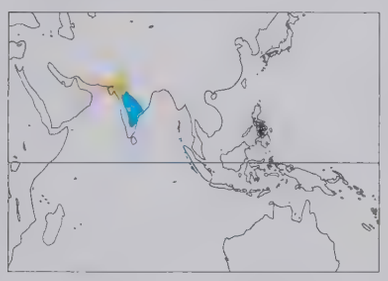
Movements. Nominate race dispersive, with males moving short distances from breeding territories in summer, and all birds seeming to disappear from late summer to mid-winter, Sept-Jan/Feb, when they are once more found in the grasslands where they breed. Race *blandini* known only from apparent winter quarters.

Status and Conservation. ENDANGERED. CITES I. Total population of nominate race may be as low as 300-400 birds, c. 100 of which are in Nepal. Population scattered widely among a handful of protected areas, but even here species cannot be considered secure: management of such areas is not necessarily optimal for the species, e.g. high grasses spreading through Chitwan National Park, Nepal; security is uncertain in some cases. Outside these reserves almost all habitat has been converted to agriculture. Race *blandini* is extremely poorly known, with as few as 4 birds recorded in recent years, in Vietnam, on land under development.

Bibliography. Ali & Ripley (1980), Anon. (1994c), Collar & Andrew (1988), Collar *et al.* (1994), Cornwallis (1983b), Goriup & Mundkur (1990), Hazarika (1981), Inskipp & Collar (1984), Inskipp & Inskipp (1983, 1985, 1991), Karim (1985), Lal (1993), Majumdar & Brahmachari (1988), Narayan (1990, 1992), Narayan & Rosalind (1990a, 1990b), Narayan *et al.* (1989), Rahmani (1988a), Rahmani & Sankaran (1988), Rahmani, Narayan, Rosalind & Sankaran (1990), Rahmani, Narayan, Rosalind, Sankaran & Ganguli-Lachungpa (1991), Rahmani, Narayan, Sankaran & Rosalind (1988), Ripley (1982), Sankaran (1990a, 1991), Vardhan (1985), Weaver (1990, 1991).

Genus *SYPHEOTIDES* Lesson, 1839

24. **Lesser Florican**



Sypheotides indica

French: Outarde passarage **German**: Flaggentrappe **Spanish**: Sisón de Penacho
Other common names: Leekh/Likh

Taxonomy. *Otis indica* J. F. Miller, 1782, India.

Genus occasionally merged with *Eupodotis*, but differs notably from all other bustards except *Houbaropsis bengalensis* in showing reversed sexual size dimorphism. Monotypic.

Distribution. NW India, mainly in Gujarat. In non-breeding season, moves to Deccan of C & S India; occasional records from Nepal.

Descriptive notes. Male 46 cm, 450 g; female 51 cm. Unique among bustards in possessing c. 4-6 long, upcurving, spatulate black plumes projecting behind head; upperwing-coverts white, conspicuous in flight. Smaller than *Houbaropsis bengalensis*, with thinner neck, white band over shoulders, and distinctive head plumes. Non-breeding male is like female but white patch on wing much larger, visible on closed wing. Female has black areas replaced by buff and brown, extensively mottled and patterned with blackish markings; lacks ornamental head plumes of male; smaller and thinner-necked than female *H. bengalensis*. Immature similar to female, but more heavily mottled and lacks white on wing.

Habitat. Flat open grasslands, chiefly of *Sehima nervosum* and *Chrysopogon fulvus*, even patches smaller than 1 ha; also scrubland and crop fields, notably of soybean and groundnut; now chiefly in protected grasslands known as *vidis* or *rakhaals* that are set aside for fodder production.

Food and Feeding. Shoots, grass, herbs, seeds and berries; also grasshoppers, beetles (notably *Mylabris* blister beetles at certain times), centipedes, lizards and frogs.

Breeding. Jul-Sept, with exact timing depending on distribution and intensity of SW monsoon. Nest situated on bare ground in patch of grass or crops. Eggs 3-5; chick has dirty pale yellow down blotchily striped with blackish.

Movements. Leaves breeding region around Oct-Nov, apparently mostly dispersing south-eastwards, returning in Apr-May. Breeding area dependent on degree of rainfall, so birds commonly nomadic.

Status and Conservation. CRITICALLY ENDANGERED. CITES II. No longer visits W Pakistan or E India, a range contraction attributable to large-scale habitat loss and disturbance, with exceptionally high and ever-increasing grazing pressure from cattle; hunting is also a chronic problem. A decline of 80%, from 4374 birds in 1982 to 750 birds in 1989, is blamed on consecutive years of drought, but pesticides and loss of winter habitat also possibly implicated; however, reanalysis of data suggests 1989 total was really 1672 birds, and fieldwork in 1994 resulted in an estimate of 2206 birds.

Bibliography. Ali & Ripley (1980), Ali *et al.* (1986), Collar & Andrew (1988), Collar *et al.* (1994), Cornwallis (1983b), Dharmakumarsinhji (1950, 1983), Ganguli-Lachungpa & Rahmani (1990), Goriup & Karpowicz (1983a, 1983b, 1985), Hazarika (1981), Inskipp & Inskipp (1991), Lal (1993), Magrath *et al.* (1985), Majumdar & Brahmachari (1988), Narayan *et al.* (1989), Rahmani (1988a), Ridley *et al.* (1985), Ripley (1982), Roberts, T.J. Genus *TETRAX* T. Forster, 1817

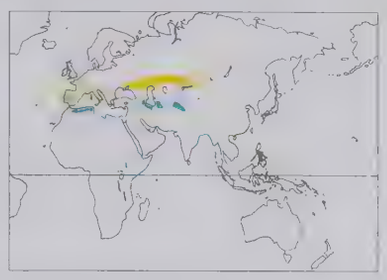
25. **Little Bustard**



Tetrax tetrax

French: Outarde canepetière **German**: Zwergtrappe **Spanish**: Sisón Común

Taxonomy. *Otis Tetrax* Linnaeus, 1758, France.

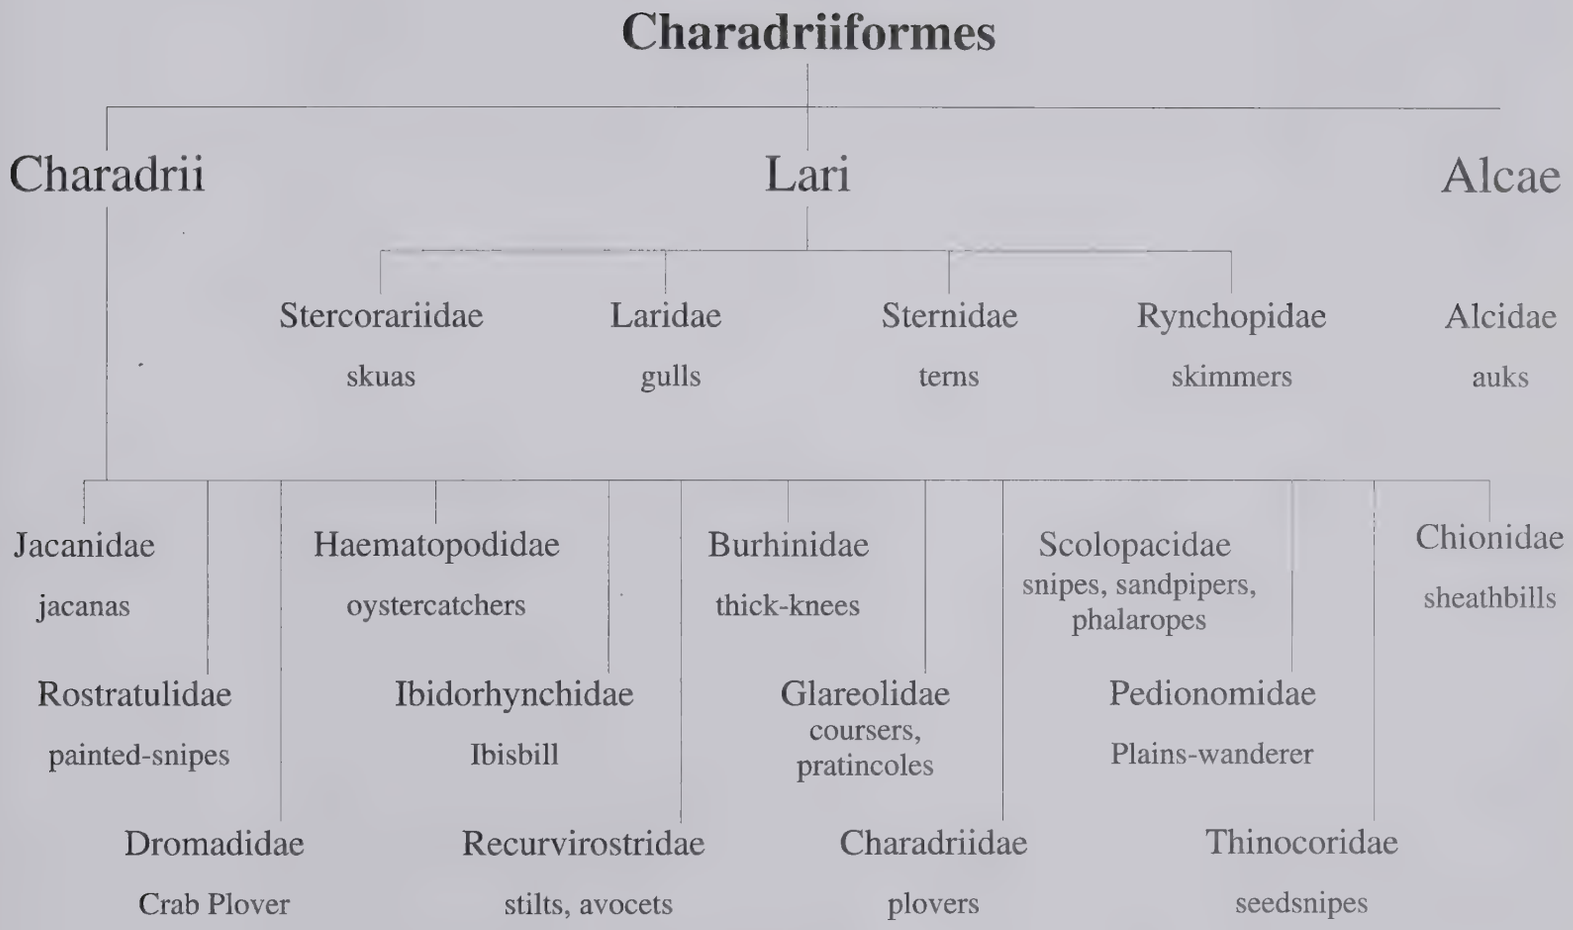
In past, frequently placed in genus *Otis*, and considered to be closely related to *O. tarda* mainly on grounds of similar bill shape and extensive sympatry; nowadays almost universally awarded separate monotypic genus; may be more closely related to *Sypheotides* (see page 240). Eastern birds have been awarded separate race *orientalis*, on grounds of larger size and greyer, more heavily marked upperparts; but much individual variation and considerable overlap between populations, so not nowadays accepted. Monotypic.

Distribution. Morocco and Iberia to France, Sardinia and SE Italy; Ukraine and SW Russia through Kazakhstan to Kirgizia and extreme NW China; extreme N Iran. Winters from Mediterranean zone through Turkey and Caucasus to Iran, and erratically elsewhere in S Asia.

Descriptive notes. Male 43 cm, 794-975 g; female 43 cm, 680-945 g. Breeding male has streaked brown crown, blue-grey face shading to black on neck and breast, with broad white V across foreneck and broad white band across breast; upperparts buffy brown, lightly vermiculated with black; flight-feathers and greater wing-coverts white, tail white mottled brown with three bars; undersides white; legs greyish yellow, bill slate. Non-breeding male has buff face and neck, with buff breast streaked and barred. Female like non-breeding male, but uppersides more coarsely marked. Juvenile similar to adult female, but wing-coverts show more extensive buff with dark barring.

Habitat. Steppe and steppe-like landscapes, level or undulating short-grass plains, rich pastureland, fallow areas and certain kinds of cultivation, notably legume crops; preferably with vegetation over 20 cm high. Birds actively select areas with high diversity of plant species and high abundance of arthropods; hence, they prefer pasture to arable land, on both counts.

Food and Feeding. Beetles, grasshoppers and other terrestrial invertebrates; also much plant material such as shoots, leaves, flowerheads and seeds. Animals may predominate in the summer diet, plants in winter.



Breeding. Feb-Jun. Nest is a shallow scrape usually in dense short-grass cover. Eggs 2-6; incubation 20-22 days; chick has buff down with darker brown streaking and mottling; fledging period 25-30 days or possibly longer; young remain with female into first autumn.

Movements. Largely sedentary or dispersive in Iberia, Sardinia and Italy; migratory in France, with southward shift within the country in Sept-Oct, birds returning in Mar-Apr. Also migratory in Russia, Kazakhstan and rest of Asian range, where birds observe the same schedule when moving to and from Iran, Azerbaijan and, less regularly, other areas of S Asia.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Total breeding population probably numbers more than 100,000 individuals, with 50,000-70,000 birds in Spain, 10,000-20,000 in Portugal, 4000-5000 in France, 2000-2500 in Italy, 18,000-20,000 in Russia, and c. 20,000 in Kazakhstan. Declines noted in most countries; massive depletion in Russia over past century; now almost extinct in Ukraine, with only 8-10 birds recorded in 1978. In Azerbaijan, formerly wintered in huge numbers, with estimates of at least 200,000-300,000 birds in 1930's; current wintering numbers fluctuate at 10,000-40,000 individuals, with fewest birds in milder winters, but as many as 62,300 recorded in Kizil Agach Reserve in Dec 1971; most recent data include almost 30,000 birds counted in Mugan Steppe in Jan 1990. Extinct as breeder in much of C & E Europe, with last breeding records in 1907 in Germany, 1909 in Poland, 1921 in Austria, 1918 and 1952 in Hungary, 1948 in Serbia, and mid-20th century in Greece, Bulgaria and probably Azerbaijan. Formerly abundant breeder in Algeria and Tunisia, but now probably only irregular winter visitor. Agricultural intensification, mostly related to arable farming but also through overgrazing and disturbance, has been main factor in decline, at any rate in recent decades, and remains the chief threat. Nest predation by Rooks (*Corvus frugilegus*) and trampling by cattle cause breeding failure. Shooting may still be significant problem in some places, e.g. Sardinia; official records from 1930's of 40,000-50,000 birds shot annually in Azerbaijan, where poaching still remains a problem.

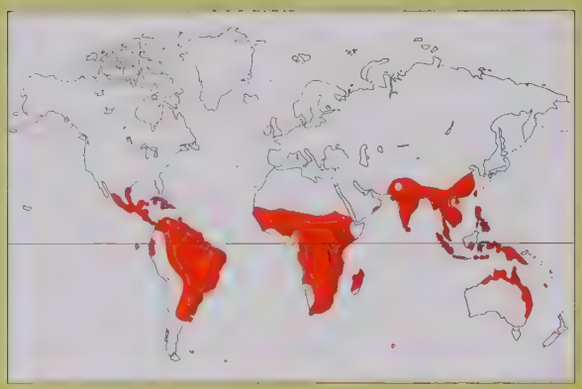
Order CHARADRIIFORMES



Class AVES

Order CHARADRIIFORMES

Suborder CHARADRII

Family JACANIDAE (JACANAS)

- Medium-sized, strikingly coloured waterbirds, with elongated legs, toes and claws.
- 15-58 cm.

- Pantropical, extending into subtropics.
- Shallow freshwater wetlands.
- 6 genera, 8 species, 17 taxa.
- No species threatened; none extinct since 1600.

Systematics

There is general agreement that the jacanas belong to the assemblage of shorebirds, or waders, but in the past there has been considerable confusion as to whether or not the jacanas are more closely related to the Charadriiformes or to the Gruiformes, specifically the Rallidae. This confusion has occurred in part because the shorebirds and the cranes and rails have many similarities, and because the jacanas, although distinct, superficially resemble rails, but careful analysis of a number of osteological characters and also recent biochemical analyses place the jacanas alongside the other shorebirds of the Charadriiformes. Behaviour, including that of the precocial young, also shows their affinity with the sandpiper family, Scolopacidae. They are most closely related to the painted-snipes of the family Rostratulidae, and, in fact, are commonly placed with them in the superfamily Jacanoidea, set apart from all other Charadrii.

The Charadriiformes apparently diverged from the Gruiformes in the late Cretaceous, but the jacanas appear to be much more recent in origin, with few fossils found to date. One large species, assigned to the extant genus *Jacana*, occurred in Florida during the middle Pliocene. Three other species, assigned to two extinct genera, including one species much larger than any existing species, came from an Oligocene formation in Egypt.

At the species level, the taxonomy generally seems pretty clear. There have been scattered records of possible hybridization between Northern Jacanas (*Jacana spinosa*) and Wattled Jacanas (*Jacana jacana*), where the two species come into contact in western Panama; indeed, their ranges used to overlap but no longer do so. This possible hybridization suggests that the two species might not be distinct, but the arguments that they constitute separate species are compelling. For instance, the local race *hypomelaena* of the Wattled Jacana is melanistic, and is easily the race that differs most in plumage from the Northern Jacana, suggesting the possibility of character displacement. With the exception of these two species, the jacanas have highly distinctive plumages.

Some systematists reduce the number of genera to two or three, and place the Lesser Jacana (*Microparra capensis*), the African Jacana (*Actophilornis africanus*), the Madagascar Jacana (*Actophilornis albinucha*), the Comb-crested Jacana (*Irediparra gallinacea*) and the Bronze-winged Jacana (*Metopidius indicus*) all in the genus *Metopidius*; and the Pheasant-tailed Jacana (*Hydrophasianus chirurgus*) along with the Northern and Wattled Jacanas in the genus *Jacana*. Others would keep the Pheasant-tailed Jacana in its own monotypic genus, *Hydrophasianus*. Still others retain *Microparra* and *Hydrophasianus* as monotypic genera, but lump all the remaining forms in *Jacana*. Although these arrangements doubtless reflect relationships amongst the several species, there are no compelling arguments for combining the genera, and such lumping may actually do more towards obscuring relationships.

Despite the fact that the family is largely sedentary (see Movements), five of the eight living species show next to no geographical variation. Two species, the Comb-crested and

The jacanas constitute a very distinctive family of colourful, remarkably long-legged, long-toed waterbirds found around the world in the tropics. Madagascar boasts an endemic species which is very similar to the larger of the two African species, except that the crown, back and sides of neck are white, while the face and lower neck are black. There is no sexual plumage dimorphism in jacanas, but the female is generally larger than the male, sometimes much larger and heavier.

[*Actophilornis albinucha*, Lake Ampijoroa, Madagascar. Photo: Margaret Welby/ Planet Earth]

Long legs with extravagantly elongated toes and claws characterize all members of the Jacanidae, enabling them to walk on floating aquatic vegetation, especially lily pads, without fear of sinking. Apart from its spectacular colourful plumage, a maroon-chestnut body contrasting with brilliant yellow-green flight feathers, the Northern Jacana presents two interesting details: the sharp, bright yellow carpal spur, which shows up well against the dark coverts; and the fleshy yellow comb or frontal shield, which in this species is not continuous with the bill.

[*Jacana spinosa spinosa*, Costa Rica. Photo: Michael & Patricia Fogden]

Northern Jacanas, each have three subspecies. The Comb-crested Jacana's races differ in the darkness of their plumage and in size, whereas the Northern Jacana varies primarily in size, and its different populations may really be ecotypes rather than genuine subspecies. The eighth species, the South American Wattled Jacana, is divided into six distinct subspecies that differ substantially in colour.

Morphological Aspects

Jacanas are small to medium-sized waterbirds. The Lesser Jacana measures only about 15-16 cm in overall length, whereas the Northern, Wattled and Comb-crested Jacanas are slightly larger at 17-24 cm. The remaining species are about 30 cm long, except for the Pheasant-tailed Jacana during the breeding season, when, because of the long tail characteristic of both sexes, its overall length approaches 58 cm.

The jacanas are characterized by having greatly elongated toes and claws that spread their weight out over a significant area, allowing them to walk on floating aquatic vegetation, especially lily pads, whence the popular name "lily trotters". Sometimes they walk on submerged vegetation, giving the distinct impression that they are walking on water. In adult Northern Jacanas, which weight roughly 90-160 g, the toes and claws of each foot splay out over an area approximately 12 x 15 cm, while the toes on each foot of the largest Comb-crested Jacana caught to date covered an area 15 x 20 cm. All jacanas have elongated tarsi, measuring 45-72 mm, and tibiae which are also mostly bare. The elongate legs and feet keep the birds' bodies well above the substrate, and make the jacanas appear relatively rather tall for their body size.

At all seasons adult females are significantly larger than the males. Jacanas show more extreme reversed sexual size dimorphism than any other bird or mammal species. Females of some species average 78% heavier than males, and some female Pheasant-tailed Jacanas may weigh more than twice as much as the males. Sexual differences in weight and linear measurements may actually be greater than the differences reported in the literature, because jacanas have monomorphic plumages and distinguishing between the sexes is difficult without dissection or observation of colour-marked birds during egg-laying or copulation. The size difference between the sexes is significantly less in the Lesser Jacana, in which females weigh only about 41 g.

Weights of individual jacanas fluctuate widely depending on season, amount of rain, food and an individual's ability to monopolize a territory. In the midst of a serious drought in northern Queensland, Australia, Comb-crested Jacanas were weighed at two locations: the first was a large artesian marsh that was serving as a refugium for several hundred jacanas; and the second was a small artificial impoundment, about 200 km distant, where some 12 birds were attempting to breed. At the first location adult females averaged 132 g and males 80 g, while at the second site the females averaged 153 g and the males 86 g; a biandrous female at the second site weighed 168 g, and the second largest female's weight increased from 145 to 158 g when she attempted to breed. In Northern and Comb-crested Jacanas, females that succeed in maintaining territories weigh significantly more than non-breeding females at the same locations.

Except for behavioural differences, and those in weight and measures, the sexes can not be distinguished in the field. In spite of their smaller body size, male Comb-crested Jacanas invariably have larger combs than those of females, and experienced observers can discriminate the sexes on the basis of the relationship of the size of the comb to the bill, the head and the rest of the body. The inability to distinguish the sexes has lead to much confusion in the literature, especially where parental behaviour has often been attributed to the female rather than to the male.

Coloration varies greatly amongst the species, but most are reddish or greenish brown to black above and below, although some are white below, one species has extensively white wings, and another a white nape and hindneck. Two species have yellowish flight-feathers. The Lesser Jacana is interesting in that it retains the juvenile plumage pattern throughout its adult life. Plumage is identical all year round, except in the Pheasant-tailed Jacana, which has a distinct breeding plumage including a much longer tail. All other jacanas have relatively short tails, and all have only ten tail feathers, compared to 12-28 in other shorebirds.

African Jacanas moult all their flight-feathers simultaneously and are flightless during this period. Other species, such as the Northern Jacana, moult their flight-feathers sequentially and never experience a flightless period, nor an interruption in their

The Lesser Jacana bears a superficial resemblance to the juvenile African Jacana (Actophilornis africanus), *though a careful examination shows that the former has the bill and legs shorter, a chestnut crown and supraloral patch, and a darker back. The confusion arises because the two species are sympatric and frequent basically the same type of habitat: extensive freshwater wetlands with floating vegetation. However, the Lesser Jacana does seem to favour rather shallower areas of sparse sedges and aquatic grasses. It is an uncommon species and is difficult to see.*

[*Microparra capensis*, Chief Island, Okavango, Botswana.

breeding activities in those areas where they breed all year round. Although moult in the jacanas is not well understood, the strategy of gradual moult appears to be an adaptation that allows the birds to breed at unpredictable times, whenever conditions are suitable, or at those locations where they can breed year round.

Adult jacanas of both sexes have conspicuous, bare, fleshy frontal shields, wattles or combs, except in the Pheasant-tailed Jacana, which has a strikingly visible white crown, and the Lesser Jacana, which either lacks the frontal shield or sometimes has a very small one. These head ornaments range from the small shields on the Lesser Jacana to large frontal shields that are continuous with the upper bill, to the distinctly flattened fleshy comb on the head of the Northern Jacana and the smaller, but more colourful, comb of the Wattled Jacana, which continues down to hang below the base of the bill in the form of conspicuous lappets or wattles. The most highly developed is the flattened, fleshy shield, with its well developed central comb, found in the Comb-crested Jacana. This entire structure may range from yellow, when the birds are relatively inactive, to bright red, when actively engaged in social interactions or other high stimulus situations; when the bird is excited, the comb also becomes engorged and fully erect, but at other times it may lie flat on the head.

Three species, the Pheasant-tailed, Northern and Wattled Jacanas, have sharp metacarpal spurs, while the Comb-crested and the Bronze-winged have hard, heavily cornified leading edges to the radii. Several species have conspicuously enlarged and flattened radii, which allow them to incubate their eggs and carry their young between the wings and the body.

Jacanas are weak fliers, and they typically fly only for relatively short distances. When they make short hovering display flights and in very short flights, their long feet dangle, but in prolonged flight their feet and toes trail behind the body and tail. Upon alighting, they extend their wings vertically over the body and hold this conspicuous position briefly before folding them. The sudden apparent decrease in size and the disappearance of the conspicuous wing patches in some species make them seem to disappear from view.

They are good swimmers, in spite of their having long, thin toes and tarsi. Presumably, their folded toes pass forward with ease and when the foot is pulled backwards the toes spread out clutching any submerged vegetation. Males and their chicks commonly swim through open water from one lily pad to the next while foraging or moving away from potential danger. Young birds, including very young chicks, take refuge under water when danger threatens; they may stay submerged for long periods with only the tips of their bills above water, and may be hidden in the leaves of emergent vegetation or beneath a water-lily leaf. Adult jacanas can swim beneath the surface, and African Jacanas routinely use this technique to avoid potential predators during the flightless period.

Habitat

Jacanas occur in shallow freshwater wetlands throughout the tropics and subtropics. Breeding occurs on floating, floating-emergent and, less commonly, emergent vegetation, over water usually 0·5 to 2 m deep, although on some reservoirs with dense mats of floating vegetation they may nest over deep water.

Water-lilies (*Nymphaea*) are widely used wherever they occur, as are any other low profile floating aquatic plants, especially *Ludwigia*, *Salvinia*, *Potamogeton* and *Polygonum*. Jacanas also use dense mats of submerged species, such as *Myriophyllum*, for feeding from, but not for nesting on. Emergent plants, such as bulrushes, reeds, papyrus and robust stands of water hyacinth (*Eichhornia crassipes*), may be used for feeding and escape cover, but not for breeding. Jacanas may also feed in wet grasslands and other wetlands that are not suitable for breeding. They appear to use any plant community that has an extremely low profile of floating vegetation, but a few, dispersed emergents are acceptable and sometimes appear to be preferred. Small water hyacinths, when dispersed among other plant species, provide suitable breeding habitat, but dense, lush monocultures of this species do not. Non-breeding Comb-crested, Northern and Wattled Jacanas may also feed on short-grass uplands away from the water, especially where these are artificially maintained at a low profile by mowing or grazing. Likewise, Bronze-winged Jacanas sometimes feed in uplands and in croplands; even territory-holding individuals of these species, especially females, may leave their territories to feed on nearby uplands.

Throughout much of their tropical and subtropical distribution, suitable habitat for jacanas is widely dispersed. In some areas water levels remain fairly constant all year round, and jacanas may breed during any month. In areas with pronounced wet and dry seasons, however, habitat conditions may be extremely ephemeral and the birds may have suitable breeding habitat only during the wet season.

African Jacanas occupy more open areas over deeper water, while the sympatric Lesser Jacanas tend to occur over shallower water in areas with more emergent grasses, sedges and reeds. In Asia, the similarly sympatric Pheasant-tailed and Bronze-winged Jacanas both breed on large marshes, but the more widely distributed Pheasant-tailed also breeds on much smaller marshes and ponds than does the Bronze-winged.

General Habits

The jacanas exploit a unique niche. Their elongate toes and claws allow all members of the family to walk on floating aquatic vegetation where they glean food, establish territories, pair, nest, raise their young, fend off potential predators and sometimes fall prey to avian or aquatic predators. Although they spend much of their lives on floating water-lily leaves where they are conspicuously exposed, sometimes they can be extremely difficult to see. Their dark, or dark and white, coloration makes them inconspicuous in certain situations, for instance when wind or dropping water levels turn lily leaves on edge.

Jacanas frequently turn the head on its side and peer into the sky, apparently tracking aerial predators. They sometimes stand upright with the neck stretched forward at an angle of 60° above horizontal, the feathers on the back of the head raised and the bill pointed downward, as they peer into the water apparently looking at potential aquatic predators. Conspecific intruders and potential egg and chick predators on the substrate elicit similar upright postures but without the bird peering into the water. Northern Jacanas approach and partially or fully extend the wings laterally in a slightly crouched position, with the neck and head up, while they call raucously. This display exposes important fighting weapons, the bright yellow carpal spurs of some species and the cornified leading edge of the radii in others (see Morphological Aspects). Birds also extend their wings vertically as a visual signal in certain social situations and sometimes in response to territory invasion by jacanas and other species, or in response to potential threats in the water. Conspecific aerial intruders elicit raucous calling from one territorial bird after the other, as the intruders fly across their territories.

Outside the breeding seasons jacanas tend to be gregarious. It is not clear whether these are true social groups or whether the birds are simply aggregating on the few suitable sites available during the dry season. During times of severe drought in northern Queensland, Australia, Comb-crested Jacanas congregated in large numbers on a few permanent marshes. At one such site, some birds attempted to establish territories, but intraspecific competition for food and space was so great that most adults came to weigh only 75-80% of their breeding weight.

Voice

Jacanas are often noisy, and make calls variously described as thin, piping and squeaky, sharp and cackling or rattling, or a series of chittering or twittering notes. Calls given in response to predators, potential predators, or when the mate is not present are loud and raucous, but those uttered between mated jacanas that are close together are soft, as are those directed by a male at his chicks. Calls are highly variable within individuals and species and between species. They vary from hoarse-sounding notes that cover a wide range of frequencies to purer-toned whistled notes. Vocalizations have been studied only in the Comb-crested and Northern Jacanas, but descriptions in field guides and regional works suggest that other species are similar in this respect.

Jacanas have two distinct types of call. One is soft with a distinct stuttering cadence, composed of regularly repeated groups of 2-5 rapidly reiterated notes. These soft calls, which can be heard for only a few metres, are relatively stereotyped and often very long in duration, sometimes exceeding 600 notes. They are given by both sexes, but most often by males when accompanying chicks. Both sexes may give the calls during solicitations, mounting and copulation. Sometimes the calls are so soft that the repetitive movements of the bill or throat feathers can be seen, but no calls heard. Chicks often move closer to the male giving this call, but the function of the call between a mated pair is less obvious. In some species it is also given during flight.

The best known vocalizations are the louder, often raucous, calls that consist of anything from one to a few, but sometimes as many as 60 or more, similar notes. The regular unbroken cadence of these calls is completely different from the stuttering cadence of the soft calls. Within each call the notes are quite similar, but between calls there is much variation in volume, length of the individual notes, and number of notes comprising the call. When eggs, chicks, or territorial integrity are seriously threatened, these calls are louder and include more raucous, longer individual notes that are repeated more often. In less serious situations, the calls are quieter and consist of fewer notes that are individually shorter in duration. When these calls are persistent, the mate often approaches the vocalizing bird, but most of the time there is no overt response. The calls clearly advertise the presence of the caller and the level of danger it faces.

Food and Feeding

All species of jacana spend a significant part of every day foraging, sometimes simply walking in a normal upright position looking for food, but most often searching for food with the head and bill lowered toward the substrate and the back and neck angling down, while they walk quickly over the substrate.

Jacanas are small carnivores. Their primary food comprises insects, which they glean from floating vegetation; they also take a wide range of invertebrates by picking them from the root systems of small floating plants, such as *Salvinia*, which they grasp and flip upside down with their bills. From these upturned root masses they pick snails, crustaceans, insects and anything else that wiggles. Adults may also use their toes to grasp the edges of water-lily leaves and turn them over, at least partly, while they pick prey from the undersurface. They occasionally catch insects that fly by, especially flies and bees, and occasionally plunge the entire head beneath the surface of the water in pursuit of prey. Tiny fish, attempting to flee aquatic predators, sometimes slide up onto water-lily leaves where they may be eaten by

A Wattled Jacana preening. Like all birds, jacanas have to spend a considerable amount of time in feather care, as it is essential to keep the plumage in tip-top condition. This is particularly important for waterbirds that frequently soak their plumage, as any dirt could quickly become caked, and the feathers would lose many of their remarkable qualities, for example lightness and insulation. As well as simple cleaning, preening also involves the removal of parasites, and the zipping up of ripped feather barbs.

[*Jacana jacana intermedia*, Hato el Frío, Llanos de Apure, Venezuela. Photo: X. Ferrer & A. de Sostoa]

This juvenile Wattled Jacana has captured a water bug from among floating vegetation. In addition to insects and other invertebrates this species feeds on seeds, but most of the plant matter taken is thought to be ingested accidentally. Jacanas typically take most of their prey from the surface of the aquatic vegetation or from underneath, after turning it upside down. Note the incipient shield and wattles and the almost grotesquely long toes and claws.

[*Jacana jacana jacana*, Pantanal, Brazil. Photo: Hubert Klein/Bios]

jacanas. Birds may spend several minutes rapidly picking minute insects from the surface of the water, where they float after having been washed off water-lily leaves submerged by the weight of the foraging birds.

A female jacana spends an average of about 70-90% of her time foraging, except when one or more of her males has eggs or chicks. At such times, female Northern Jacanas spend a considerable amount of time resting and loafing near the chicks, where they can look out for potential predators. Male jacanas spend up to 90% of their time foraging unless they have eggs or chicks, when their foraging time drops to less than 50%. The precise amount of time spent foraging also depends on prey abundance and weather, and during cool, rainy periods males spend increased time with their eggs or chicks.

Jacanas commonly ingest at least small amounts of vegetation, especially when plucking prey from amongst mats of submerged algae and the upturned roots of plants. Whether all such material is taken incidentally, or whether some of it is taken intentionally, is not clear, with the possible exception of some reports that jacanas eat small seeds. In Guyana, 20% of the food taken by 30 Wattled Jacanas was composed of seeds. This sample came from an agricultural development, where the birds fed on flooded lawns and in shallow rice paddies and is probably atypical. In Costa Rica, Northern Jacanas frequently peck at the bases of water-lily blossoms and fruits that have been opened by Common Moorhens (*Gallinula chloropus*). Reports that jacanas in India are vegetarians are probably in error. It is unlikely that jacanas, especially chicks and juveniles, could survive, and even more unlikely that the females could lay replacement clutches so frequently, without a high protein and fat diet.

Jacanas sometimes associate with a variety of animals that stir up food while they swim or move through the water. They have also been reported picking ticks from capybaras (*Hydrochaeris hydrochaeris*) in Panama and standing on the backs of hippopotami (*Hippopotamus amphibius*) in Zimbabwe.

Adults never feed the precocial chicks, but lead young chicks to food and reportedly point to food with their bills. They accompany their chicks as they feed. Chicks feed at a significantly higher rate when in the presence of the adult, and are much more likely to feed at all when an adult feeds with them. Young chicks are more likely to sit quietly on the substrate rather than feed when unaccompanied than they are when the male is with them. Young chicks of the Northern Jacana die of starvation in the absence of the social facilitation of an adult male feeding with them, which may occur if their father disappears, or when he is preoccupied in interacting with a new female replacing or attempting to replace his mate.

Breeding

Little is known about the small, neotenic Lesser Jacana, but it differs from the other jacanas in being monogamous. In this species the sexes share, apparently equally, all the business of nest construction, incubation and care of the young.

All other jacanas exhibit sexual role reversal, with the males performing most or all nest building, all incubation and all brooding in most species, although in a few species females occasionally brood their chicks. In general, females perform some parental behaviour, such as predator defence, that does not involve direct interactions with the chicks. Female Northern Jacanas perform a disproportionate amount of maintenance behaviour, preening and resting in the general vicinity of the young, where they are able to look out for predators, when the male is feeding away from the chicks; only the male accompanies the young while they feed. Although the male sometimes feeds while accompanying his chicks, his feeding rate is slow and he must spend some time away from them, when he walks and pecks at a faster rate than when he is with them.

All these sexual role reversed species have polyandrous mating systems. The expression of polyandry occurs when ecological conditions allow a female to have access to two or more males either simultaneously or sequentially, and when a female is able to exclude other females from the males' territories. When the breeding habitat is so small that only one male can establish a territory; when the male's territory is extremely long and narrow, as along a narrow waterway; or where habitat quality is otherwise sub-optimal and male territories are unusually large, the female has no opportunity to monopolize more than one male, and mating is monogamous. An individual female may have up to four or more mates simultaneously, with an average of two or three, but sequentially she may have a higher number of mates.

Apart from the monogamous Lesser Jacana (Microparra capensis), *in all other jacanas the usual sexual order is reversed, with males undertaking nest building, incubation and rearing of the young. These species have complicated polyandrous mating systems, whereby a female has access to several mates simultaneously or sequentially and holds territories against other females. Where competition for males is fierce among females, some males may be sequentially polygynous, since new females may replace their previous mates. Courtship behaviour is not usually elaborate in the African Jacana. Both male and female solicit, often from a rudimentary nest platform, by walking round each other holding their heads low. The female assumes a copulatory position and the male pecks at her, beginning at the neck but usually ending near the vent. In only one in four cases do these preliminaries result in the male actually mounting the female, and even then cloacal contact is not frequent, although the male may remain mounted for more than a minute.*

Although female jacanas will toss vegetation, it is the male that is responsible for building one or more platforms of floating aquatic vegetation to house the eggs. The construction may appear alarmingly flimsy, but it proves sturdy enough to bear the weight of the two copulating adults. This female Comb-crested Jacana would seem about to complete the usual clutch of four eggs as she straddles the nest with her legs spread widely at the joints. The eggs of most jacanas are very glossy and bear heavily scrolled dark markings.

[*Irediparra gallinacea novaehollandiae*, Kakadu National Park, Northern Territory, Australia. Photo: Belinda Wright/ DRK]

When competition for males is especially fierce among females a territorial male may find his mates being replaced one after the other during the season. The smaller male can have no influence on the interactions between the females, and, as there is no suitable, unoccupied habitat to move to, consequently he has no choice but to mate with the new female and become sequentially polygynous.

Female jacanas may exhibit sequential or simultaneous polyandry, but many authors are confused as to whether a female remains mated to her earlier males when she is involved in copulation and egg-laying with an additional, nearby male. Males are sexually inactive during the incubation period of up to 28 days, as well as for two to three months after hatching. If the male is successful in rearing his brood and the female is occupied with another male, or males, she may consort only rarely with her successful partner. She may return to his territory to help him repel potential predators or rival females attempting to pair with him. If a male loses his clutch, his partner typically resumes copulating with him and replaces the clutch, often within a few days. If his chicks disappear, he quickly becomes receptive and the female may start consorting with him again. Sometimes the female will persist with a current reproductive effort with another mate and not resume copulation with, and laying for, the first until she has completed a clutch for the other mate, but most often females lay replacement clutches before providing clutches for additional males. Only careful long-term observations of marked individuals in a breeding population can determine whether the relationships are sequential or simultaneous.

Considerable, conspicuous effort goes into the building of one to several platforms of floating aquatic vegetation, from which the birds solicit one another and where they copulate. The female almost always lays the clutch on one of these platforms. In spite of their flimsy appearance, these sodden masses of vegetation must be buoyant enough to support the two adults while they copulate, and repeated attempts to copulate on several sites may allow the female to select the most sturdy for egg-laying. Some of the nest-sites can not be distinguished from the surrounding floating vegetation, while others consist of a mat of stems and other pieces of aquatic vegetation. The upper surface of the nest sits barely above the water and sometimes the undersurfaces of the eggs are in contact with the water.

Males perform most of the nest building but after soliciting the male, or being mounted by him, females often perform nest building movements by picking up stems and pieces of vegetation and throwing them to the side or over the shoulder in the same way as the male does. These movements are performed as the female moves away from the nest-site and sometimes at a considerable distance from the nest, and may actually result in her moving vegetation away from the nest-site. Some of this behaviour must serve some function other than nest building, and it has been described as "substrate tossing" rather than nest building. Nest building behaviour by the male includes treading or pressing down on the nest itself, and involves building up a pad of vegetation. The bulk of the nest structure may be beneath the surface of the water, which would explain why so much nest building often results in such an inconspicuous nest. During incubation, the male frequently adds to the nest by reaching out in front or to the side, grasping plant material and pulling it up toward his breast, and by throwing additional stems toward the nest as he walks away from it.

In those species that have been studied closely, both members of a mated pair do a great deal of sexual solicitation of one another. Solicitations involve assuming the copulatory position with the male mimicking the female's posture, a procedure often referred to as courtship; these usually do not result in mounting, and may end with both sexes soliciting before one of them wanders off. A soliciting Comb-crested Jacana sometimes orientates itself towards its approaching mate and performs a ritualized "Bow Display" by gradually extending its wings laterally and rotating them so that the dorsal surface faces the approaching mate. A Comb-crested Jacana male extends his head and neck under the female's neck, and rubs her underneck with his head and comb. A male African Jacana prods at the soliciting female with his bill, sometimes starting as far forward as her neck, but usually ending near the vent.

Less than 1 in 3 solicitations in the Northern Jacana, and about 1 in 4 solicitations in the African Jacana, are followed by the male actually mounting the female. A high proportion of mounts end with the female straightening up and the male sliding off her back, or with the male simply dismounting, and only 1 in 4, to 1 in 5, mounts by male Northern Jacanas resulted in cloacal contact. Successful copulations lasted two seconds or

less, but prior to cloacal contact males are mounted on the females for up to a minute or more. A male initially stands or crouches without moving, but then, while crouching, he begins shuffling his feet toward the female's tail, while waving the wings for balance. He eventually grasps the female's wings with his toes, as he lowers his posterior over one side, while wagging his tail from side to side. At the same time, the female raises her tail to the opposite side and rotates her vent area upward towards the male until cloacal contact is made.

Successful contact ends with the male moving forward over the female, and the two abdomens stretching until cloacal contact is lost. Successful contact is usually followed by the female remaining in the copulatory position at least briefly, and in the Northern Jacana she typically turns away from the male. She keeps her tail raised and the feathers around the vent spread away from it; the vent is alternately everted and inverted, alternately exposing its creamy interior, which contrasts conspicuously with the dark reddish feathers around it, and which then disappears only to reappear again. This cloacal winking at the male only follows successful copulations.

Females lay determinant clutches of four eggs, three in the Lesser Jacana, early in the morning, producing one egg every 24-25 hours. Reports of smaller clutches are fairly common, but these are probably the result of egg losses. There have been reports of very few larger clutches, but there is no satisfactory explanation of their causation. The posture of the female prior to egg-laying is conspicuous. She shuffles her feet apart, spreads her legs widely at the intertarsal joint, and holds her back up at an angle of about 30° with her vent area lowered between her legs. Sometimes she remains in this posture for several minutes, occasionally lowering herself so that she touches the nest or eggs with her breast feathers. Eventually she lowers the vent area, now swollen with the egg, between her legs and places the egg in the nest or drops it onto the nest platform from a height of a few centimetres. She then raises her body to a position near horizontal, as she shakes and resumes a normal posture and then walks away.

Jacana eggs are conspicuously glossy and shiny so that sunlight reflecting off them gives them the appearance of being wet and resembling the glossy surface of some aquatic vegetation. Pheasant-tailed Jacanas eggs are unmarked and uniformly brown in shades of yellowish, greenish or rufous. The eggs of all other jacanas are heavily, to very heavily, scrolled with dark brown or blackish markings; individual differences in markings and egg shape are consistent within and between clutches. Shell pores are plugged, but the significance of this is not clear. Jacanas lay extremely small eggs relative to their own body size. If egg weight is expressed as a percentage of the female's weight, jacanas lay eggs of about 25-50% of the relative weight of those laid by other shorebirds. The reasons for such small egg size are unknown. The hypothesis that small egg size is an adaptation allowing for production of multiple clutches appears invalid when jacanas are compared to high latitude shorebirds, but the tropical jacanas have a shorter period of daylight in which to feed.

While a male lowers himself onto his eggs to incubate, he rocks his body from side to side, slightly lifting first one leg then the other. He sits on the eggs with his legs closed together behind the abdomen, and with his tarsi and toes extending forward and laterally along the outside of the body and wings. While he rocks from side to side, he raises one wing and then the other very slightly from the body, lowering the edge of the wing down and under the eggs. At the same time, he reaches down and with the underside of the bill rolls the eggs up onto his wings. He ends up with the outside edges of his wings touching or almost touching in the middle, and with two eggs in a row held against his body on the inner surface of each wing. When he ends an incubation bout, the male rocks slightly, sliding the wings out from under the eggs, as he starts to stand. When startled, he jumps to his feet, then quickly flicks his wings to the side, so that two eggs fall from under each wing back onto the nest.

When a male returns to his nest, he often stops and leans forward over the eggs. In this position he raises and lowers each leg in what appears to be a slow, exaggerated dance as he circles the eggs compressing the nest material. He stops on the highest part of the rim and settles on the eggs, rolling them up to him as he tucks them under his wings.

Males occasionally move their clutches. When a nest platform begins to disintegrate, for example during rising water levels, a male may build a new nest, even several metres from the first, and move the eggs to it, one at a time. Sometimes he may simply move them to a new location with no apparent provocation, and without any nest building at the new site. He moves the eggs by backing up with an egg held against the breast with the undersurface of the chin and bill, or by simply backing up toward the new nest, dragging and rolling the egg over the vegetation and through the water with the underside of the bill. The male African Jacana may hold the eggs between his wings and body while he walks across the vegetation. He may set them

The Bronze-winged Jacana's nest, built by the male, is a typical construction of aquatic vegetation, mainly rushes or reeds twisted to form a circular pad. The male is alone responsible for incubating the eggs and caring for the chicks, while the polyandrous female defends her mates' territories against other females. The male sits on the nest with the tarsi and toes stretched forward alongside the body and wings. The bill of this heavily built species is very sturdy and the frontal shield briefly becomes bright red during courtship.

[*Metopidius indicus*, India. Photo: Belinda Wright/ DRK]

The Pheasant-tailed Jacana's eggs are olive brown, very glossy, remarkably pyriform in shape and, unlike other jacana eggs, unmarked. A chick may remain in the egg for a day or more after pipping, apparently in order to facilitate synchronous hatching. Once the chick has emerged, the male picks up the shell and flies off some 10 metres or so before he drops it, a behavioural trait shared with the Northern Jacana (Jacana spinosa), *and believed to guard against predators being attracted to the nest by the empty shells.*

[*Hydrophasianus chirurgus*, Sri Lanka. Photo: Joanna Van Gruisen/Ardea]

down on a water-lily leaf rather than on a nest, and apparently may move them around to several different sites.

The initiation of incubation is not well known, but it typically starts with the laying of the third egg, or rarely late in the day of the second egg. It appears that some of this early incubation may not be effective, because the male appears to sit with the eggs outside his breast feathers rather than next to his brood patches. The inaccessibility of nests makes determination of the incubation period difficult, but it is reported to last roughly 22-28 days. Incubation constancy is highly variable and seems to be most influenced by ambient temperature and the amount of cloud cover. In general, males incubate for much longer periods, with shorter periods off the nest, in the early morning and late afternoon than during the middle of the day. Except in the Lesser Jacana, females are not known to incubate; however, at least in the Northern Jacana, females occasionally shade the eggs during the midday heat.

At midday males often stand over their eggs, shading them rather than incubating them, often sitting very briefly on them before again standing over them. Because of high ambient temperatures, some development of the first-laid eggs probably occurs before the male begins actively incubating them. It is highly unlikely that incubation begins with the laying of the first egg, as has been reported for some species. Because of the need for the male to accompany the chicks, in order to facilitate their feeding, it is adaptive for him to abandon any unhatched eggs within a day of first hatching. Synchronous hatching is therefore advantageous, and postponing the initiation of incubation until the clutch nears completion would be adaptive. The chicks themselves apparently help to co-ordinate hatching, for they begin calling in the egg a day or two before hatching, and the first to pip may remain in the egg for a day or more before emerging. Shortly after each egg hatches male Pheasant-tailed and Northern Jacanas pick up the empty shell and fly 10 m or more before dropping it, a behavioural pattern not reported in the other species, which is assumed to be an anti-predator adaptation, as is similar behaviour in gulls.

It is not clear how a simultaneously polyandrous female decides which one of two to four available males should receive her eggs. The problem is moot when the males are acquired sequentially, or when all but one are unavailable because they are incubating or caring for young less than 2-3 months old, but sometimes all her males are available to care for eggs simultaneously. Consorting with and copulating with each male on his individual territory may provide clues by which the female can compare their readiness to incubate and care for chicks, but just what these clues may be is unknown. As a female Northern Jacana becomes gravid, she spends increasing amounts of time with the male that will eventually receive the clutch. She copulates more frequently with him, and indeed may stop copulating with her other males. After laying each of the first three eggs, she copulates with the owner of the nest within a few minutes to an hour of laying. As the clutch nears completion, she copulates more frequently with any of her other males that are available, and, after laying the third or fourth egg, does not appear to copulate with the male as he becomes more involved with the clutch.

In some species, a female associates exclusively with one territorial male and seldom leaves his territory except to feed or chase other birds. She does not consort with other males until the clutch is complete, after which she pays little attention to him, and begins consorting with and copulating with an additional male. Such females appear to be sequentially polyandrous, but the probability of returning to the territories of earlier males probably depends on the need to help the males repel potential predators. These females return to lay replacement clutches when a clutch is lost. Incubating males do not copulate.

Males run some risk of cuckoldry, that is incubating eggs and raising young sired by other males. Because clutch loss is so high in the jacanas, females produce many more clutches than survive, and there is much replacement laying and much copulating with other males. Cuckoldry probably occurs in some situations. It is possible that males stand as reasonable a chance of cuckolding other males as of being cuckolded themselves which would result in reciprocal cuckoldry! However, recent research with other shorebirds shows that females can store sperm in their reproductive tracts for some time, and apparently select which insemination will be used for fertilization. The question of paternity in polyandrous jacanas remains unanswered. Sperm from earlier copulations will persist in the female tract, so there will always be the possibility that a male will receive one or more eggs fertilized by sperm from one of his female's earlier mates.

A close scrutiny of the tangle of legs protruding from this male Comb-crested Jacana's wings will reveal that he has at least two chicks on board! Jacana chicks are precocial, well able to swim and dive soon after hatching, sometimes even remaining under water with only the head or bill visible. At other times when danger threatens, the male parent may simply lead the chicks away or he may carry them under one or both of his wings and deposit them in a safer place.

[*Irediparra gallinacea novaehollandiae*, Kakadu National Park, Northern Territory, Australia. Photo: Belinda Wright/ DRK]

Confounding the issue is the fact that female jacanas usually copulate with the male that is receiving the clutch shortly after laying. Because ovulation occurs shortly after laying, copulation at this time might enhance the male's probability of fertilizing the next morning's egg.

Territoriality is very complex in polyandrous jacanas. One possibility is that males compete with one another for suitable breeding territories, and females compete with one another for ownership of one to several males and their territories, as appears to be the case where Northern Jacanas breed year round. Alternatively, females might compete for large territories which could be subdivided by males. Where jacanas breed seasonally, the initial territories established by males and females are quite large and the birds are often temporarily monogamous, but when the males start incubating their first clutches they defend much reduced areas. Additional males are able to establish themselves on more distant parts of the first males' original territories. The new male or males pair with and form bonds with the original female, which subsequently helps them to defend their territories against the first male, one another and neighbouring males. Thus, female jacanas help their individual males defend their territories even against their other mates. Following such interactions, females frequently visit each of their males on their territories and copulate with all that do not have clutches or young chicks.

Replacement of individuals within an established breeding population is straightforward. A female may defeat a neighbouring female and take over her male or males, or a previously non-breeding female may displace a territorial female and take over hers. Sometimes a new female appears to be unaware of how many males the previous female had, and neighbouring females take over one or more of them. In all species, non-territorial individuals appear to be available to take over any territory within a few hours of the disappearance of its owner. When a male Northern Jacana has a clutch of eggs from his previous female, the replacement female typically destroys the eggs by pecking at them until they break and then partially eating them. The new female, at least in Northern and Wattled Jacanas, may peck young chicks of the previous female to death, but she will not eat them. If the chicks are old enough to avoid the female's attack, they may be driven from the territory by her. Once the male is no longer involved in incubation or caring for the young of his previous mate, he soon becomes receptive to the new female and to the concern of caring for a new clutch.

Much of what has been called courtship behaviour in the literature is actually pre-copulatory behaviour between already paired or bonded birds. Courtship (in the sense of behaviour leading to the establishment of pair-bonds) at the beginning of the breeding season in seasonal populations differs from courtship of replacement individuals during the breeding season. At the beginning of the wet season, flocks of jacanas appear on the recently flooded wetlands and there is much aerial chasing. When a female and male succeed in excluding other jacanas from an area, the female charges the male, which crouches and shows subordinate behaviour rather than fleeing, and the two birds settle there and continue to consort with one another as a territorial pair. In an established breeding population, however, a territorial male, when he encounters a strange female that has succeeded in displacing his mate, responds by threatening and calling at her, behaviour that should attract his mate, but, of course, his displaced mate does not respond. In the meantime, the new female ignores him or behaves aggressively toward him. In response to her aggression, he may partially extend his wings while moving away, or he may crouch on the substrate or water and the female may peck at his back. By the second day, the new female typically assumes the copulatory posture and the male responds with upright postures, but he soon begins mounting her, and shortly thereafter aggression returns to a low level and he copulates with his new female. Because breeding habitat is limited and alternative territories are not available to him, the male has no choice. The seemingly endless calls of a male that has had its mate killed eventually attract a new female, and interactions between the two are identical with those following active displacement by a new female.

Compared to other shorebirds, the post-hatching rate of development in jacanas is extremely slow. It is also highly variable both between and within broods, with first flight occurring between six and twelve weeks of age. Chicks may disperse from their natal territory as early as at six weeks old, but more commonly associate with the male until 10-12 weeks old. In the Northern Jacana, juveniles may continue to reside on the male's territory until they complete their moult into adult plumage at about 12

months of age. Replacement females are more tolerant of older chicks than of younger ones.

Chicks are brooded almost continuously by the male for the first day or two, and for several weeks are brooded early and late in the day, whenever it is particularly cool, and when it rains. The male sits on the substrate with young chicks nestled between his wings and his body. The chicks' feet and legs grow quickly and within 1-2 weeks of their hatching the male crouches over them, and later stands to brood them while they stand on the substrate. The male often picks the chicks up off the substrate between his wings and body. In the Northern Jacana, chicks brooding between their father's wing and body sometimes stick their heads up through his plumage: they peer around for several seconds before withdrawing beneath the male's plumage again. In several species, most notably the African and Comb-crested Jacanas, the male walks about his territory while holding his chicks between his wings and his body, with the chicks' feet dangling beneath him. Chicks several weeks old may attempt to be brooded when only one of them can fit under each wing. An interesting parallel to the jacanas may be seen in male Sungrebes (*Heliornis fulica*), which brood one young chick in the depressions on each side of his body beneath the wings (see page 214).

Anti-predator defence by both males and females increases dramatically immediately after the chicks hatch. Potential predators that were ignored, except in the immediate vicinity of the nest, are suddenly not tolerated even in distant parts of the territory. Low levels of response to predators include the bird merely orientating itself towards the threat, followed by an upright alert posture that may include raising the crest. The male may simply lead his chicks away from less serious threats, or scoop them up under his wings and carry them off to safety. However, if the threat is significant, the alarmed jacana calls loudly, and very loud calls or screams usually attract the mate. Birds may threaten the potential predator by extending the wings laterally and charging, or they may make aerial attacks diving on and striking at the enemy with their feet. They may also attempt to lure the source of the threat away by making hunched "rabbit runs" away from it, or with a variety of distraction displays, ranging from lying on the substrate or water with the wings partly extended, sometimes flapping them as if trying to escape. They may drag one extended foot and leg, or circle it, as if it were caught on something.

Nesting success is very low in all species studied. During a dry year, all 16 African Jacana clutches laid at one study site were predated. One female laid 10 clutches at an average inter-clutch interval of only 9·8 days, but her male failed to hatch any of them. During a wet year, some clutches were lost to flooding and others to predators, but 15 clutches (38%) produced 30 young from the 145 eggs laid in 39 clutches. For all species, less than half the clutches survive until hatching. Except for the African Jacana, losses are probably greater than estimated in the literature because nests, eggs and incubating males are all inconspicuous and a significant number of clutches are lost during the laying period before they are ever discovered. In addition, predation itself is very seldom observed. Purple Swamphens (*Porphyrio porphyrio*) and American Purple Gallinules (*Porphyrio martinica*) do prey on eggs and chicks of African and Northern Jacanas respectively, but the lists of predators on jacanas are basically hypothetical. Many clutches are lost due to being upset or trampled by ungulates and large reptiles, and to the disintegration of nests, often aggravated by rapidly rising or falling water levels.

Movements

The Pheasant-tailed Jacana is migratory, at least in part. Its northernmost populations move southwards after breeding, and during the northern winter the species occurs south beyond its normal breeding range. However, very little is known about the migrations of this species, and both the origins of the birds turning up in the south and the destinations of those leaving the north remain uncertain.

All other species are basically sedentary, but may make extensive local movements, spreading out over seasonal wetlands during the wet season and retreating to permanent wetlands during the dry season. These irregular movements may actually extend over relatively large distances, up to several hundred kilometres in Africa, and may include large numbers of birds which move together. In Guanacaste Province, Costa Rica, Northern Jacanas sometimes frequent newly flooded sugar cane and

Two African Jacana chicks forage as they walk on floating vegetation in the company of the adult male. The downy chicks are white below and striped black and brown above. While growth in general is slow, already the legs and feet seem disproportionately large for the size of the body. The male does not feed them directly, but is reported to point food items out to them. In all jacana species the male's presence with the chicks is vital to their development as it activates them to forage: without him they may just sit passively, showing no inclination at all to feed.

[*Actophilornis africanus*, Masai Mara, Kenya. Photo: Ferrero & Labat/ Auscape]

In polyandrous jacanas territoriality is complex and to date imperfectly understood. Territories are maintained in the breeding season; where populations are dense, disputes are frequent. In general, a male holds his small territory on floating vegetation against intruders, whereas the female, facing pressure from other females, has the task of defending 1-4 males and their respective territories. In fights between two male Comb-crested Jacanas, wings and feet can become so entangled that a few well aimed pecks from the female are needed for them to extricate themselves and order to be restored!

rice fields during the dry season. In Guyana, Wattled Jacanas may feed in adjacent rice fields while breeding on permanent waterways.

Relationship with Man

Most jacana species have long been well known to local fisherfolk. They are generally rather colourful birds and, as they can scarcely be seen as competitors to the fishermen, they have tended to suffer relatively little persecution, so they are often tame and confiding. This is all the more evident in that in many parts of the world they can be seen on artificial water bodies created or extensively modified by man, frequently in fairly close proximity to human habitation.

The name Jacana was derived from the Portuguese transliteration of a Brazilian Indian name for the Wattled Jacana. Although the name may be pronounced in a variety of ways, the original Portuguese spelling was Jaçaná.

Status and Conservation

None of the jacanas is considered to be threatened at present, but the Pheasant-tailed Jacana appears to be much less common than it was formerly in subtropical and south-eastern China. However, the species ranges extensively across southern Asia and is not known to be declining elsewhere in its immense range.

Like all birds that inhabit wetlands, jacanas are dependent on the maintenance of wetlands, in their case specifically extensive shallow wetlands that support water-lilies and other floating vegetation; draining of these areas, or their flooding to increase water storage are perpetual threats. In contrast, the creation of small ponds for livestock watering or irrigation purposes by damming or excavation provides many new sites for the birds, especially in semi-arid areas and those with distinct wet and dry seasons. Indeed, most of the studies of jacanas reported in the ornithological literature have been carried out on relatively small artificial impoundments of some sort. Lake Kariba, an immense impoundment in northern Zimbabwe, supports extensive floating mats of *Salvinia*, which in turn provide breeding habitat for a very large population of African Jacanas. Jacanas are quick to take advantage of shallow artificial wetlands created as water storage areas or botanical parks. One artificial impoundment in Costa Rica was made unsuitable for the jacanas that had bred there previously, when the water-lilies and other floating vegetation were removed to increase the open water area for aesthetic reasons, but when the floating vegetation was allowed to re-establish itself, the birds returned and began breeding again.

The destruction of wetlands is a significant factor: drainage of wetlands and overgrazing by livestock, especially during droughts, both destroy habitat. In some areas, introduced water hyacinth has displaced other floating vegetation and formed monocultures which are too tall and lush to provide suitable nest-sites for jacanas. Native water-lilies completely disappeared from Lake Naivasha, Kenya, in the late 1970's, in response to overgrazing by introduced coypus (*Myocastor coypus*) and a crayfish. However, large mats of the exotic water plant *Salvinia* replaced the native vegetation, and the jacanas utilize it as a feeding and breeding substrate. Overgrazing on floating and emergent vegetation by ungulates, especially horses and wild pigs, during severe drought years in Queensland, Australia, further reduced the limited amount of suitable habitat available. Likewise, destruction of aquatic vegetation by intentionally introduced herbivorous cichlid fishes causes habitat loss in parts of Africa.

It does not appear that jacanas are extensively pursued by humans for food, as pets or for other reasons anywhere in the world, although in Guyana children sometimes take their eggs. Their most serious threat is undoubtedly the filling or draining of their wetland habitat or its conversion for rice fields, aquaculture or other agricultural development. Pollution that kills insects or vegetation has also caused the loss of some habitat and could be, or become, a more serious problem.

Genus *MICROPARRA* Cabanis, 1877

1. Lesser Jacana

Microparra capensis

French: Jacana nain **German**: Zwergblatthühnchen **Spanish**: Jacana Chica
Other common names: Lesser African Jacana, Lesser Lily-trotter

Taxonomy. *Parra capensis* A. Smith, 1839, Algoa Bay, South Africa.
Genus occasionally lumped with *Actophilornis* and *Irediparra* in *Metopidius*, but this proposal not widely accepted. Species considered to represent a neotenic form of *Actophilornis africanus*. Monotypic.
Distribution. Mali to Sudan and Ethiopia, then S through Uganda and Kenya to Zambia, Zimbabwe, Mozambique and E South Africa, extending W to E Angola and E Namibia.

Descriptive notes. c. 15-16 cm; c. 41 g. Much smaller than other jacanas; frontal shield very small or lacking. Extended wings dark with conspicuous white trailing edges of inner primaries and secondaries; forehead golden rufous, crown cinnamon, hindneck and mantle darker, rest of back rufous to cinnamon; underparts white. Plumage superficially similar to that of juvenile *Actophilornis africanus*, but back darker. Sexes nearly identical, but female slightly larger; higher proportion of males are darker on the back and have black lateral margins to crown, but not reliable difference between sexes; subtle difference between mated birds makes it possible to distinguish them; most males and some females have violaceous black feathers on hindneck and mantle. Juvenile similar to adult except mantle, scapulars, back, rump and uppertail-coverts fringed buff.
Habitat. Shallow water around edges of permanent and seasonally flooded wetlands, especially areas of relatively sparse sedges and aquatic grasses; also uses less dense stands of floating vegetation, e.g. water-lily leaves. May appear in moderate numbers when pans that have been dry for five or more years are flooded in an unusually wet year.
Food and Feeding. Primarily insects; also reported to take bits of aquatic vegetation on occasion. Insects are gleaned from the substrate and from emergent vegetation, while bird walks at water level or climbs on stems of grasses; sometimes swims and picks food off the water like phalaropes (*Phalaropus*).
Breeding. Season highly variable throughout range, in response to wide range of wet seasons and availability of suitable habitat; May in Kenya; mainly Feb-Mar (-Aug) in Zambia; Jun, Sept, Oct in Malawi; mainly Mar-May (Feb-Oct) in Zimbabwe; Nov in South Africa. Differs from all other jacanas in being monogamous, both sexes sharing in nest building, incubation, care of young and defence of territory. Nest is a small mound of aquatic vegetation, often free-floating, with eggs up to 1 cm above the water level; nest building continues throughout incubation period. Normally 3 eggs, rarely 4; eggs relatively small; incubation 22-24 days, with constancy of over 80%, much higher than for other jacanas, perhaps because of very small egg size; chicks similar to those of *Actophilornis africanus* but smaller; accompany adult until at least half-grown. Very few nests found and nesting success unknown.
Movements. Poorly known. Species is permanent resident on permanent wetlands apparently throughout most of range; appears in reasonable numbers at beginning of wet season at seasonally flooded pans, even after years of absence during periods of drought. Vagrant to Sierra Leone.
Status and Conservation. Not globally threatened. Small size and secretive habits contribute to uncertainty as to precise distribution, especially in N of extensive range; for same reasons, local relative abundance poorly known, and true status not clear in most areas. Uncommon in N Nigeria; reported to be abundant at Okavango Delta; uncommon and local in E South Africa.

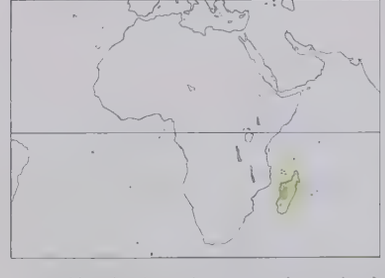
Genus *ACTOPHILORNIS* Oberholser, 1899

2. African Jacana

Actophilornis africanus

French: Jacana à poitrine dorée **German**: Blaustirn-Blatthühnchen **Spanish**: Jacana Africana
Other common names: Greater African Jacana, Lily-trotter

Taxonomy. *Parra africana* Gmelin, 1789, Ethiopia.
Genus occasionally lumped with *Microparra* and *Irediparra* in *Metopidius*, or alternatively with *Irediparra* and *Metopidius* in *Jacana*, but neither proposal widely accepted. Forms superspecies with *A. albinucha*. Monotypic.
Distribution. Wetlands throughout sub-Saharan Africa; largely absent from forest belts and arid zones.
Descriptive notes. 23-31 cm; male averages c. 137 g, female c. 261 g. Bill continuous with large frontal shield, both pale blue to grey-blue; rest of crown and hindneck black; sides of face, chin and throat white changing to golden yellow on upper breast; most of upperparts chestnut to rufous cinnamon, but rump, secondaries and underbody darker maroon chestnut; primaries black, but seen only during flight or display. Female similar to male, but larger. Immature has crown and hindneck blackish with some brown feathers; supercilium white, upperparts pale brown with glossy green, except for chestnut rump, secondaries and greater coverts; underparts white with weak yellowish breast band and chestnut on side of thighs.
Habitat. Permanent and seasonally flooded shallow freshwater wetlands, especially swamps and backwaters of slow-flowing rivers. Restricted to floating vegetation especially water-lilies, and floating-emergent vegetation, which provides more cover but does not appear to reduce predation. Occurs over deeper water with less emergent vegetation than extensively sympatric *Microparra capensis*. Seeks shelter in taller emergent vegetation near shore, but does not use this for nesting in. In Sierra Leone, during dry season, sometimes wanders onto river sandbanks, or even shallow streams with wooded banks.



Food and Feeding. Mainly insects and worms, but also other arthropods, including spiders and crustaceans, and molluscs; seeds sometimes taken. Prey typically gleaned from surface of vegetation or water; also from roots of floating vegetation turned upside down by the feeding jacanas, and undersurfaces of lily leaves. Will also catch flies and other flying insects.
Breeding. Breeds year round in suitable permanent wetlands, but seasonally in seasonally flooded areas; most nests apparently Oct-Nov in Sierra Leone; Jun-Sept in Ghana; mainly Jun-Sept (Apr-Jan) in Nigeria; Jun-Aug/Sept in Ethiopia; mainly Mar-Apr (Nov-Jun) in Zambia; all months in Malawi and Zimbabwe, with peak Jan-Mar; Nov-Jul in South Africa. Polyandrous, but strategy highly variable; males hold nesting, breeding, feeding and chick rearing territories, while females, one to several adjacent males, hold their territories against other females; some males sequentially polygynous, because new females keep replacing their former mates. Sexual role reversal essentially complete, with male apparently performing most nest building, all incubation and all care of the precocial young. Cloacal contact occurs in only a small proportion of initiated courtship interactions. Nest is flimsy, mostly submerged pad of aquatic vegetation, extending to 2 cm above water surface; over deeper water, nest often placed on small floating islands; eggs sometimes laid on floating vegetation with no nest. Determinate layer, 4 eggs laid c. 24 hours apart, in early morning; male begins incubation after laying of 3rd egg, period c. 20-26 days; nest attentiveness varies with weather and temperature, but averages 52% in Transvaal; incubation much reduced during warm, sunny parts of day, when male may spend more time shading eggs than incubating them; sometimes carries eggs under wings to new nest site (see page 283); male celibate during incubation and for at least first several weeks of chick care. Female will lay replacement clutches, or clutches for additional males, every 4 days to 3 weeks (average c. 9 days). Downy chicks white below, with light and dark brownish striping above; young not fed by male, but he points out food to very young chicks, and accompanies chicks while they feed; broods chicks under wings, and may pick them up and carry them under wings, as in other jacanas; young birds stay with male 40-70 days; attain full adult plumage at c. 1 year, but age of first breeding unknown. Nest success very low, from 0% some years, to almost 50% in exceptionally good conditions, but averages c. 26%; brood survival much higher, up to c. 90%.
Movements. Not migratory, but extremely nomadic, often in connection with changing water levels; in wet years, birds may show up on pans from which species has been absent for several years. Birds may apparently move as much as several hundred kilometres, but non-breeding birds inconspicuous, so pattern of movements remains poorly known.
Status and Conservation. Not globally threatened. Generally common to abundant throughout most of extensive range, although few population figures available. Abundant on shallow freshwater wetlands in Sierra Leone, and also in Ghana and Nigeria except in brackish swamps along coast, where less common; common in Gambia and Malawi, on Zanzibar and Pemba, and locally in South Africa. May be locally threatened by habitat loss or deterioration through flooding of shallow wetlands for hydroelectric projects, draining of wetlands, or overgrazing; but, particularly in southern parts of its range, creation of stock watering ponds and small reservoirs has substantially increased amount of suitable habitat available. Introduced coypu (*Myocastor coypus*) destroyed water-lily habitat on L Naivasha, Kenya, during late 1970's, but present species switched to nesting on less stable mats of the exotic waterfern *Salvinia*.

(1980), Cunningham-van Someren & Robinson (1962), Dowsett & Forbes-Watson (1993), Elgood *et al.* (1994), Every (1989), Fry (1983b), Ginn *et al.* (1989), Goodman & Goodman (1985), Gore (1990), Grimes (1987), Hodgson (1983), Hopcraft (1968), Irwin (1981), Mackworth-Praed & Grant (1957, 1962, 1970), Maclean (1993), Pakenham (1979), Pinto (1983), Pitman (1960), Postage (1984), Short *et al.* (1990), Simpson (1961), Steyn (1973), Tarboton (1976, 1992c, 1992d, 1993), Taylor & Harper (1988), Urban *et al.* (1986), Vernon (1973), Wilson (1974), Winterbottom (1961a).

3. Madagascar Jacana

Actophilornis albinucha

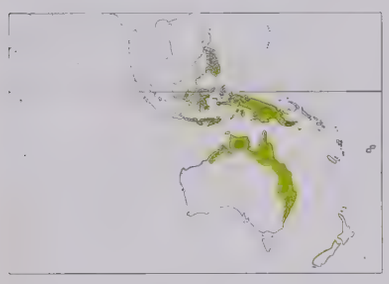
French: Jacana malgache **German**: Madagaskarblatthühnchen **Spanish**: Jacana Malgache
Other common names: Malagasy Jacana

Taxonomy. *Parra albinucha* I. Geoffroy Saint-Hilaire, 1832, Madagascar.
Genus occasionally lumped with *Microparra* and *Irediparra* in *Metopidius*, or alternatively with *Irediparra* and *Metopidius* in *Jacana*, but neither proposal widely accepted. Forms superspecies with *A. africanus*. Monotypic.
Distribution. Madagascar, except for highlands and shrub desert of S & SE of island.

Descriptive notes. c. 30 cm; one female 139 g. Similar in size to *A. africanus*, to which identical except for crown, hindneck and sides of neck white, with golden yellow next to mantle; face and lower neck black; band of white sometimes from thighs across uppertail-coverts; tips of middle tail feathers black. Female slightly larger. Immature similar to immature *A. africanus*, but crown, hindneck and eyestripe blacker.
Habitat. Floating vegetation in freshwater marshes, on shallow lake margins, on ponds and along slow-flowing rivers. Occurs from sea-level up to 750 m.
Food and Feeding. Insects and their larvae, and presumably other invertebrate prey; also seeds of aquatic plants. Forages over floating or floating-emergent vegetation, presumably gleaning prey off vegetation or water.
Breeding. Appears to breed throughout the year but little studied; definite records Dec-Jun. Nest is floating heap of aquatic plants. One clutch of 4 eggs reported. Very little information available, but habits assumed to be similar to those of *A. africanus*.
Movements. No definite reports, but probably makes local movements as water conditions vary.
Status and Conservation. Not globally threatened. Abundant in N & W, but rare in E Madagascar. Now uncommon on L Alaotra, where formerly common; Alaotra, Madagascar's largest lake, has been

On following pages: 4. Comb-crested Jacana (*Irediparra gallinacea*); 5. Pheasant-tailed Jacana (*Hydrophasianus chirurgus*); 6. Bronze-winged Jacana (*Metopidius indicus*); 7. Northern Jacana (*Jacana spinosa*); 8. Wattled Jacana (*Jacana jacana*).

seriously degraded by siltation, agricultural development, drainage, overfishing and poaching. Species poorly known, but apparently secure at present.
Bibliography. Benson *et al.* (1976-1977), Dee (1986), Delacour (1932), Dowsett & Forbes-Watson (1993), Fry (1983b), Langrand (1990), Milon *et al.* (1973), Rand (1936).



Genus *IREDIPARRA* Mathews, 1911

4. Comb-crested Jacana

Irediparra gallinacea

French: Jacana à crête **German**: Kammblatthühnchen **Spanish**: Jacana Crestada
Other common names: Lotusbird, Lily-trotter, Christbird

Taxonomy. *Parra gallinacea* Temminck, 1828, Menado, Sulawesi.
Genus occasionally lumped with *Microparra* and *Actophilornis* in *Metopidius*, or alternatively with *Actophilornis* and *Metopidius* in *Jacana*, but neither proposal widely accepted. Validity of races uncertain and frequently challenged; there is apparently clinal increase in size from N to S, but considerable variation in size in any one population; supposed subspecific differences in tone of upperparts also seems variable; birds from Kai Is (SE Moluccas) may represent a racially mixed and possibly unstable population, although general characters perhaps closest to *novaeguinae*; species may be more appropriately considered monospecific, but further study required. Three subspecies currently recognized.
Subspecies and Distribution.
I. g. gallinacea (Temminck, 1828) - SE Borneo, Sulawesi, SE Philippines (Mindanao), Moluccas and Lesser Sundas.
I. g. novaeguinae (Ramsay, 1878) - N & C New Guinea, Misool I and Aru Is.
I. g. novaehollandiae (Salvadori, 1882) - S New Guinea, D'Entrecasteaux Is, N & E Australia S to Sydney.

Descriptive notes. 21-24 cm; male c. 75-97 g, female c. 122-168 g. Mantle, back and upperwing-coverts brown, rest of plumage black except for white belly, undertail-coverts, face and upper neck; sides of neck bright golden yellow; bill pink to red, with black tip; bright pinkish red flat, fleshy shield up to 2 cm wide x 3 cm long, and a conspicuous comb rising up 1 cm or more in centre; shield and comb yellow to orangish in non-excited state becomes bright pinkish red with infusion of blood during breeding and other periods of excitement, but control of comb colour not understood; carpal knob (no carpal spur as reported in literature) has hard cornified leading edge along distal part of radius. Female similar to male, but considerably larger. Juvenile brown above, white below lacking black breast of adult; comb and wattle rudimentary; incomplete moult to immature plumage during first year, adult plumage at c. 1 year old. Racial differences somewhat masked by individual variation; *novaeguinae* has darkest upperparts; *novaehollandiae* largest, with palest upperparts.
Habitat. Floating, floating-emergent and emergent vegetation in freshwater wetlands, lagoons, billabongs, swamps, slow-moving rivers and lakes. Makes extensive use of artificial impoundments. Occasionally feeds on adjacent uplands with short vegetation.
Food and Feeding. Insects and other invertebrates; seeds also recorded. Prey gleaned from substrate and from just below surface of water, while bird walks on floating vegetation.
Breeding. Can breed year round when floating vegetation persists, but only during the wet season throughout most of range in Australia. Polyandrous with 1-3 (1-4) males per female; one very large female was able to monopolize 2 males in face of pressure from 4 other adult females. Males defend territory on floating vegetation, and females defend 1-4 adjacent males and their territories. In territorial fights males crouch, extend wings to the side and head and neck forward as they call loudly and lunge at one another; sometimes their feet and wings become entwined and they end up semi-submerged in water, whereupon female comes and pecks at the males until they separate. Either sex, but usually female, performs a unique pre-copulatory display: bird assumes copulatory position ("soliciting"); if the other bird approaches, displaying bird orientates self towards it and extends wings, while keeping tail high and head low, so wings nearly vertical; if second bird continues to approach, displaying bird folds wings and continues to hold copulatory position. Nest of stems and pieces of aquatic vegetation built primarily by male, but female does much vegetation tossing. Determinate layer, 4 eggs; female produces replacement clutches for her primary male as well as clutches for her other males; incubation 28 days; incubation and chick-care by male; chick striped above, white below; fledging c. 50-60 days.
Movements. Dispersive. Sedentary on permanent wetlands. Not known to be migratory anywhere within range; the few records reported from most of Wallacea have been taken by some authors as possible evidence of migration from Australia, although apparent subspecific differences do not support this. In Australia, birds moves considerable distances to occupy recently flooded wetlands at beginning of wet season, and disappear again when they dry.
Status and Conservation. Not globally threatened. Not known to be threatened anywhere within range, but degradation or loss of wetlands is a continual threat. Artificial impoundments have greatly increased the amount of breeding habitat in Australia. Few precise data available; Kakadu National Park in N Northern Territory, Australia, estimated to hold 1500 birds in 1987. Few records from most of Wallacea, but species recently found to be locally abundant on freshwater swamps in S Sulawesi.

Genus *HYDROPHASIANUS* Wagler, 1832

5. Pheasant-tailed Jacana

Hydrophasianus chirurgus

French: Jacana à longue queue **German**: Wasserfasan **Spanish**: Jacana Colilarga
Other common names: (Chinese) Water-pheasant

Taxonomy. *Tringa Chirurgus* Scopoli, 1786, Luzon.
Genus occasionally included within *Jacana*, but alternatively considered to be one of the forms most distant from that genus. Monotypic.
Distribution. Pakistan, Nepal, India and Sri Lanka through Myanmar to SE China and Taiwan, and S to SE Asia and Malay Peninsula, S Borneo and Phillippines. Winters sparsely S to Sumatra and Java, and also W to Oman and Yemen.

Descriptive notes. 39-58 cm (including 25-35 cm tail), in non-breeding plumage c. 31 cm; male c. 126 g, female c. 231 g. The only jacana with different breeding and non-breeding plumages. Conspicuous white wings, with black outermost primaries, and black tips to other primaries, outermost secondaries and greater primary coverts; sharp, pointed carpal spur. Breeding plumage: head and lower neck white, black patch at rear of crown continues as black line down each side of neck separating glossy golden yellow hindneck from white foreneck; body and tail feathers vary from blackish brown to paler brown, with greenish wash on back; tips of outer primaries with 2 cm spatulate extension; tail graduated with central two feathers greatly elongated, 19-38 cm. Non-breeding plumage: upperparts paler greenish brown extending onto outer parts of lesser and median coverts; crown and hindneck blackish, golden yellow on sides, with blackish brown eyestripe continuing down sides of neck and forming breast band; tail graduated but much shorter, 11-12 cm. Female similar to male, but significantly larger, although precise linear data lacking. Juvenile similar to non-breeding adult, but back paler, no yellow on sides of neck, and breast band indistinct.
Habitat. Extensive freshwater wetlands, including lakes, ponds and swampy ground; breeds on floating and floating-emergent aquatic vegetation, including water-lilies. Typically nests in wetlands cultivated for the edible seeds *Trapa* and corms of water chestnuts (*Eleocharis*), lotus (*Nelumbo*) and water-lilies. Winters in similar habitat, but may use more emergent vegetation.
Food and Feeding. Insects and invertebrates; reports that diet is vegetarian in India must be in error, but some aquatic vegetation ingested accidentally or incidentally, while seeds or ovules of lotus and lily may be taken intentionally. Prey gleaned from water surface and from surfaces and root systems of floating and emergent vegetation. Swims and feeds in open water more commonly than other jacanas.
Breeding. Season limited to summer months, Jun to early Sept at N limits, and to wet or monsoon months in India, Sri Lanka and SE Asia. Polyandrous, with female defending 3 males or more, and laying c. 10 clutches per year. Male reportedly remains mounted on female for up to 5 minutes before brief, 1-2 second, cloacal contact. Nest is a pad of stems and pieces of aquatic vegetation; construction primarily by male; some nests substantial, others disintegrate rapidly in rising water and sometimes eggs simply laid on floating leaf; male often moves clutch to new location. Clutch 4 eggs; replacement clutches laid every 6-15 days; male alone incubates and provides all direct parental care, but female aids in territory defence; downy chicks white below, striped with brown above; incubation and fledging periods unknown, but chicks may remain with male for up to 50-60 days. In N China, male becomes receptive to female much sooner after hatching a clutch than in other species: may consort and copulate with female when chicks only 2 weeks of age, and 1 clutch of 4 eggs laid for male with chicks only 19 days old. Breeding success unknown, but low. Age of maturity at least 1 year.
Movements. Makes local movements all year round, in response to changing water conditions throughout most of distribution. The only jacana with established migratory patterns, populations from China and high altitudes of Himalayas migrate S, but migration routes and behaviour unknown. Non-breeding birds occur throughout most of breeding range, and regularly in small numbers in Sumatra, Java, Oman and S Yemen; e.g. up to 50 recorded at Khawr Rawri, W Oman, in Feb. Probably breeds in SE Borneo, but no definite records. Single records in Bali and NW Australia; vagrant to S Japan.
Status and Conservation. Not globally threatened. Totally dependent on suitable wetlands; use of shallow water by human populations for growing seeds and corms causes much loss of nests and their contents. Conversion of wetlands to agricultural use, such as duck ponds and aquaculture, threatens birds on local levels. Common in Pakistan, with up to 150 birds wintering on single lake in S Sind; common resident and winter visitor in Thailand; uncommon in Peninsular Malaysia. Formerly bred as far N as Beijing, E China, but now apparently only S of R Yangtze; numbers apparently decreasing throughout E China. May have declined at major wintering site in S Sumatra: at Meggala (NC Lampung), generally common with 30+ birds on each swamp in 1976, but no birds recorded during surveys in 1992-1994.
Bibliography. Ali (1979), Ali & Ripley (1980), Anon. (1982), Bates & Lowther (1952), Betterton (1947), Biddulph (1954), Brazil (1991), Deignan (1945), Dickinson *et al.* (1991), Étchécopar & Hüe (1978), Gallagher & Woodcock (1980), Hoffmann (1949, 1950), Holmes & Rusila Noor (1995), Hüe & Étchécopar (1970), Indrawan (1991), Inskipp & Inskipp (1991), King *et al.* (1975), Kirkpatrick (1952), Kotagama & Fernando (1994), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Marchant & Higgins (1993), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Neelakantan (1953b), Perennou *et al.* (1994), Phillips, T.J. Genus *METOPIDIUS* Wagler, 1832

6. Bronze-winged Jacana

Metopidius indicus

French: Jacana bronzé **German**: Hindublatthühnchen **Spanish**: Jacana Bronceada

Taxonomy. *Parra indica* Latham, 1790, India.
Genus occasionally considered to include *Microparra*, *Actophilornis* and *Irediparra*, or alternatively lumped with *Actophilornis* and *Irediparra* in *Jacana*, but neither proposal widely accepted. Monotypic.
Distribution. India through SE Asia to S Sumatra and W Java.
Descriptive notes. 28-31 cm; 94-210 g. Glossy, black plumage with back, scapulars and upperwing-coverts greenish, tail and vent rufous; greenish yellow bill with yellow tip and red base, lappets and small frontal shield bluish, becoming all bright red during courtship; conspicuous white stripe extends from eye to nape; cornified carpal knob. Female similar to male, but larger. Juvenile has rufous cap and eyestripe, with small white supercilium; front of neck buff becoming yellowish buff on sides; rest of underparts white, upperparts dark.
Habitat. Floating and emergent vegetation on freshwater lakes, swamps, tanks, ponds, etc., especially in plains and in plateau country; also occurs in denser vegetation, wet grasslands, and overgrown paddyfields. On larger wetlands coincides with *Hydrophasianus chirurgus*, but latter not normally found on smaller ponds. Although present species sometimes dives when harassed, will also seek cover in vegetation away from wetlands.

Food and Feeding. Reported to be chiefly vegetarian, but probably feeds extensively on insects, snails and other invertebrates. Food items taken from the water surface and aquatic vegetation. Apart from wetlands, in some areas probably forages often in grasslands and crop fields.
Breeding. Season during monsoons. Polyandrous; males vigorously defend territories against other males, females defend their mates' territories against other females. Scanty nest of aquatic vegetation on water-lily leaves or in emergent grasses, placed in denser vegetation than those of other jacanas; both sexes toss potential nest material, but it is not clear that female helps to build nest. Clutch 4 eggs, but 1 or more eggs sometimes lost; female has inter-clutch interval of c. 10 days; incubation c. 26 days; male alone incubates eggs and cares for chicks; male defends chicks aggressively, and in this is assisted by female. Unlike case of *Hydrophasianus chirurgus*, male does not resume sexual activity for over 2 months, reducing likelihood of his raising 2 broods during breeding season of c. 4 months. Fledging period, nesting success and age at sexual maturity unknown.
Movements. Sedentary, making local movements as necessary, in response to seasonal changes in water conditions; at Rawa Tenuk, S Sumatra, species appears to disperse throughout swamp during wet season, returning in dry season, presumably to breed.
Status and Conservation. Not globally threatened. Dependent on existence of wetlands, but apparently able to utilize some agricultural lands, e.g. wet grasslands, paddyfields. Apparently hunted in some areas, but elsewhere unmolested. Common in Thailand. Locally common in wetlands in lowland S Sumatra, especially at Rawa Tenuk; now very rare in Java, where formerly common.

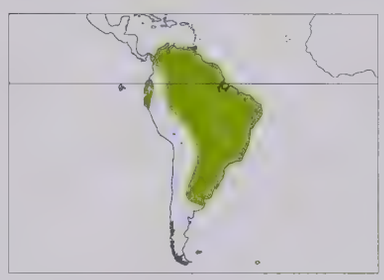
Genus *JACANA* Brisson, 1760

7. Northern Jacana

Jacana spinosa

French: Jacana du Mexique **German**: Gelbstirn-Blatthühnchen **Spanish**: Jacana Centroamericana
Other common names: (Middle) American Jacana

Taxonomy. *Fulica spinosa* Linnaeus, 1758, South America; error = western Panama.
Genus occasionally considered to include *Hydrophasianus*, or alternatively *Actophilornis*, *Irediaparra* and *Metopidius*, but neither proposal widely accepted. Forms superspecies with *J. jacana*, and considered conspecific by some authors, but evidence not convincing. Accepted races differ mainly in size, and may represent ecotypes rather than genuine races. Three subspecies normally recognized.
Subspecies and Distribution.
J. s. gymnostoma (Wagler, 1831) - Mexico, from SC Sinaloa and C Tamaulipas S to Chiapas, Yucatán and Cozumel I; rarely SE Texas (USA).
J. s. spinosa (Linnaeus, 1758) - Belize and Guatemala S to W Panama.
J. s. violacea (Cory, 1881) - Cuba, I of Pines, Jamaica and Hispaniola.



Descriptive notes. 17-23 cm; average of male 91 g, female 161 g. Head, neck, upper breast and upper mantle black; rest of upperparts, coverts, tertials and tail reddish to maroonish chestnut; rest of underparts maroon-chestnut; flight-feathers conspicuously yellow with pale greenish or chartreuse wash, tipped with brown which extends up outer margins of outer primaries and over primary coverts, alula and carpal area; bright yellow carpal spur contrasts conspicuously with dark plumage; bill yellow with pale blue to whitish base; conspicuous yellow soft, fleshy frontal shield tri-lobed, with central lobe larger; shield not continuous with bill as in other jacanas. Female similar to male but much larger. Juvenile has underparts white with pale buff breast; cap, hindneck, upper tail and rump dark brown, rest of upperparts pale brown; flight-feathers as in adult. Races very similar, differing slightly in size.
Habitat. Floating and floating-emergent vegetation in permanent and seasonally flooded shallow wetlands throughout range; in Mexico, even breeds on roadside ponds. Preferred territorial sites contain mixture of aquatic vegetation rather than monoculture of lily or hyacinth. Also occurs but does not breed in grassy marshes, nearby wetlands, and dry adjacent uplands; occurs up to c. 1500 m in Costa Rica.
Food and Feeding. Insects and other invertebrates; plant material apparently ingested incidentally, but species feeds actively on ovules or seeds of water-lilies opened by American Purple Gallinule (*Porphyrio martinica*); occasionally takes tiny fish. Feeds primarily by gleaning insects from the substrate, and picking invertebrates from root masses of floating vegetation which are systematically flipped upside down; occasionally plunges entire head beneath water in pursuit of prey.
Breeding. Virtually all year round in permanent wetlands. Polyandrous; females defend 1-4 (average 2·2) adjacent males and their territories; almost complete sex role reversal. In seasonally flooded sites, initial territories are large and additional males occupy sites on distant margins of territories as incubating males defend smaller areas closer to nests. Much of nest structure sits below water surface; nest material varies from virtually nothing to small pad of aquatic vegetation and stems; nest building movements performed by female primarily as part of interactions with male and not obviously related to nest building. Potential for cuckoldry highly variable, but female typically copulates preferably with male receiving eggs, especially shortly after egg-laying. Clutch 4 eggs; incubation 28 days; female highly variable in attention to nest and eggs, occasionally touching eggs with outside of breast feathers, but not known to incubate, and only male has brood patches; downy chicks white below with cinnamon to dark brown stripes above. Female performs vigilance behaviour near brood and attacks potential predators; both sexes spend much time attacking and chasing a variety of species from their territories. Chick-care normally by male alone; after two days of heavy rains, female sometimes broods chicks while male feeds; a monogamous female assumed care for a brood less than 2 weeks old while male incubated second clutch. Young stay with male up to 12 weeks, and may remain on his territory up to 12 months when adult plumage becomes complete. Normally male not receptive to female until chicks are 5-6 weeks old, and does not receive second clutch until later. In permanent habitats, individual females replaced by new females, which take over displaced female's territory and males; they commonly destroy any existing clutches and kill young broods, presumably bringing male into reproductive condition earlier than would occur if he were allowed to continue parental behaviour. Males replaced after 6-24 months' occupancy. Nesting success c. 30-40%, but 80+% of chicks survive. Does not breed until more than 1 year old, probably not until 2 or older.
Movements. Sedentary. Makes local movements between wetlands in areas with seasonal flooding. Immatures disperse along coast as much as 800-1000 km to N of northernmost breeding sites. Rarely wanders to S USA, where formerly bred and may still do so sporadically. Vagrant to Puerto Rico.
Status and Conservation. Not globally threatened. Common to fairly common throughout Mexican range; locally abundant in Costa Rica; common in W Panama. Creation of small artificial wetlands, including roadside ditches, has created new habitat, but economic development, drainage and development of rice production have reduced habitat elsewhere. Use of herbicides and insecticides sometimes eliminates prey and stunts plant growth. Large breeding colony near Houston, Texas, disappeared after poisoning of aquatic vegetation was followed by extreme freezing.

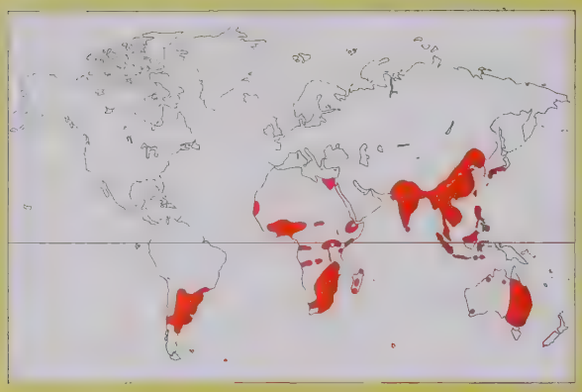
(1983a), Betts (1973), Betts & Jenni (1991), Biaggi (1983), Blake (1977), Fleetwood (1973), Hellmayr & Conover (1948), Howell & Webb (1995a), Jenni (1974, 1979, 1983), Jenni & Betts (1978), Jenni & Collier (1972), Jenni *et al.* (1975), Mace (1981), Miller (1931), Monroe (1968), Ridgely & Gwynne (1989), Rutgers & Norris (1970), Schaldach (1963), Slud (1964), Stephens (1982, 1984a, 1984b, 1984c, 1984d), Stiles & Skutch (1989), Wetmore (1965), Williams, S.O. (1987).

8. Wattled Jacana

Jacana jacana

French: Jacana noir **German**: Rotstirn-Blatthühnchen **Spanish**: Jacana Suramericana

Taxonomy. *Parra Jacana* Linnaeus, 1766, Surinam. Genus occasionally considered to include *Hydrophasianus*, or alternatively *Actophilornis*, *Irediaparra* and *Metopidius*, but neither proposal widely accepted. Forms superspecies with *J. spinosa*, but probably not conspecific as suggested by some authors. Range almost overlaps with that of *J. spinosa* in W Panama, and in past did so; local race *hypomelaena* of present species is the least similar to *J. spinosa*. Six subspecies recognized.
Subspecies and Distribution.
J. j. hypomelaena (G. R. Gray, 1846) - WC Panama (Veraguas) to N Colombia (Magdalena Valley).
J. j. melanopygia (P. L. Sclater, 1857) - W Colombia (Cauca Valley) to W Venezuela (L Maracaibo).
J. j. intermedia (P. L. Sclater, 1857) - N & C Venezuela.
J. j. jacana (Linnaeus, 1766) - SE Colombia E through S Venezuela to Trinidad and the Guianas, and S through most of Brazil to E Bolivia, N Argentina and Uruguay.
J. j. scapularis Chapman, 1922 - lowlands of W Ecuador and NW Peru.
J. j. peruviana Zimmer, 1930 - NE Peru (lower R Ucayali) and adjacent NW Brazil (upper R Amazon).



Descriptive notes. 21-25 cm; male 89-118 g, female 140-151 g. Red bi-lobed frontal comb or shield and conspicuous rictal lappets contrast with yellow bill and black head; blackish to reddish chestnut brown above; yellow to pale greenish yellow flight-feathers with dark brown to black tips, broader distally, and outermost edges of outermost primaries, primary coverts, alula and carpal area; bright yellow carpal spur. Female significantly larger and heavier than male, often with bluish caste along upper edge of comb. Juvenile very similar to that of *J. spinosa*, but has small frontal shield bi-lobed, rather than tri-lobed; lacks rictal wattles. Races vary from blackish above and below in *hypomelaena* to rich chestnut brown above and black below in *intermedia*, although some forms have chestnut flanks and vent, or black feathers mixed with chestnut in scapulars. Race *peruviana* resembles *J. spinosa* most closely, as is the least melanistic race. Immature *hypomelaena* differs from immatures of other races and that of *J. spinosa* in having darker brown back and black flanks, axillaries and underwing-coverts.
Habitat. Permanent and seasonally flooded freshwater wetlands with floating and floating-emergent vegetation. Also forages in shallow water and in adjacent cropland and grassland. In Guyana, nests in ditches, canals and small ponds, and regularly feeds on adjacent rice fields.
Food and Feeding. Primarily insects and other invertebrates; apart from seeds, most plant material may be ingested accidentally, but at a rice plantation in Guyana 20% of diet consisted of seeds. Prey gleaned from the surface of floating and emergent vegetation and picked from roots of floating plants upturned by bird.
Breeding. Polyandrous; females defend and breed with 1-3+ neighbouring, territorial males; number of mates highly variable and apparently depends on size of habitat and especially on quality, with more, smaller territories occurring in areas of dense, mixed species mats of floating vegetation. Females vigorously exclude other females and assist their mates to drive out intruders. Few details reported about breeding behaviour, but sex role reversal occurs and species is generally assumed to have similar behavioural traits and ecology to those of *J. spinosa*. Nest small, often partially submerged, collection of stems and aquatic vegetation. Clutch 4 eggs; incubation 28 days; incubation and chick-care by male; downy chicks white below with cinnamon and brown stripes above; male accompanies, broods and defends precocial chicks, but does not feed them; fledging age and age of sexual maturity assumed to be as in *J spinosa*. Male does not copulate during incubation and for first several weeks of brood care; female lays replacement clutches and clutches for other males with as little as 8 days between clutches. Following removal of resident female, replacement females from nearby commonly kills chicks, especially those 3 weeks old or younger. In Guyana only 8 of 52 nests (15%) produced 1 or more young.
Movements. Sedentary, with local movements during dry season, when many marshes dry out. Occurs in flocks outside breeding season.
Status and Conservation. Not globally threatened. Dependent on preservation of suitable wetlands. Development of rice production, as in Guyana, can produce additional habitat or can cause its destruction, but invariably leads to greatly increased human disruption of breeding efforts. Development of grazing and pasture lands, and associated small reservoirs, has increased habitat in much of South America. Formation of L Gatun in Panama created immense amount of new habitat for local race *hypomelaena*. Attempts to drain wetlands constitute a threat in many areas, but, despite this, overall species not seriously threatened over most of distribution.

Class AVES

Order CHARADRIIFORMES

Suborder CHARADRII

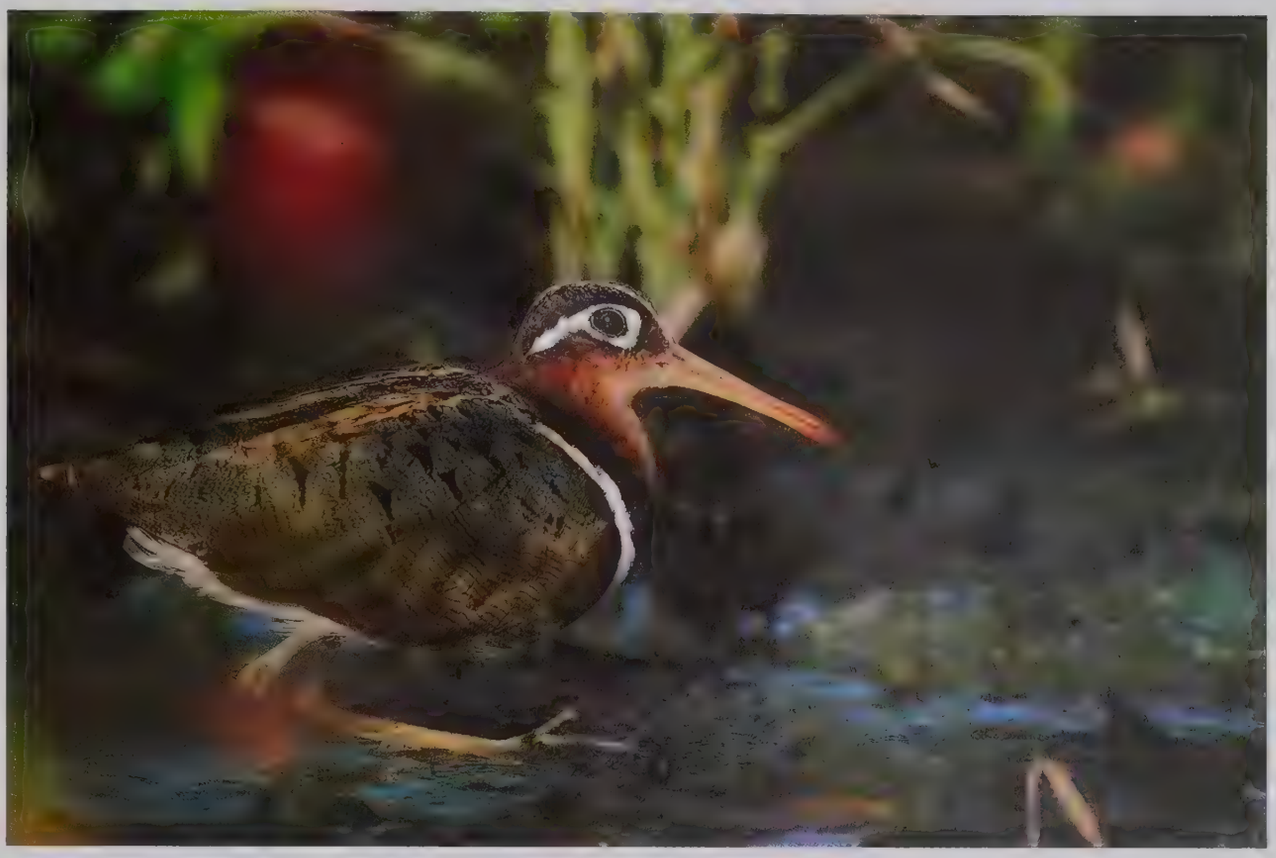
Family ROSTRATULIDAE (PAINTED-SNIPES)

- Medium-sized waders, superficially resembling true snipes, with large eyes, long bill and relatively short, broad wings.
- 19-28 cm.

- All regions except Nearctic and Antarctic.
- Wetlands, especially swamps and wet grassland, normally at low altitude.
- 2 genera, 2 species, 3 taxa.
- No species threatened; none extinct since 1600.

Systematics

The family Rostratulidae is normally considered to comprise two well defined species, each in its own monospecific genus: the Greater Painted-snipe (*Rostratula benghalensis*), widely distributed throughout warmer parts of the Old World; and the South American Painted-snipe (*Nycticryphes semicollaris*), with a more restricted range in the southern half of South America. The relationship between them has long intrigued taxonomists, and the two have frequently been lumped together in the genus *Rostratula*. At the other extreme, the two commonly recognized races of the Greater Painted-snipe, nominate *benghalensis* of Africa and Asia east to Indonesia and *australis* of Australia, were formerly regarded as distinct species. However, they exhibit very limited morphological differences and are apparently similar in all aspects of their behaviour.



The recognition of two genera seems justified, as there are significant differences between *Rostratula* and *Nycticryphes*. For example, the Greater Painted-snipe shows notable reversed sexual dimorphism in plumage, while the sexes are virtually identical in the South American Painted-snipe. The latter species differs from the former in having the toes partially webbed, while the bill and tail shapes are markedly different in the two species. Most importantly, the female Greater Painted-snipe has an oesophageal crop unique among the Charadriiformes. It plays no part in the digestive process but instead has a role in courtship: the trachea is capable of considerable enlargement and the two act as a resonance chamber during the species' prolonged vocal displays (see Voice). A study of the feeding apparatus of the Greater Painted-snipe has revealed that the species possesses a simple adductor muscle, of a style not found in any other waders, in addition to a bill structure which is also unique within the order. Nonetheless, several of the painted-snipes' other anatomical characteristics, such as the lack of a complexus origin, are features which are shared with other waders that feed more or less wholly in aquatic environments.

As no fossilized remains of painted-snipes have yet been unearthed, their ancestral origins remain unclear. There are some skeletal and anatomical characters that are reminiscent of either rails (Rallidae) or cranes (Gruidae). The rather short, broad, rounded wings have been compared to those of *Rallus* rails and *Crex* crakes in appearance, but they are perhaps most closely akin to those of jacanas, and nowadays the Rostratulidae are generally agreed to belong with the waders, or shorebirds, in the order Charadriiformes. Within this order, superficial resemblances to the true snipes (*Gallinago*) have been viewed by most authorities as carrying no taxonomic significance, and the painted-snipes have traditionally been considered most closely related to the jacanas. There are important skeletal reasons for this, such as a similarly shaped sternum, with two notches on the rear border, a distinctive feature which is also found in cranes. Also, the two families differ from all other waders in having ten primaries, as opposed to eleven. The colour patterns of downy young were used by J. R. Jehl as the basis of an internal classification of the suborder Charadrii, involving the recognition of three superfamilies. The unfledged young of the painted-snipes have striking and complex down patterns with bold dorsal bands adorning the upperparts, as in young jacanas, thus emphasizing the similarity between these two families, as well as their distinctiveness from the more typical striped patterns exhibited by most other waders. Therefore, Jehl separated off the painted-snipes and the jacanas in the superfamily Jacanoidea, with a second superfamily for the Crab Plover (*Dromas ardeola*), and a third containing all the remaining wader families. This proposal has subsequently received widespread acceptance.

The hypothesis of a close relationship with the jacanas has recently received important additional support from the field of biochemical research. Work on DNA-DNA hybridization suggests that the painted-snipes' closest relatives may include the jacanas, the phalaropes (Phalaropodinae) and the *Tringa* and *Calidris* sandpipers. Other recent studies of charadriiform phylogeny, based upon character compatibility analysis, have viewed the painted-snipes as part of a monophyletic group which also includes the jacanas, the woodcocks (*Scolopax*) and the true snipes, as well as phalaropes and seedsnipes (Thinocoridae), and which is defined by a number of close similarities in skeletal make-up. Due to the fact that they possess basipterygoid processes, painted-snipes are clustered with the Scolopacidae in such work, in preference to the ideas of most earlier students of charadriifrom taxonomy and systematics.

Morphological Aspects

Painted-snipes are medium-sized waders, measuring up to 28 cm in overall length, with relatively long bills. Female Greater Painted-snipes weigh up to 200 g, but South American Painted-snipes usually weigh only 65-86 g, with females perhaps ave-

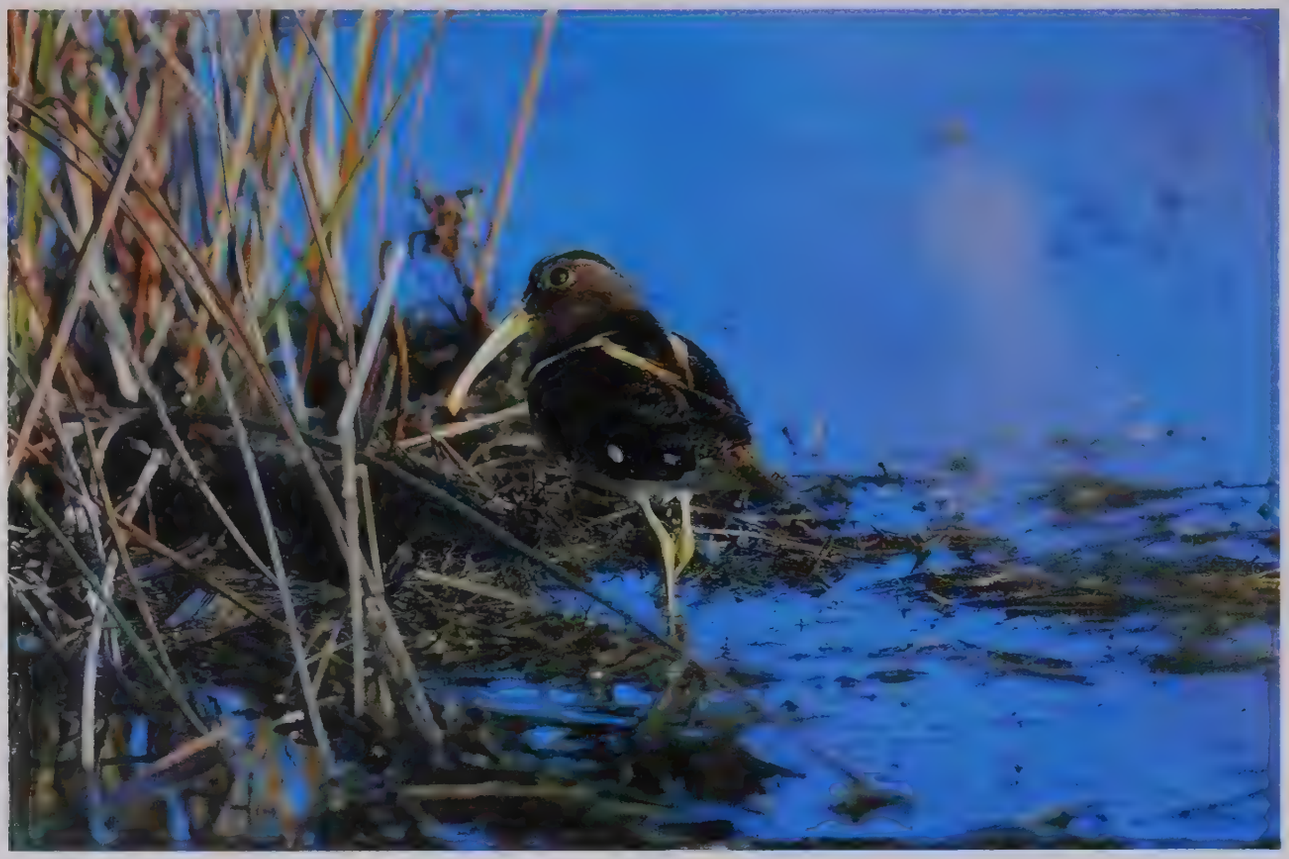
The painted-snipes bear a superficial resemblance to the true snipes of the family Scolopacidae. Their plumage, however, is more arresting, as can be seen in this female Greater Painted-snipe. The bill is shorter with the distal third distinctively swollen, while the legs are longer with very long, slender toes. Another feature typical of this family is the large eye, an adaptation to the birds' lifestyle, generally crepuscular, and even fully nocturnal on moonlit nights.

[*Rostratula benghalensis benghalensis*, Gambia. Photo: Mike McKavett/ Bruce Coleman]

raging slightly heavier. The race *australis* of the Greater Painted-snipe is distinctly longer-winged, with a shorter bill and tarsus than the nominate race.

As a consequence of their role reversal, the male Greater Painted-snipe is characteristically smaller and more cryptically plumaged than the brighter female: she initiates courtship, whilst he is primarily responsible for incubation and chick-care (see Breeding). In contrast, there is little, if any, evidence to suggest that the South American Painted-snipe is at all sexually dimorphic in respect of its plumage. This is presumably due to the fact that in this species the sexes undertake more normal roles, with the female responsible for incubating, and not taking the lead in courtship.

Structurally, painted-snipes bear a superficial resemblance to the true snipes, but they have brighter, more strikingly patterned plumage; shorter bills, with a markedly decurved and swollen distal third being especially noticeable in the South American Painted-snipe; broader, more rounded wings, with extensive yellowish spotting; shorter tails; and longer legs, which dangle down in flight, closely recalling rails. Both species have large eyes, set well forward on the head for binocular vision, and orientated towards the end of the bill; these are adapted for their crepuscular, and in the Greater Painted-snipe at least, semi-nocturnal lifestyle.



In plumage, the two species are broadly similar. As befits their name, the painted-snipes are striking and intricately patterned waders, with a conspicuous white or yellowish white orbital ring and streaks behind the eye, a white or golden scapular line and median crown stripe, and a whitish belly and flanks. Most of the head and breast are deep rufous brown, or sooty olive brown in the South American Painted-snipe; the mantle is greyish green, finely barred with dark brown, or dark brown with grey barring in the South American Painted-snipe; and the wing-coverts are dark olive green or dark brown with fine barring, except in males of the Greater Painted-snipe; whilst the flight-feathers are ash grey or brown, and either barred or spotted.

Male Greater Painted-snipes generally appear like duller versions of the female, except for their boldly patterned wing-coverts, which are greenish gold with striking pairs of golden buff spots near the tip of each feather. Better camouflaged than the bright females, they take most, if not all of the incubating duties. The South American Painted-snipe shows a few bold white spots on the wing-coverts, chiefly on the greater coverts. Although there is little evidence to suggest sexual plumage dimorphism in this species, some observers have conjectured that brighter individuals might be females.

Juveniles of the Greater Painted-snipe appear very similar to adults upon fledging. The South American Painted-snipe possesses a slightly more complex moulting pattern: juveniles lack the sooty olive brown coloration on the head and neck, and also show strongly patterned upperparts; in addition to the broad white "V" on the mantle, most mantle and wing feathers are broadly fringed with white or pale buff, producing a distinctly scaly appearance. Juvenile plumage is later replaced by a distinct subadult plumage, largely similar to that of the adult, as the bird gains both the sharp pattern on the head and neck and also the bold spots on the wing-coverts.

Within the Charadrii, the painted-snipes are, along with the jacanas, unique in possessing just ten primaries, as opposed to the eleven usual in other waders; there are around 15 secondaries. The tail consists of 14-16 feathers, and is rounded in the Greater Painted-snipe, but wedge-shaped or graduated in the South American species, which has the median rectrices tapered and soft at the tip.

Painted-snipes generally appear sluggish and weak in flight, although their wingbeats are quite deep and their movement buoyant, the fluttery, bat-like nature being accentuated by the dangling legs. In contrast to *Gallinago* snipes, the flight is usually direct, not zig-zagging, although the South American Painted-snipe, in particular, may occasionally perform a more erratic escape flight. Neither species, if flushed, will usually fly far, or much above about 10 m over the ground, the bird usually running on into deeper cover upon landing. In fact, both species are reluctant fliers, when alarmed preferring either to skulk in dense cover, like rails or crakes, or freeze in their adopted position, as in some herons (Ardeidae) and waders, particularly *Tringa* sandpipers and *Gallinago* snipes. Although both species have been reported to tower up and disappear some distance, such behaviour is apparently rare, but the South American Painted-snipe may at times fly around its breeding area for several minutes, and this species appears to have a much greater tendency to take flight. On alighting, Greater Painted-snipes

The South American Painted-snipe and the more widespread and better known Greater Painted-snipe (Rostratula benghalensis) *are usually placed in separate genera for a number of reasons. The American species shows no clear sexual dimorphism and the sexual roles are not apparently reversed. It is smaller, has darker plumage and a different shape of bill, more curved and sharply kinked towards the tip. The tail is not rounded, but wedge-shaped, with the central rectrices tapered and soft at the tip. In contrast, other features, such as the large eyes, the golden "V" on the mantle and the long greenish legs, are shared by both species.*

[*Nycticryphes semicollaris*, Argentina.
Photo: R. Seitre/Bios]

may occasionally bob the rear body and tail, in a manner reminiscent of a Common Sandpiper (*Actitis hypoleucos*), but the head is bobbed only very rarely. Female Greater Painted-snipes characteristically perform low roding display flights during the breeding season (see Voice).

Both species have long legs, with the upper half of the tibia feathered, and the tarsus comparatively stout. The very long slender toes are adapted for the birds' life amidst a semi-aquatic environment. The middle toe of the Greater Painted-snipe can measure as much as 95% the length of the tarsus, and even the hind toe can measure up to nearly a third of the length of the central toe. The toes are unwebbed in the Greater, but the South American has basal webbing between the middle and outer toes. Both species have green or brownish legs and feet.

The South American Painted-snipe's bill is rather more markedly decurved and sharply kinked towards the tip, and is also more bulbous than its Old World counterpart, being much expanded and flattened on both the upper and the lower mandibles, but especially the latter; the bill is also pitted distally. The colour varies in this species, and is rarely uniform throughout its entire length, grading from yellow-brown and yellowish through green to reddish brown, and occasionally even approaching black on the nail or elsewhere on the distal half. The bill of the Greater Painted-snipe is usually brown, olive or even purplish, with a greyer brown base and dark or reddish brown tip. In this species, the nostrils are situated in deep, narrow grooves that extend over half way along the entire length of the upper mandible, a feature unique within the Charadriiformes.

Habitat

The two species have broadly similar habitat preferences. The South American Painted-snipe may show a greater willingness to utilize more open areas of wetland, including estuaries in Argentina and Uruguay, and wet meadows throughout its range, but the Greater Painted-snipe also inhabits rice fields, freshwater lakes with grassy islets for nesting, overgrown mudflats and dam-lakes, and it will move onto damp agricultural land, including ploughed areas, to feed at dawn or dusk. It has also been recorded from mangroves in Bangladesh. Both species live and feed primarily in swamps and marshes interspersed with fairly deep pools up to 30-50 cm deep, soft muddy areas and dense shrubbery or reedbeds. In Africa, the Greater Painted-snipe has also been recorded breeding in flooded waste ground with low scrub, and in thickly vegetated areas along the banks of rivers in both coastal and inland areas. However, it will also feed on the margins of pools, sewage tanks and irrigation channels, or wherever there is exposed mud in sufficiently close proximity to dense cover. Neither species exhibits any partiality for a particular habitat on a seasonal basis, but both seem to prefer recently flooded areas, and they will swiftly abandon sites where the water levels are either too high or too low.

Painted-snipes are only rarely recorded at high altitudes, being principally birds of the lowlands, although the Greater Painted-snipe is regularly encountered in the eastern and northern highlands of Madagascar up to 1500 m. The same species is also resident in Sumatra up to 800-900 m, where it has been recorded up to 1400 m; in Sri Lanka up to 1300 m; and in the Himalayas and Myanmar up to c. 1800 m. An exceptional record at the altitude of 5200 m in Tibet, in September, presumably corresponded to a vagrant, or perhaps a migrant. There is no evidence to suggest that the South American Painted-snipe will ever wander to truly montane areas, and its movements are usually confined to areas close to sea-level, although it has been recorded up to over 1000 m in Brazil.

General Habits

Both species are largely solitary, although the South American Painted-snipe breeds semi-colonially and, in conjunction with its polyandrous lifestyle, the Greater Painted-snipe also often nests in groups. Small groups consisting of two or more family units may congregate in the post-breeding season. Exceptional flocks of Greater Painted-snipes include one of 30 birds in Myanmar, and also one of 100 birds in Senegambia, where the species regularly forms flocks of up to 20 birds between March and May in the few remaining freshwater swamps in the dry season. However, even outside the breeding season, when feeding or loafing, most birds spend their time alone. A minimum individual distance spacing of at least 2 m is nearly always maintained be-

In accordance with the sexual role reversal, the plumage of the male Greater Painted-snipe is duller than his mate's. However, each median and greater upperwing-covert shows a striking pair of golden buff spots near the tip, making the bird particularly stunning when it performs the Spread-wing Display. This is a multi-purpose display, with different levels of intensity and several variants. It is carried out in heterosexual situations, females performing it after allopreening the male during courtship. It also forms part of the species' antagonistic behaviour, as territorial females use it to deter other females. Finally, it constitutes a basic element of the species' anti-predator strategy, since it is performed by birds of both sexes, and even small chicks only one week old, when confronting predators or human intruders. It is similarly used by males as a Distraction-threat Display when disturbed either at the nest or whilst accompanying the chicks.

[*Rostratula benghalensis australis*, swamps north of Sydney, Australia. Photo: Jean-Paul Ferrero/ Auscape]

tween birds outside the family grouping, although flocks can be observed flushing in close unison. Both species usually roost singly, by day or night, although parties of up to three birds have been encountered, either on dry ground under dense cover, or in shallow water under the overhang of emergent sedges or other vegetation.

The two painted-snipes are essentially crepuscular birds, although on moonlit nights they may be wholly nocturnal. The South American Painted-snipe is apparently only rarely active during the day. The Greater Painted-snipe, although typically confined to marshy or wetland areas, may visit nearby grassland, or even ploughed areas in order to feed at dawn or dusk. If undisturbed by humans or livestock, this species will also feed during the day at certain favoured, well vegetated sites.

Secretive and unobtrusive birds, painted-snipes are difficult to flush, preferring to freeze in their currently adopted position when disturbed, although they will on occasion scurry back to the safety of cover. They can hold their posture motionless for many minutes if necessary, staring fixedly at the object of danger throughout. Alarmed birds, unlike other Charadriiformes, do not appear to head-bob, but they regularly perform a tail-dipping action, like that of *Actitis* sandpipers, and presumably fulfilling a similar function. The South American Painted-snipe will lean towards the object of presumed danger with the bill virtually touching the ground, displaying almost the entire upperside, whilst otherwise remaining frozen in its alarmed posture; or it may just crouch flat against the ground, even if very close to an observer.

Even when surprised on the nest, the Greater Painted-snipe will typically slink away in the manner of a rail, as opposed to taking flight; it may then crouch in nearby vegetation until the danger has receded. However, the male may also run from the nest, then make a short flight before running forward again, in the manner of *Charadrius* plovers. Apparently, an incubating South American Painted-snipe will usually leave the nest several minutes ahead of approaching danger. When walking, this species always appears as if it is stooping or crouching, with the head and neck held in. When with eggs or small young, both species infrequently perform distraction displays in response to close approach by humans, in common with many other Charadriiformes. Juveniles of both species are capable of swimming some distance, when necessary, in order to escape danger, even though the Greater Painted-snipe has unwebbed toes. Both species will also swim across narrow deep channels whilst foraging. If flushed, neither species often flies far, its escape being direct, not zig-zagging like several of the true snipes, although the South American Painted-snipe will occasionally employ a stronger and more erratic, almost bat-like escape flight, alternatively flapping and then gliding on stiffened wings.

Voice

Painted-snipes are largely silent outside the breeding season. Both species are normally quiet when flushed, the South American Painted-snipe rarely, if ever, calling in flight. The Greater Painted-snipe will occasionally utter an explosive "kek", or a guttural croak when disturbed. A variety of deep, almost snake-like, alarm calls have been recorded from the latter species; when caught, both sexes are known to give a throaty hiss, and anxiety may also manifest itself as a low purring.

As with many other facets of its behaviour, the Greater Painted-snipe, apparently unlike its Neotropical counterpart, exhibits relatively strong sexual differences in vocalizations. The female is generally the more vocal and pugnacious of the sexes, being capable of stronger, more resonant calls than the male, due to her convoluted trachea, which actually measures twice the length of the neck. Folds of subcutaneous fat form in the neck, allowing the trachea great freedom of movement. Displaying females utter a series of soft, metallic drawn out hooting calls, occasionally over 80 notes long, likened by some to a human blowing across the top of an empty bottle, or a hiccough. These advertisement calls can be audible over a kilometre away. They are given from the ground, or alternatively as single notes during a low, woodcock-like roding flight. Such territorial displays gather momentum during the breeding season. In the Northern Hemisphere, they continue from March through to October, initially being confined to the twilight period, with daylight calling commencing in late April, although activity peaks in the hour immediately prior to dawn, and two to three hours after sunset. However, during the egg-laying and incubation periods, females can persist in display-calling almost continuously throughout the day and long into the night. A similarly mellow-sounding series of calls is used by females in a number of other situations: in response to human intruders; when combating rival females; and also to accompany the frontal "Spread-wing Display" (see Breeding) aimed at a prospective mate.

Male Greater Painted-snipes have, in contrast, few specific vocalizations, most of which are used around the nest. Indeed, males are known to call only comparatively rarely. Low calls are infrequently uttered when the male approaches the nest-site and he may make explosive or growling calls whilst performing the frontal Spread-wing Display in defence of his nest. The male will use "Assembly Calls" in order to summon his small young to follow him, and will also utter a short, sharp squeak call in response to courting females.

The South American Painted-snipe is known to utter a plaintive whistle on occasion during the breeding season, but otherwise it is virtually silent. Neither sex indulges in the prolonged nuptial roding flights and nocturnal "song" so characteristic of the female Greater Painted-snipe. Captive birds have been recorded as uttering a querulous, hoarse or hissing dual-noted whistle, when approached too closely either by humans or by conspecifics. It has been suggested that this call, used in varying degrees of intensity, may serve as a contact or warning note, as well as to accompany heterosexual or antagonistic displays.

Food and Feeding

Both species are omnivorous, feeding on both invertebrates and seeds. Invertebrates known to be taken by the Greater Painted-snipe include insects, particularly grasshoppers and crickets (Orthoptera); snails (Mollusca); earthworms (Annelida); and crustaceans. Crustaceans are also recorded in the diet of the South American Painted-snipe, as are a variety of aquatic insects and other invertebrates. Several grasses, including millet (*Panicum*) and rice (*Oryza*), have been reported as being eaten by both species; indeed, stomach analysis of ten Greater Painted-snipes in Japan found vegetable matter to be the predominant constituent. No other detailed food study of either species has been attempted. An adult Greater Painted-snipe kept in captivity in Australia was successfully fed on worms, insects and unspecified meat products.

The two species employ similar feeding techniques, largely involving shallow probing in the soft muddy margins of pools, marshes, rivers and other wetland areas where suitably dense cover is to be found nearby. Typically, they are crepuscular, emerging to feed in the early morning and towards dusk, although some feeding make take place at night, especially if there is sufficient moonlight. When feeding in shallow water, painted-snipes employ a scythe-like motion of the head and bill, sweeping from side to side in a short, semi-circular movement, keeping the bill tip permanently submerged, whilst the mandibles open and close, catching small molluscs and crustaceans. The South American Painted-snipe may, very rarely, fully immerse the head in water whilst feeding. In order to reach suitable feeding areas, both species will also swim short distances, for instance across narrow water courses, and the Greater Painted-snipe will occasionally travel to adjacent farmland in order to feed.

Breeding

As with so many aspects of the painted-snipes' life history, it is the better studied Greater Painted-snipe that furnishes most of the information currently available on breeding biology and behaviour. It is apparent that the two species adopt rather different

The painted-snipes are wetland birds, typically inhabiting swamps and marshes interspersed with fairly deep pools, and freshwater lakes with vegetated islets. The Greater Painted-snipe is largely solitary, but outside the breeding season it can form small groups, especially when suitable habitat is scarce; for example, during the dry season flocks of over 20 birds are occasionally recorded at the few freshwater swamps remaining in a particular area.

[*Rostratula benghalensis benghalensis*, India. Photo: Gertrud & Helmut Denzau]

systems, but as yet very little research has be carried out and little has been published on the breeding and nesting habits of the South American Painted-snipe.

The Greater Painted-snipe is well known for its polyandrous mating system, although in parts of its range where densities are low, such as southern Africa, it may occasionally practise monogamy. In contrast, its Neotropical counterpart appears to adopt a solely monogamous approach. Females of the former species will mate with at least two, and perhaps three to four males each year, the pair-bond surviving only until the point when the eggs are laid, whereupon the female seeks a new mate. The process is often rapid, with the second clutch often laid before the first has hatched. In Japan, a female was recorded to have completed one clutch and within twelve days to have commenced laying a second. Both species probably breed throughout much, or all, of the year, the key factor being the timing of the rainy season.

The displays of the Greater Painted-snipe have been comparatively well studied, considering that there is much concerning this species which remains wholly unknown. The "Spread-wing Display" is a multi-purpose display used in antagonistic, heterosexual and anti-predator situations; it is chiefly performed by the female, but sometimes by the male, mainly against predators. It is used in two degrees of intensity: in the lesser form, the near wing is extended, whilst the far wing is both raised and extended, and the tail is often fanned and depressed; in the full frontal version, the bird faces its opponent or prospective mate head-on, with both wings fully extended and arched slightly forward, the tail fanned and raised, and the whole body, including the bill, tilted downward and toward the object of display. On occasion, the bird will also fluff up its body feathers, or alternatively raise rather than lower its bill. Although females are intensively territorial, rival birds will actually go as far as fighting only in defence of an already established partner. Nonetheless, such aggression can be quite vicious, and captive individuals have been known to peck their human captors during such display.

During courtship the female Greater Painted-snipe will allopreen her prospective mate, before adopting the full frontal Spread-wing Display, and circling the male whilst calling softly, for approximately two minutes. She persists in displaying, even if the male is initially unresponsive. Once the pair have copulated, both sexes stand side by side calling, the female occasionally opening and lifting both wings straight upwards.

Painted-snipes are solitary nesters, with territories on average about 200 m wide, although due to the Greater Painted-snipe's polyandrous habits, its nests may be found grouped closer together, sometimes as little as 4-10 m apart, occasionally as much as 200 m, but more usually 15-50 m apart. Individuals will utilize the same nest in successive years, if undisturbed or if the ground is relatively stable, but in any case they usually nest within a few metres of the previous year's site.

Nest building commences a few days prior to the laying of the first egg, and is usually completed by the time the second egg has been laid. During this period both parents remain in close proximity to each other and the nest for the vast majority of the time. Thereafter, the female spends a steadily decreasing proportion of time at the nest, and by the time the last egg is laid her visits have become minimal, and she usually seeks a new mate. On occasion, female Greater Painted-snipes may casually drop a single egg away from the nest-site.

The nest of both species is a shallow cup, lined with a few stems and leaves from available vegetation, and occasionally some small dead sticks. Sometimes this structure is elaborated and built up into a small platform, with the addition of more significant amounts of plant material. The South American Painted-snipe apparently shows a greater tendency to construct a nest platform, presumably as most nests described have been located in wet pasture or grazing marsh, situations where the water table can rise or fall dramatically in a short space of time. Nonetheless, this species will, just as likely, make use of a cow's hoofmark for its nest-site, or create its own shallow scrape. The site is usually concealed within dense vegetation, frequently on semi-floating water weeds and always in relatively close proximity to open water. The Greater Painted-snipe, at least, on occasion builds its nest atop the small bunds that enclose inundated paddyfields or lotus fields, provided these are vegetated; one nest of this species was found in a hollow under dead trees. However, it is probably unusual for the nest to be placed more than a couple of metres above the prevailing water level.

In the vast majority of cases in the Greater Painted-snipe, the male builds the nest, incubates the eggs and broods the young, and he is also responsible for rearing his offspring to fledging. He often remains with the juveniles for one or two months after fledging. Although the female usually takes a wholly passive role in chick-care, she may stay in close proximity to her mate, occasionally assisting in territorial defence of the nesting area, and even less regularly in nest construction and apparently also in sitting on eggs or small chicks; in South-east Asia, females have been flushed from chicks, and collected, whilst they were incubating eggs.

The eggs of painted-snipes are ovaloid or oblong, like those of sandgrouse, not high-topped like true snipe. They are slightly glossy, and are heavily marked with black or blackish brown

blotches, streaks and spots on a pale buffy yellow background. In both species, but especially the South American, the background may instead be cream-coloured and occasionally the markings grey. Those of the Greater Painted-snipe average 36 x 26 mm and weigh approximately 13 g, or up to 9·5% of the female's body weight, a significant proportion, given that a typical clutch contains four eggs, and that females tend to lay two to four clutches per season, to be incubated by different males. Although the laying interval has not been accurately recorded, it is probably one day between each egg. The eggs of the South American Painted-snipe average very slightly smaller. Two eggs are the norm in this species, although clutches of three have been recorded. Females are monogamous, laying a single clutch and participating in the incubation of the eggs and care of the young. Their breeding and display habits have been little studied, and although it is probable that the species shows similarities to the Greater Painted-snipe in some aspects of its breeding biology and courtship behaviour, further research is required.

The incubation period lasts 15-21 days in the Greater Painted-snipe, the average probably being 18-19, with incubation only commencing once the last egg has been laid. Observations of nesting males in Japan suggest that the male usually leaves the nest on average just over once per hour, for a ten minute period, although he sometimes remains at the nest for several hours at a time, especially in the morning; occasionally, a male may leave the eggs for as long as 40 minutes. He characteristically spends approximately 50% of daylight hours on the nest, and 89% of the night.

The Greater Painted-snipe's downy young are precocial and nidifugous, leaving the nest virtually as soon as they are dry, so hatching is almost certainly near-synchronous; they are not known to return to the nest at any later stage. They wear a covering of pale buff down, with a bold pattern of dark lines on the upperparts and an orange-brown patch on the centre of the back. They are brooded for several days by the male, or occasionally by the female, and remain dependant upon the male for food for several days at least; in Nigeria, a small chick hand-reared for three days never learned to peck of its own volition, and had to be fed forcibly.

The young birds behave as a group, following the male closely, and crouching close together when threatened, until they are able to run away with ease. In one case, the members of a brood were observed to freeze in a crouching position with their heads all facing inwards. However, the chicks are soon able to give the full frontal Spread-wing Display towards intruders, sometimes at only one week old. Young of both species taken into captivity soon after hatching swiftly learn to imprint themselves on their human foster parents.

In a monogamous system, as has been observed in southern Africa, and which may presumably operate elsewhere, the female appears to remain as part of the family group. It is possible that, for instance, nest building and brooding by the female constitute normal behaviour in a monogamous pair relationship, and that observations of such family activity by females elsewhere in the species' range of the Greater Painted-snipe are also indicative of monogamy.

The fledging period is unknown in both species, as is the age of independence. Male Greater Painted-snipes are probably capable of breeding after a year, while females may take two years in order to reach sexual maturity.

Neither species' reproductive success has been accurately studied. Casual observations suggest that the male Greater Painted-snipe may raise up to four young to the stage of fledging: there are records from several Asian countries of males with three well grown young; and from South Africa with four fledglings.

Movements

In both species, the flight action appears slow and buoyant or, especially in the South American Painted-snipe, erratic, and they can resemble some of the larger species of rails or crakes. Notwithstanding this apparent feebleness, painted-snipes are actually capable of movements over considerable distances. In northern India, for instance, a Greater Painted-snipe which was trapped and ringed at Bharatpur, Rajasthan, in December was later recovered 900 km away to the east, in Bihar. Vagrants of this species have been recorded from Afghanistan, Israel, Oman, Somalia, Zanzibar, Pemba and Tasmania, indicating certain mobility.

This species is largely resident in Egypt and throughout most of Asia, although the populations in northern China and northern Japan are migratory. However, African birds are partially nomadic and perhaps opportunistic, responding to local climatic conditions, and even undertaking more regular, but nonetheless relatively short distance, migrations in order to locate suitable breeding habitat. For example, in Chad the Greater Painted-snipe is recorded as a wet season visitor to the Sahel zone, where it arrives with the first rains in early July, returning south between September and November after breeding. The principle is the same but the pattern slightly different in Nigeria, where the species breeds in the south during the rainy season, before moving slowly northwards to spend the dry season in the remaining areas of marshland. In Zimbabwe, movements would, however, appear to be wholly random, as, of 134 birds trapped, none was recaptured in the same area in which it had been ringed. In much of Australia, the species behaves as a true nomad, appearing after good rains in areas where it has not been recorded for several years, sometimes even decades, and remaining temporarily to breed, before moving on in search of freshly flooded areas.

The South American Painted-snipe also performs regular seasonal movements in some parts of its range, for instance in the province of Buenos Aires, Argentina, and in parts of Brazil. Further south in Argentina, in northern Chubut and southern Río Negro, the species is known only as a non-breeding migrant.

After the breeding season is over, Greater Painted-snipes can gather in small flocks, or even, exceptionally, large ones, although in many areas, for example southern Africa, they are reported to remain essentially solitary or in pairs. Larger concentrations may form as a function of a lack of suitable habitat. South American Painted-snipes, however, seem to keep to themselves or in pairs, although they may sometimes be found in small, dispersed groups of fewer than ten individuals. It is unknown whether, or to what extent, movements outside the breeding season are influenced by factors other than climate. Both species exhibit a propensity for colonizing freshly flooded areas for breeding, and it would seem highly likely that climatic factors play a similarly important role in determining the movements in the non-breeding period.

Relationship with Man

In comparison to the true snipes, painted-snipes are largely silent upon flushing. This is reflected in the popular Portuguese name for the South American Painted-snipe, *Narceja-muda*, the "mute snipe". In Argentina it is known as the "sleepy-head", presumably largely in reference to its habit of roosting during the day, but perhaps also due to its generally quiet, unobtrusive habits, whilst in Chile its local names *Becasina pintada* and *Porotera pintada* reflect features such as its patterned plumage, its long bill and its typical habitat requirements. Amongst British sportsmen in India, the Greater Painted-snipe was colloquially referred to simply as the "Painter". In southern India it was called the "Peacock Snippet", a comment on the fine plumage, particularly of the female, over that of *Gallinago* snipes.

The Greater Painted-snipe was regarded as an easy shot for the competent sportsman in the Indian hill states, for instance in Kashmir, because of its relatively slow, heavy escape flight, added to which in some areas it was commoner than either the Common Snipe (*Gallinago gallinago*) or the Pintail Snipe (*Gallinago stenura*). Consequently the species was looked upon with some disfavour as being an unworthy bag for the true sportsman, although this did not necessarily prevent it from being hunted, sometimes in quite large numbers. In contrast, the flesh of the South American Painted-snipe is highly prized by hunters in Argentina and Chile, for its fine taste. Both species often live in relatively close proximity to man, utilizing partly flooded areas that also serve

The male Greater Painted-snipe's more cryptic plumage offers him better camouflage whilst incubating the eggs, a task which, like nest building, brooding and chick-care, is carried out virtually without help from the female. She remains with him only until she has completed the clutch, whereupon she normally goes off in search of a new mate. Incubation lasts an average of 18-19 days, during which time the male is reckoned to spend 50% of the daylight hours and 89% of the night on the nest. The eggs are pale buffy yellow, heavily marked with blackish brown blotches.

[*Rostratula benghalensis benghalensis*, Virunga National Park, Zaire. Photo: M. R. Phicton/ Bruce Coleman]

as grazing land for livestock. Indeed, the Greater Painted-snipe, in addition to its traditional use of paddyfields and lotus fields, has also been able to adapt to life in other man-made habitats, such as sewage farms and the shores of dam-lakes. South American Painted-snipes will also breed in and around rice fields.

Not surprisingly, as with most Charadrii, neither species is commonly held in zoos or collections, although limited studies of both have been conducted using captive birds. Small chicks of both species easily become imprinted, closely following human feet. However, although adult birds can be easy to feed, the chicks will not peck at food instinctively, and have to be force-fed, making rearing more difficult.

Status and Conservation

There are few detailed population estimates available for either species, and their skulking and retiring habits make it very difficult to produce accurate assessments of their exact status and sometimes even their precise distribution. Nonetheless, at present, neither species is considered to be threatened. Both species remained unrecorded in certain areas now known to support them, until relatively recently. For instance, the South American Painted-snipe was known from Brazil by only a single specimen, taken in 1891, until the early 1960's, while in West Africa the Greater Painted-snipe, although long suspected to breed, was not conclusively shown to do so until the same decade.

The Greater Painted-snipe is generally regarded as uncommon, although it may be locally common in parts of its range in mainland Africa and Asia. Fluctuations in populations are undeniably hard to gauge, but in Egypt, for example, which boasts a wealth of historical data on its birds, and where recent standardized ornithological activity has been relatively intensive, the species is regarded as stable. During the period of British rule in India the species was quite commonly shot for sport, sometimes in comparatively large numbers. It is not known if such hunting pressure had serious effects, and the fact that the species is currently regarded as generally uncommon throughout the Indian Subcontinent might more probably be put down to habitat loss and deterioration, although judging from the evidence available it may only ever have been common locally. In contrast, in Japan, where the Greater Painted-snipe was apparently a common resident in the southern islands towards the end of the last century, it is now regarded as local and uncommon there. Habitat destruction and alteration have probably had a negative effect in many parts of its range, but the species is able to use semi-reclaimed wetland areas and has historically made use of rice and lotus paddies for both breeding and feeding, throughout extensive parts of South-east Asia. Indeed, this species also regularly visits reservoirs, sewage pools and other man-made wetlands throughout much of its range, provided that there is suitably thick vegetation close by, suggesting that it may be able to adapt quite readily to new conditions. The effects of long-term drought, a real problem in parts of its African range, are more or less unknown, but could theoretically be more damaging than either hunting or wetland reclamation, at any rate on a relatively localized scale. The race *australis* is generally considered to be rare throughout much of Australia, especially the drier western half, although even in the east it may be locally very rare, for example around Sydney, New South Wales.

There are very few population data available for the South American Painted-snipe. It is regarded as very local in Chile, but during the first half of the 1970's in central Argentina the species was not uncommon, and was even considered to be locally frequent, for instance in parts of Mendoza and Córdoba. Up-to-date information is not available, but given the decline in many species of drier grassland birds in both Argentina and many parts of Brazil, it would not be surprising if a similar decline were discovered in wet grassland birds, such as this species. Throughout its range, the species is highly prized by hunters for its flavoursome meat. Unfortunately, it is frequently shot during the breeding season, because it is a relatively early nester, the shooting season terminating on September 1st, well into the nesting period in many areas.

Genus *ROSTRATULA* Vieillot, 1816

1. Greater Painted-snipe

Rostratula benghalensis

French: Rhynchée peinte **German**: Goldschnepfe **Spanish**: Aguatero Bengalí

Taxonomy. *Rallus benghalensis* Linnaeus, 1758, Asia.
Races formerly regarded as separate species, but nowadays almost invariably lumped into one, as they differ so little in morphology and behaviour. Two subspecies normally recognized.
Subspecies and Distribution.
R. b. benghalensis (Linnaeus, 1758) - Africa and Madagascar; Pakistan E to NE China, extreme SE Russia (S Ussuriland) and Japan, and S through SE Asia, Greater Sundas and Philippines to Lesser Sundas (Lombok, Sumbawa, Flores).
R. b. australis (Gould, 1838) - Australia.

Descriptive notes. 23-28 cm; c. 90-200 g; wingspan 50-55 cm. Strong sexual dimorphism in plumage and also in size. Male has golden eye-patch, crown stripe and "V" on mantle; rest of head greyish brown, with ashy grey on neck, and throat streaked whitish; extensive golden buff on upperparts, especially upperwing-coverts; rest of underparts and underwing white. Female longer-winged, and brighter and more clearly patterned; head and neck mostly dark rufous, eye-patch clean white; most of upperparts, including wings, dark bronze green, barred finely with black. Both sexes differ from *Nycticryphes semicollaris* in larger size, straighter bill and many details of plumage; tail rounded. Juvenile similar to adult male, but initially lacks sharply separation between dark upper breast and white lower breast; wing-coverts greyer, with smaller, paler buff spots. Race *australis* averages considerably longer-winged; no significant plumage differences.
Habitat. Wetlands in tropical and subtropical lowlands, generally up to c. 1800 m in Himalayas, but usually much lower elsewhere; affects swamps, reedbeds, *jheels*, overgrown rice fields and muddy margins of pools, freshwater lakes with grassy islets, sewage pools, dam-lakes, even mudflats overgrown with marsh grass and mangroves. Habitat use governed by rains, and tends to favour recently flooded areas; in Kenya, usually absent from areas with less than 500 mm of rain annually; in S Africa, absent from large parts of the much drier western half. Occasionally feeds on more open grassland, adjacent to wetlands.
Food and Feeding. Omnivorous. Invertebrates taken include insects, snails, earthworms and crustaceans; also seeds, including a variety of grasses, rice and millet. May feed extensively on seeds, but few precise data on dietary preferences collected to date. In captivity, fed successfully on meat, earthworms and insects. Probes soft ground like true snipes (*Gallinago*); also uses scything action of bill and head in shallow water. Chiefly crepuscular, and may also feed at night. Usually solitary, occasionally in small parties, exceptionally large groups of up to 100.
Breeding. Mostly breeds during or immediately after rains in Africa, with laying mainly Mar-Jun in W Africa, Aug-Nov in S South Africa, but extensive local variation elsewhere, covering all months; also breeds throughout much of year in Asia, with eggs recorded in Nov-Apr in Sri Lanka, chiefly Jul-Sept in India, Jul-Aug in Myanmar, Oct-Dec in Philippines, Feb in Sumatra, and Jul on Flores; recorded in all months in Australia, but mainly Sept-Dec. Female normally polyandrous, but monogamous in some areas, e.g. in S Africa. Solitary nester, but nests may be grouped together due to polyandrous behaviour. Nests on ground, sometimes on low hummock or mound, normally concealed in thick, marshy vegetation; alternatively in more open aquatic environments, e.g. on dense mat of floating water weed; nest is shallow cup usually lined with leaves and stems, occasionally built up with interwoven plant material, but infrequently bare. Usually 4 eggs (2-5); female may lay up to 4 clutches in one season; incubation 15-21 days; downy chicks pale buff with bold pattern of lines on upperparts, greyish below; chicks precocial and nidifugous, brooded and dependent for first few days; fledging period unknown. First breeding probably occurs after 1 year in male, 2 years in female.
Movements. Mainly sedentary in Asia, and in Egypt. Short migrations reported from NE China, NW India (Kashmir) and Japan. Within Africa performs seasonal, but irregular, short distance movements, responding to feeding and breeding habitat requirements, principally in N tropics. Largely nomadic in Australia. Usually remains solitary in non-breeding season, but small, occasionally large, flocks may gather, probably due to scarcity of suitable habitat. Accidental in Afghanistan, Israel (where recently found breeding), Oman, Somalia, Pemba and Zanzibar, and Tibet and Tasmania; listed for Turkey, but probably erroneously.
Status and Conservation. Not globally threatened. Generally uncommon to frequent and even locally common. Few population estimates available, and population trends difficult to establish, due to inconspicuous habits; breeding not recorded in W Africa until 1960's. Perhaps declining in many areas due to drainage of wetlands and destruction of suitable habitat, although recorded in semi-reclaimed areas in Kashmir, and in rice paddies in many countries, e.g. Egypt and Ivory Coast; population considered stable in Egypt. In Japan, was considered a common resident in southern islands during 19th century, but now classed as uncommon and local. Generally rare in Australia, where apparently commoner in E than in drier W, although even in E is locally very rare in apparently suitable habitat, e.g. around Sydney, New South Wales. Uncommon in much of Africa; also in Nepal, China and over much of SE Asia. In past, was commonly hunted in India, although generally regarded as poor sport. Abnormally long periods of drought presumably have serious impact on populations, as breeding appears to hinge on availablity of suitable wetlands, especially in Africa, where species often dependent on seasonally flooded areas.

Genus *NYCTICRYPHES* Wetmore & J. L.Peters, 1923

2. South American Painted-snipe

Nycticryphes semicollaris

French: Rhynchée de Saint-Hilaire **Spanish**: Aguatero Americano
German: Weißflecken-Goldschnepfe

Taxonomy. *Totanus semi-collaris* Vieillot, 1816, Paraguay.
Sometimes included in *Rostratula*, but exhibits marked differences in morphology and behaviour (see page 292). Monotypic.
Distribution. Paraguay E to SE Brazil and Uruguay, and S to C Chile and C Argentina.

Descriptive notes. 19-23 cm; c. 65-86 g. Longish decurved bill; golden crown stripe, supercilium and "V" on mantle; head, neck and upper breast dark reddish brown; buff on lores and supercilium can be more extensive than depicted; upperparts mainly dark greyish brown and black, with variable white drops on scapulars and wing-coverts, and smaller buff spots on flight-feathers; rump and wedge-shaped tail greyish buff with narrow dark bars; belly white. Virtually no sexual dimorphism known, but female averages slightly larger; may also tend to be slightly brighter, although good evidence lacking. Differs from *Rostratula benghalensis* in generally darker plumage, more sharply decurved bill and distinctive white spots on scapulars and upperwing-coverts; large golden patch around eye reduced to supercilium; bill more bulbous at tip, due to expanded upper mandible, which is pitted towards base; tail distinctly wedge-shaped. Juvenile has drops on scapulars and wing-coverts creamy buff; buff spots on flight-feathers much reduced; throat and breast streaked white and dark brown.

Habitat. Tropical and subtropical lowlands, occurring in open swamps and marshes, along rivers and streams, and in rice fields and wet grassland. Generally favours more open areas than *R. benghalensis*, including estuaries in Argentina and Uruguay. Usually found close to sea-level, but recorded up to over 1000 m in parts of Brazil; unlike *R. benghalensis*, not recorded from montane areas.

Food and Feeding. Crustaceans, insects and their larvae, aquatic invertebrates in general, and seeds. In shallow water, takes shellfish using semi-circular sweeping action of bill, opening and shutting mandibles while tip remains submerged.
